Preface

Purpose

The purpose of *The Electrical Engineering Handbook* is to provide a comprehensive reference work covering the broad spectrum of electrical engineering in a single volume. It is written and developed for the practicing electrical engineers in industry, government, and academia. The goal is to provide the most up-to-date information in classical fields of circuits, electronics, electromagnetics, electric power systems, and control systems, while covering the emerging fields of VLSI systems, digital systems, computer engineering, computer-aided design and optimization techniques, signal processing, digital communications, and communication networks. This handbook is not an all-encompassing digest of everything taught within an electrical engineering curriculum. Rather, it is the engineer's first choice in looking for a solution. Therefore, full references to other sources of contributions are provided. The ideal reader is a B.S. level engineer with a need for a one-source reference to keep abreast of new techniques and procedures as well as review standard practices.

Background

The handbook stresses fundamental theory behind professional applications. In order to do so, it is reinforced with frequent examples. Extensive development of theory and details of proofs have been omitted. The reader is assumed to have a certain degree of sophistication and experience. However, brief reviews of theories, principles, and mathematics of some subject areas are given. These reviews have been done concisely with perception. The handbook is not a textbook replacement, but rather a reinforcement and reminder of material learned as a student. Therefore, important advancement and traditional as well as innovative practices are included.

Since the majority of professional electrical engineers graduated before powerful personal computers were widely available, many computational and design methods may be new to them. Therefore, computers and software use are thoroughly covered. Not only does the handbook use traditional references to cite sources for the contributions, but it also contains *relevant* sources of information and tools that would assist the engineer in performing his/her job. This may include sources of software, databases, standards, seminars, conferences, and so forth.

Organization

Over the years, the fundamentals of electrical engineering have evolved to include a wide range of topics and a broad range of practice. To encompass such a wide range of knowledge, the handbook focuses on the key concepts, models, and equations that enable the electrical engineer to analyze, design, and predict the behavior of electrical systems. While design formulas and tables are listed, emphasis is placed on the key concepts and theories underlying the applications.

The information is organized into nine major sections, which encompass the field of electrical engineering. Each section is divided into chapters. In all, there are 72 chapters involving 108 authors, each of which was written by leading experts in the field to enlighten and refresh knowledge of the mature engineer and educate the novice. Each section contains introductory material, leading to the appropriate applications. To help the reader, each article includes two important and useful categories: defining terms and references. *Defining terms* are key definitions and the first occurrence of each term defined is indicated in boldface in the text. The *references* provide a list of useful books and articles for following reading.

Locating Your Topic

Numerous avenues of access to information contained in the handbook are provided. A complete table of contents is presented at the front of the book. In addition, an individual table of contents precedes each of the nine sections. The reader is urged to look over these tables of contents to become familiar with the structure, organization, and content of the book. For example, see Section VII: Signal Processing, then Chapter 7: VLSI Signal Processing, and then Chapter 7.3: Hardware Implementation. This tree-like structure enables the reader to move up the tree to locate information on the topic of interest.

The Electrical Engineering Handbook is designed to provide answers to most inquiries and direct inquirer to further sources and references. We trust that it will meet your need.

Acknowledgments

The compilation of this book would not have been possible without the dedication and efforts of the section editors, the publishers, and most of all the contributing authors. I particularly wish to acknowledge my wife, Shiao-Ling, for her patience and support.

CIRCUIT THEORY

Krishnaiyan Thulasiraman
*School of Computer Science,
University of Oklahoma,
Norman, Oklahoma, USA*

Circuit theory is an important and perhaps the oldest branch of electrical engineering. A circuit is an interconnection of electrical elements. These include passive elements, such as resistances, capacitances, and inductances, as well as active elements and sources (or excitations). Two variables, namely voltage and current variables, are associated with each circuit element. There are two aspects to circuit theory: **analysis and design**. Circuit analysis involves the determination of current and voltage values in different elements of the circuit, given the values of the sources or excitations. On the other hand, circuit design focuses on the design of circuits that exhibit a certain prespecified voltage or current characteristics at one or more parts of the circuit. Circuits can also be broadly classified as **linear or nonlinear circuits**.

This section consists of five chapters that provide a broad introduction to most fundamental principles and techniques in circuit analysis and design:

- Linear Circuit Analysis
- Circuit Analysis: A Graph-Theoretic Foundation
- Computer-Aided Design
- Synthesis of Networks
- Nonlinear Circuits.

Linear Circuit Analysis

1.1 Definitions and Terminology

An **electric charge** is a physical property of electrons and protons in the atoms of matter that gives rise to forces between atoms. The charge is measured in coulomb [C]. The charge of a proton is arbitrarily chosen as positive and has the value of 1.601×10^{-19} C, whereas the charge of an electron is chosen as negative with a value of -1.601×10^{-19} C. Like charges repel while unlike charges attract each other. The electric charges obey the principle of conservation (i.e., charges cannot be created or destroyed).

A **current** is the flow of electric charge that is measured by its flow rate as coulombs per second with the units of ampere [A]. An ampere is defined as the flow of charge at the rate of one coulomb per second (1 A = 1 C/s). In other words, current $i(t)$ through a cross section at time t is given by dq/dt, where

$q(t)$ is the charge that has flown through the cross section up to time t:

$$i(t) = \frac{dq(t)}{dt}\,[\mathrm{A}]. \tag{1.1}$$

Knowing i, the total charge, Q, transferred during the time from t_1 to t_2 can be calculated as:

$$Q = \int_{t1}^{t2} idt\ [\mathrm{C}]. \tag{1.2}$$

The voltage or potential difference (V_{AB}) between two points A and B is the amount of energy required to move a unit positive charge from B to A. If this energy is positive, that is work is done by external sources against forces on the charges, then V_{AB} is positive and point A is at a higher potential with respect to B. The voltage is measured using the unit of volt [V]. The voltage between two points is 1 V if 1 J (joule) of work is required to move 1 C of charge. If the voltage, v, between two points is constant, then the work, w, done in moving q coulombs of charge between the two points is given by:

$$w = vq\ [\mathrm{J}]. \tag{1.3}$$

Power (p) is the rate of doing work or the energy flow rate. When a charge of dq coulombs is moved from point A to point B with a potential difference of v volts, the energy supplied to the charge will be $v\ dq$ joule [J]. If this movement takes place in dt seconds, the power supplied to the charge will be $v\ dq/dt$ watts [W]. Because dq/dt is the charge flow rate defined earlier as current i, the power supplied to the charge can be written as:

$$p = vi\ [\mathrm{W}]. \tag{1.4}$$

The energy supplied over duration $t1$ to $t2$ is then given by:

$$w = \int_{t1}^{t2} vi\,dt\ [\mathrm{J}]. \tag{1.5}$$

A **lumped electrical element** is a model of an electrical device with two or more terminals through which current can flow in or out; the flow can pass *only* through the terminals. In a two-terminal element, current flows through the element entering via one terminal and leaving via another terminal. On the other hand, the voltage is present across the element and measured between the two terminals. In a multiterminal element, current flows through one set of terminals and leaves through the remaining set of terminals. The relation between the voltage and current in an element, known as the v–i relation, defines the element's characteristic. A circuit is made up of electrical elements.

Linear elements include a v–i relation, which can be linear if it satisfies the homogeneity property and the superposition principle. The homogeneity property refers to proportionality; that is, if i gives a voltage of v, ki gives a voltage of kv for any arbitrary constant k. The superposition principle implies additivity; that is, if i_1 gives a voltage of v_1 and i_2 gives a voltage of v_2, then $i_1 + i_2$ should give a voltage $v_1 + v_2$. It is easily verified that $v = Ri$ and $v = L\ di/dt$ are linear relations. Elements that possess such linear relations are called linear elements, and a circuit that is made up of linear elements is called a linear circuit.

Sources, also known as **active elements,** are electrical elements that provide power to a circuit. There are two types of sources: (1) independent sources and (2) dependent (or controlled) sources. An independent voltage source provides a specified voltage irrespective of the elements connected to it. In a similar manner, an independent current source provides a specified current irrespective of the elements connected to it. Figure 1.1 shows representations of independent voltage and independent current sources. It may be noted that the value of an independent voltage or an independent current source may be constant in magnitude and direction (called a direct current [dc] source) or may vary as a function of time (called a time-varying source). If the variation is of sinusoidal nature, it is called an alternating current (ac) source.

Values of dependent sources depend on the voltage or current of some other element or elements in the circuit. There are four classes of dependent sources: (1) voltage-controlled voltage source, (2) current-controlled voltage source, (3) voltage-controlled current source and (4) current-controlled current source. The representations of these dependent sources are shown in Table 1.1.

Passive elements consume power. Names, symbols, and the characteristics of some commonly used passive elements are given in Table 1.2. The v–i relation of a linear resistor, $v = Ri$,

is known as Ohm's law, and the linear relations of other passive elements are sometimes called generalized Ohm's laws. It may be noted that in a passive element, the polarity of the voltage is such that current flows from positive to negative terminals. This polarity marking is said to follow the passive polarity convention.

A **circuit** is formed by an interconnection of circuit elements at their terminals. A **node** is a junction point where the

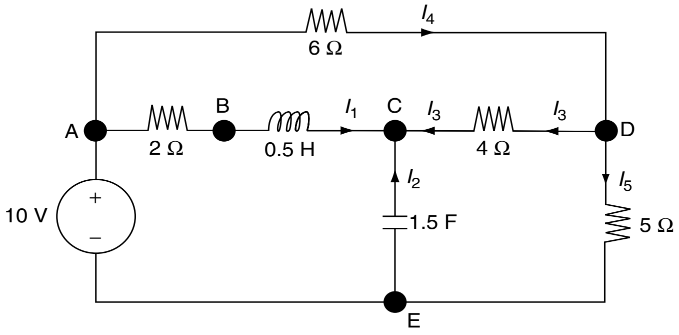

FIGURE 1.2 Example Circuit Diagram

terminals of two or more elements are joined. Figure 1.2 shows A, B, C, D, and E as nodes. A **loop** is a closed path in a circuit such that each node is traversed only once when tracing the loop. In Figure 1.2, ABCEA is a loop, and ABCDEA is also a loop. A **mesh** is a special class of loop that is associated with a window of a circuit drawn in a plane (**planar circuit**). In the same Figure ABCEA is a mesh, whereas ABCDEA is not considered a mesh for the circuit as drawn. A **network** is defined as a circuit that has a set of terminals available for external connections (i.e., accessible from outside of the circuit). A **pair of terminals** of a network to which a source, another network, or a measuring device can be connected is called a **port** of the network. A network containing such a pair of terminals is called a **one-port network**. A network containing two pairs of externally accessible terminals is called a **two-port network**, and multiple pairs of externally accessible terminal pairs are called a **multiport network**.

1.2 Circuit Laws

Two important laws are based on the physical properties of electric charges, and these laws form the foundation of circuit analysis. They are Kirchhoff's current law (KVL) and Kirchhoff's voltage law (KCL). While Kirchhoff's current law is based on the principle of conservation of electric charge, Kirchhoff's voltage law is based on the principle of energy conservation.

1.2.1 Kirchhoff's Current Law

At any instant, the algebraic sum of the currents (i) entering a node in a circuit is equal to zero. In the circuit in Figure 1.2, application of KCL at node C yields the following equation:

$$i_1 + i_2 + i_3 = 0 \tag{1.6}$$

Similarly at node D, KCL yields:

$$i_4 - i_3 - i_5 = 0. \tag{1.7}$$

1.2.2 Kirchhoff's Voltage Law

At any instant, the algebraic sum of the voltages (v) around a loop is equal to zero. In going around a loop, a useful convention is to take the voltage drop (going from positive to negative) as positive and the voltage rise (going from negative to positive) as negative. In Figure 1.2, application of KVL around the loop ABCEA gives the following equation:

$$v_{AB} + v_{BC} + v_{CE} + v_{EA} = 0. \tag{1.8}$$

1.3 Circuit Analysis

Analysis of an electrical circuit involves the determination of voltages and currents in various elements, given the element values and their interconnections. In a linear circuit, the v–i relations of the circuit elements and the equations generated by the application of KCL at the nodes and of KVL for the loops generate a sufficient number of simultaneous linear equations that can be solved for unknown voltages and currents. Various steps involved in the analysis of linear circuits are as follows:

1. For all the elements except the current sources, assign a current variable with arbitrary polarity. For the current sources, current values and polarity are given.
2. For all elements except the voltage sources, assign a voltage variable with polarities based on the passive sign convention. For voltage sources, the voltages and their polarities are known.
3. Write KCL equations at $N - 1$ nodes, where N is the total number of nodes in the circuit.
4. Write expressions for voltage variables of passive elements using their v–i relations.
5. Apply KVL equations for $E - N + 1$ independent loops, where E is the number of elements in the circuit. In the case of planar circuits, which can be drawn on a plane paper without edges crossing over one another, the meshes will form a set of independent loops. For nonplanar circuits, use special methods that employ topological techniques to find independent loops.
6. Solve the $2E$ equations to find the E currents and E voltages.

The following example illustrates the application of the steps in this analysis.

> EXAMPLE 1.1. *For the circuit in Figure 1.3, determine the voltages across the various elements.* Following step 1, assign the currents I_1, I_2, I_3, and I_4 to the elements. Then apply the KCL to the nodes A, B, and C to get $I_4 - I_1 = 0$, $I_1 - I_2 = 0$, and $I_2 - I_3 = 0$. Solving these equations produces $I_1 = I_2 = I_3 = I_4$. Applying the v–i relation characteristics of the nonsource elements, you get $V_{AB} = 2\, I_1$, $V_{BC} = 3\, I_2$, and $V_{CD} = 5\, I_3$. Applying

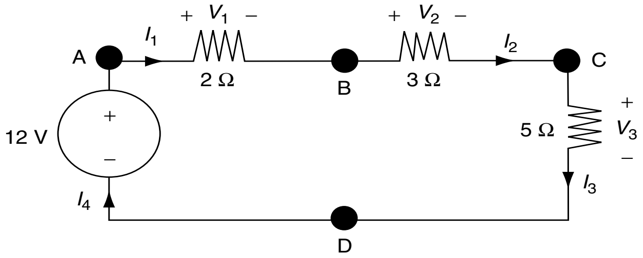

FIGURE 1.3 Circuit for Example 1.1

the KVL to the loop ABCDA, you determine $V_{AB} + V_{BC} + V_{CD} + V_{DA} = 0$. Substituting for the voltages in terms of currents, you get $2\ I_1 + 3\ I_1 + 5\ I_1 - 12 = 0$. Simplifying results in $10\ I_1 = 12$ to make $I_1 = 1.2$ A. The end results are $V_{AB} = 2.4$ V, $V_{BC} = 3.6$ V, and $V_{CD} = 6.0$ V.

In the above circuit analysis method, 2E equations are first set up and then solved simultaneously. For large circuits, this process can become very cumbersome. Techniques exist to reduce the number of unknowns that would be solved simultaneously. Two most commonly used methods are the loop current method and the node voltage method.

1.3.1 Loop Current Method

In this method, one distinct current variable is assigned to each independent loop. The element currents are then calculated in terms of the loop currents. Using the element currents and values, element voltages are calculated. After these calculations, Kirchhoff's voltage law is applied to each of the loops, and the resulting equations are solved for the loop currents. Using the loop currents, element currents and voltages are then determined. Thus, in this method, the number of simultaneous equations to be solved are equal to the number of independent loops. As noted above, it can be shown that this is equal to $E - N + 1$. Example 1.2 illustrates the techniques just discussed. It may be noted that in the case of planar circuits, the meshes can be chosen as the independent loops.

EXAMPLE 1.2. *In the circuit in Figure 1.4, find the voltage across the 3-Ω resistor.* First, note that there are two independent loops, which are the two meshes in the circuit, and that loop currents I_1 and I_2 are assigned as shown in the diagram. Then calculate the element currents as $I_{AB} = I_1$, $I_{BC} = I_2$, $I_{CD} = I_2$, $I_{BD} = I_1 - I_2$, and $I_{DA} = I_1$. Calculate the element voltages as $V_{AB} = 2\ I_{AB} = 2\ I_1$, $V_{BC} = 1\ I_{BC} = 1\ I_2$, $V_{CD} = 4\ I_2$, and $V_{BD} = 3\ I_{BD} = 3(I_1 - I_2)$. Applying KVL to loops 1 (ABDA) and 2 (BCDB) and substituting the voltages in terms of loop currents results in:

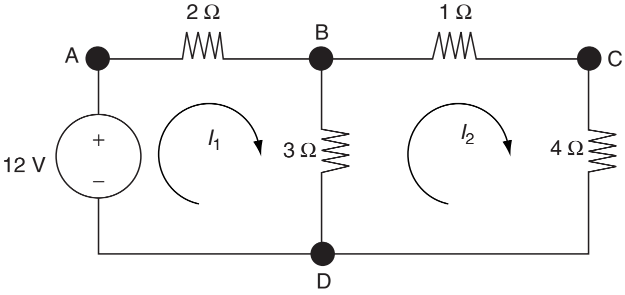

FIGURE 1.4 Circuit for Example 1.2

$$5\ I_1 - 3\ I_2 = 12$$
$$-3\ I_1 + 8\ I_2 = 0.$$

Solving the two equations, you get $I_1 = 96/31$ A and $I_2 = 36/31$ A. The voltage across the 3-Ω resistor is $3(I_1 - I_2) = 3(96/31 - 36/31) = 180/31$ A.

Special case 1

When one of the elements in a loop is a current source, the voltage across it cannot be written using the *v–i* relation of the element. In this case, the voltage across the current source should be treated as an unknown variable to be determined. If a current source is present in only one loop and is not common to more than one loop, then the current of the loop in which the current source is present should be equal to the value of the current source and hence is known. To determine the remaining currents, there is no need to write the KVL equation for the current source loop. However, to determine the voltage of the current source, a KVL equation for the current source loop needs to be written. This equation is presented in example 1.3.

EXAMPLE 1.3. *Analyze the circuit shown in Figure 1.5 to find the voltage across the current sources.* The loop currents are assigned as shown. It is easily seen that $I_3 = -2$. Writing KVL equations for loops 1 and 2, you get:

Loop 1: $2(I_1 - I_2) + 4(I_1 - I_3) - 14 = 0 =>$
$6\ I_1 - 2\ I_2 = 6.$
Loop 2: $I_2 + 3(I_2 - I_3) + 2(I_2 - I_1) = 0 =>$
$-2\ I_1 + 6\ I_2 = -6.$

Solving the two equations simultaneously, you get $I_1 = 3/4$ A and $I_2 = -3/4$ A. To find the V_{CD} across the current source, write the KVL equation for the loop 3 as:

$$4(I_3 - I_1) + 3(I_3 - I_2) + V_{CD} = 0 =>$$
$$V_{CD} = 4\ I_1 + 3\ I_2 - 7\ I_3 = 14.75\ \text{V}.$$

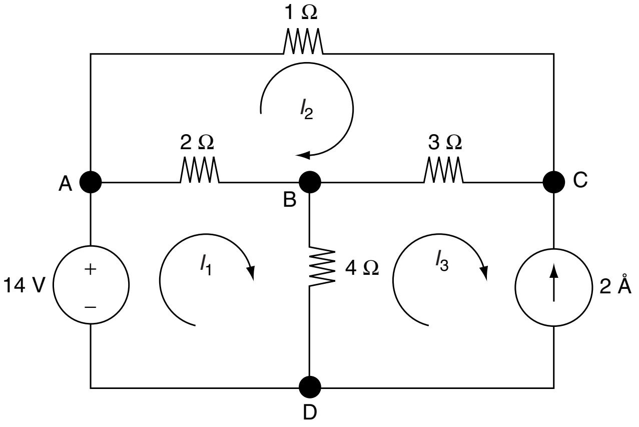

FIGURE 1.5 Circuit for Example 1.3

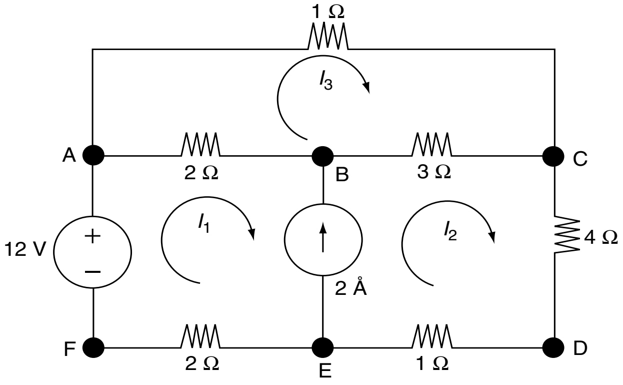

FIGURE 1.6 Circuit for Example 1.4

Special case 2

This case concerns a current source that is common to more than one loop. The solution to this case is illustrated in example 1.4.

Example 1.4. *In the circuit shown in Figure 1.6, the 2 A current source is common to loops 1 and 2.* One method of writing KVL equations is to treat V_{BE} as an unknown and write three KVL equations. In addition, you can write the current of the current source as $I_2 - I_1 = 2$, giving a fourth equation. Solving the four equations simultaneously, you determine the values of I_1, I_2, I_3, and V_{BE}. These equations are the following:

Loop 1: $2(I_1 - I_3) + V_{BE} + 2\ I_1 - 12 = 0$
$=> 4\ I_1 - 2\ I_3 + V_{BE} = 12.$
Loop 2: $3(I_2 - I_3) + 4\ I_2 + I_2 - V_{BE} = 0$
$=> 8\ I_2 - 3\ I_3 - V_{BE} = 0.$
Loop 3: $I_3 + 3(I_3 - I_2) + 2(I_3 - I_1) = 0$
$=> -2\ I_1 - 3\ I_2 + 6\ I_3 = 0.$
Current source relation: $-I_1 + I_2 = 2.$

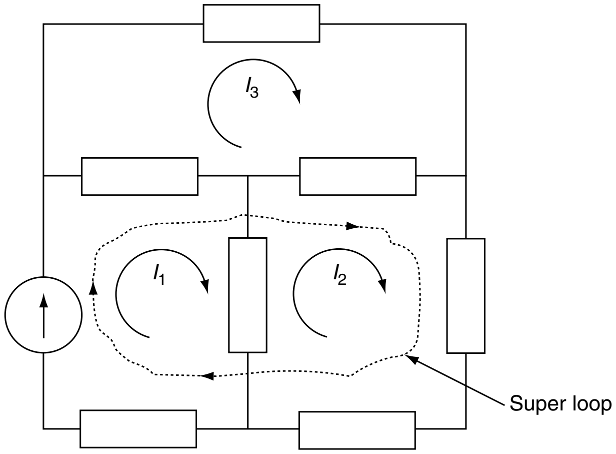

FIGURE 1.7 Circuit in Figure 1.6 with the Super Loop Shown as Dotted Line

Solving the above four equations results in $I_1 = 0.13$ A, $I_2 = 2.13$ A, $I_3 = 1.11$ A, and $V_{BE} = 13.70$ V.

Alternative method for special case 2 (Super loop method): This method eliminates the need to add the voltage variable as an unknown. When a current source is common to loops 1 and 2, then KVL is applied on a new loop called the **super loop**. The super loop is obtained from combining loops 1 and 2 (after deleting the common elements) as shown in Figure 1.7. For the circuit considered in example 1.4, the loop ABCDEFA is the super loop obtained by combining loops 1 and 2. The KVL is applied on this super loop instead of KVL being applied for loop 1 and loop 2 separately. The following is the KVL equation for super loop ABCDEFA:

$$2(I_1 - I_3) + 3(I_2 - I_3) + 4\ I_2 + I_2 + 2\ I_1 - 12 = 0$$
$$=> 4\ I_1 + 8\ I_2 - 5\ I_3 = 12.$$

The KVL equation around loop 3 is written as:

$$-2\ I_1 - 3\ I_2 + 6\ I_3 = 0.$$

The current source can be written as:

$$-I_1 + I_2 = 2.$$

Solving the above three equations simultaneously produces equations $I_1 = 0.13$ A, $I_2 = 2.13$ A, and $I_3 = 1.11$ A.

1.3.2 Node Voltage Method (Nodal Analysis)

In this method, one node is chosen as the reference node whose voltage is assumed as zero, and the voltages of other nodes are expressed with respect to the reference node. For example, in Figure 1.8, the voltage of node G is chosen as the

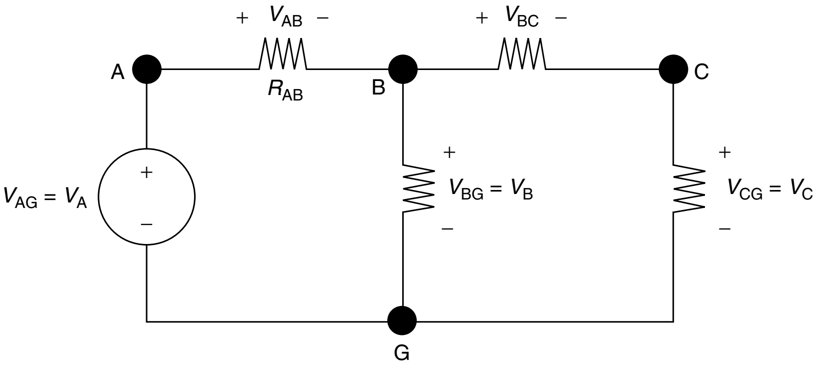

FIGURE 1.8 Circuit with Node Voltages Marked

reference node, and then the voltage of node A is $V_A = V_{AG}$ and that of node B is $V_B = V_{BG}$ and so on. Then, for every element between two nodes, the element voltages may be expressed as the difference between the two node voltages. For example, the voltage of element R_{AB} is $V_{AB} = V_A - V_B$. Similarly $V_{BC} = V_B - V_C$ and so on. Then the current through the element R_{AB} can be determined using the *v–i* characteristic of the element as $I_{AB} = V_{AB}/R_{AB}$. Once the currents of all elements are known in terms of node voltages, KCL is applied for each node except for the reference node, obtaining a total of *N*–1 equations where *N* is the total number of nodes.

Special Case 1

In branches where voltage sources are present, the *v–i* relation cannot be used to find the current. Instead, the current is left as an unknown. Because the voltage of the element is known, another equation can be used to solve the added unknown. When the element is a current source, the current through the element is known. There is no need to use the *v–i* relation. The calculation is illustrated in the following example.

Example 1.5. In Figure 1.9, solve for the voltages V_A, V_B, and V_C with respect to the reference node G. At node A, $V_A = 12$. At node B, KCL yields:

$$I_{BA} + I_{BG} + I_{BC} = 0 => \\ (V_B - V_A)/1 + V_B/4 + (V_B - V_C)/5 = 0 => \\ -V_A + (1 + 1/4 + 1/5)V_B - V_C/5 = 0.$$

Similarly at node C, KCL yields:

$$V_A/2 - V_B/5 + (1/5 + 1/2)V_C = 2.$$

Solving the above three equations simultaneously results in $V_A = 12$ V, $V_B = 10.26$ V, and $V_C = 14.36$ V.

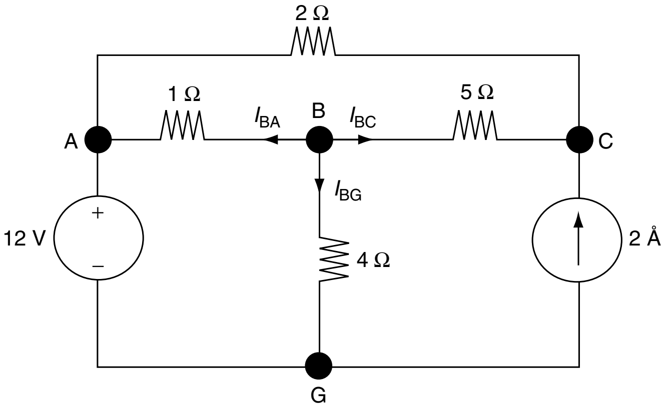

FIGURE 1.9 Circuit for Example 1.5

Super Node: When a voltage source is present between two nonreference nodes, a super node may be used to avoid introducing an unknown variable for the current through the voltage source. Instead of applying KCL to each of the two nodes of the voltage source element, KCL is applied to an imaginary node consisting of both the nodes together. This imaginary node is called a super node. In Figure 1.10, the super node is shown by a dotted closed shape. KCL on this super node is given by:

$$I_{BA} + I_{BG} + I_{CG} + I_{CA} = 0 => (V_B - V_A)/1 \\ + V_B/3 + V_C/4 + (V_C - V_A)/2 = 0.$$

In addition to this equation, the two voltage constraint equations, $V_A = 10$ and $V_B - V_C = 5$, are used to solve for V_B and V_C as $V_B = 9$ V and $V_C = 4$ V.

1.4 Equivalent Circuits

Two linear circuits, say circuit 1 and circuit 2, are said to be equivalent across a specified set of terminals if the voltage–current relations for the two circuits across the specified terminals are identical. Now consider a composite circuit

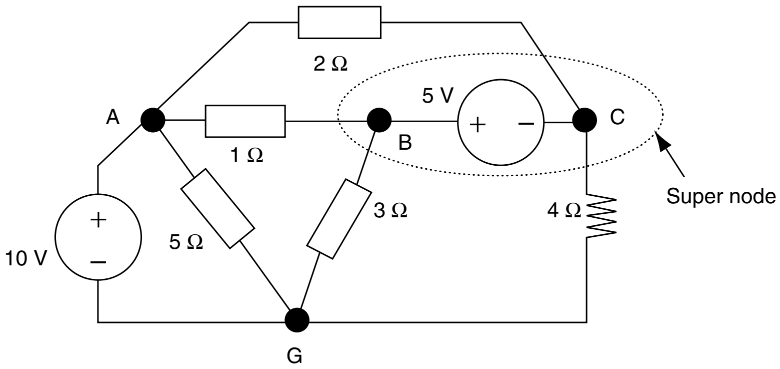

FIGURE 1.10 Circuit with Super Node

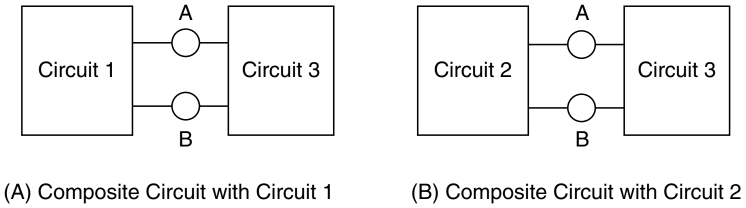

(A) Composite Circuit with Circuit 1

consisting of circuit 1 connected to another circuit, circuit 3, at the specified terminals as shown in Figure 1.11(A). The voltages and currents in circuit 3 are not altered if circuit 2 replaces circuit 1, as shown in Figure 1.11(B). If circuit 2 is simpler than circuit 1, then the analysis of the composite circuit will be simplified. A number of techniques for obtaining two-terminal equivalent circuits are outlined in the following section.

1.4.1 Series Connection

Two two-terminal elements are said to be **connected in series** if the connection is such that the same current flows through both the elements as shown in Figure 1.12. When two resistances R_1 and R_2 are connected in series, they can be replaced by a single element having an equivalent resistance of sum of the two resistances, $R_{eq} = R_1 + R_2$, without affecting the voltages and currents in the rest of the circuit. In a similar manner, if N resistances $R_1, R_2, \ldots, R_N$ are connected in series, their equivalent resistance will be given by:

$$R_{eq} = R_1 + R_2 + \ldots + R_N. \tag{1.9}$$

Voltage Division: When a voltage V_T is present across N resistors connected in series, the total voltage divides across the resistors proportional to their resistance values. Thus

$$V_1 = V_T \frac{R_1}{R_{eq}},\ V_2 = V_T \frac{R_2}{R_{eq}}, \ldots, V_N = V_T \frac{R_N}{R_{eq}}, \tag{1.10}$$

where $R_{eq} = R_1 + R_2 + \ldots + R_N$.

1.4.2 Parallel Connection

Two-terminal elements are said to be **connected in parallel** if the same voltage exists across all the elements and if they have two distinct common nodes as shown in Figure 1.13. In the case of a parallel connection, conductances, which are reciprocals of resistances, sum to give an equivalent conductance of G_{eq}:

$$G_{eq} = G_1 + G_2 + \ldots + G_N, \qquad (1.11)$$

or equivalently

$$\frac{1}{R_{eq}} = \frac{1}{R_1} + \frac{1}{R_2} + \ldots + \frac{1}{R_N}. \qquad (1.12)$$

Current Division: In parallel connection, the total current I_T of the parallel combination divides proportionally to the conductance of each element. That is, the current in each element is proportional to its conductance and is given by:

$$I_1 = I_T \frac{G_1}{G_{eq}},\ I_2 = I_T \frac{G_2}{G_{eq}}, \ldots, \ I_N = I_T \frac{G_N}{G_{eq}}, \qquad (1.13)$$

where $G_{eq} = G_1 + G_2 + \ldots + G_N$.

1.4.3 Star–Delta (Wye–Delta or T–Pi) Transformation

It can be shown that the star subnetwork connected as shown in Figure 1.14 can be converted into an equivalent delta subnetwork. The element values between the two subnetworks are related as shown in Table 1.3. It should be noted that the star subnetwork has four nodes, whereas the delta network has only three nodes. Hence, the star network can be replaced in a circuit without affecting the voltages and currents in the rest

1.4.4 Thevenin Equivalent Circuit

A network consisting of linear resistors and dependent and independent sources with a pair of accessible terminals can be represented by an equivalent circuit with a voltage source and a series resistance as shown in Figure 1.15. V_{TH} is equal to the open circuit voltage across the two terminals A and B, and R_{TH} is the resistance measured across nodes A and B (also called **looking-in resistance**) when the independent sources in the network are deactivated. The R_{TH} can also be determined as $R_{TH} = V_{oc}/I_{sc}$, where V_{oc} is the open circuit voltage across terminals A and B and where I_{sc} is the short circuit current that will flow from A to B through an external zero resistance connection (short circuit) if one is made.

1.4.5 Norton Equivalent Circuit

A two-terminal network consisting of linear resistors and independent and dependent sources can be represented by an equivalent circuit with a current source and a parallel resistor as shown in Figure 1.16. In this figure, I_N is equal to the short circuit current across terminals A and B, and R_N is the looking-in resistance measured across A and B after the independent sources are deactivated. It is easy to see the following relation between Thevenin equivalent circuit parameters and the Norton equivalent circuit parameters:

$$R_N = R_{TH} \text{ and } I_N = V_{TH}/R_{TH}. \quad (1.14)$$

1.4.6 Source Transformation

Using a Norton equivalent circuit, a voltage source with a series resistor can be converted into an equivalent current source with a parallel resistor. In a similar manner, using Thevenin theorem, a current source with a parallel resistor can be represented by a voltage source with a series resistor. These transformations are called source transformations. The two sources in Figure 1.17 are equivalent between nodes B and C.

1.5 Network Theorems

A number of theorems that simplify the analysis of linear circuits have been proposed. The following section presents, without proof, two such theorems: the superposition theorem and the maximum power transfer theorem.

1.5.1 Superposition Theorem

For a circuit consisting of linear elements and sources, the response (voltage or current) in any element in the circuit is the algebraic sum of the responses in this element obtained by applying one independent source at a time. When one independent source is applied, all other independent sources are deactivated. It may be noted that a deactivated voltage source behaves as a short circuit, whereas a deactivated current source behaves as an open circuit. It should also be noted that the dependent sources in the circuit are not deactivated. Further, any initial condition in the circuit is treated as an appropriate independent source. That is, an initially charged

capacitor is replaced by an uncharged capacitor in series with an independent voltage source. Similarly, an inductor with an initial current is replaced with an inductor without any initial current in parallel with an independent current source. The following example illustrates the application of superposition in the analysis of linear circuits.

> Example 1.6. *For the circuit in Figure 1.18(A), determine the voltage across the* 3-Ω *resistor.* The circuit has two independent sources, one voltage source and one current source. Figure 1.18(B) shows the circuit when voltage source is activated and current source is deactivated (replaced by an open circuit). Let V_{31} be the voltage across the 3-Ω resistor in this circuit. Figure 1.18(C) shows the circuit when current source is activated and voltage source is deactivated (replaced by a short circuit). Let V_{32} be the voltage across the 3-Ω resistor in this circuit. Then you determine that the voltage across the 3-Ω resistor in the given complete circuit is $V_3 = V_{31} + V_{32}$.

1.5.2 Maximum Power Transfer Theorem

In the circuit shown in Fig. 1.19, power supplied to the load is maximum when the load resistance is equal to the source resistance.

It may be noted that the application of the maximum power transfer theorem is not restricted to simple circuits only. The theorem can also be applied to complicated circuits as long as the circuit is linear and there is one variable load. In such cases, the complicated circuit across the variable load is replaced by its equivalent Thevenin circuit. The maximum power transfer theorem is then applied to find the load resistance that leads to maximum power in the load.

1.6 Time Domain Analysis

When a circuit contains energy storing elements, namely inductors and capacitors, the analysis of the circuit involves the solution of a differential equation.

1.6.1 First-Order Circuits

A circuit with a single energy-storing element yields a first-order differential equation as shown below for the circuits in Figure 1.20.

Consider the RC circuit in Figure 1.20(A). For $t > 0$, writing KVL around the loop, the result is equation:

$$Ri + v_c(0) + \frac{1}{c}\int_0^t i dt = v_s. \tag{1.15}$$

Differentiating with respect to t yields:

$$R\frac{di}{dt} + \frac{1}{c} i = 0. \tag{1.16}$$

The solution of the above homogeneous differential equation can be obtained as:

$$i(t) = Ke^{-1/RCt}. \tag{1.17}$$

The value of K can be found by using the initial voltage $v_c(0)$ in the capacitor as:

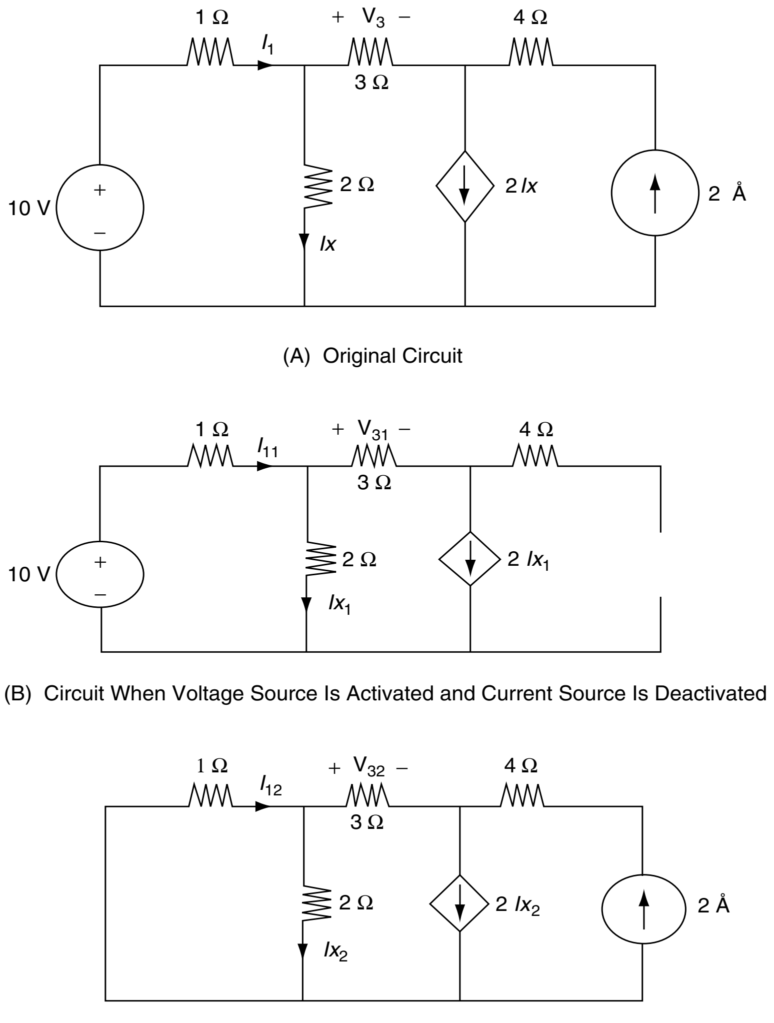
$$K = i(0) = \frac{v_s - v_c(0)}{R}. \tag{1.18}$$

Substituting this value in the expression for $i(t)$ determines the final solution for $i(t)$ as:

$$i(t) = \frac{v_s - v_c(0)}{R} e^{-(1/RC)t}. \tag{1.19}$$

This exponentially decreasing response $i(t)$ is shown in Figure 1.21(A). It has a time constant of $\tau = RC$. The voltage $V_c(t)$ is also shown in Figure 1.21(B)

In a similar manner, the differential equation for $i(t)$ in the RL circuit shown in Figure 1.20(B) can be obtained for $t > 0$ as:



(A) Original Circuit

(B) Circuit When Voltage Source Is Activated and Current Source Is Deactivated

(C) Circuit When Current Source Is Activated and Voltage Source Is Deactivated

FIGURE 1.18 Circuits for Example 1.6

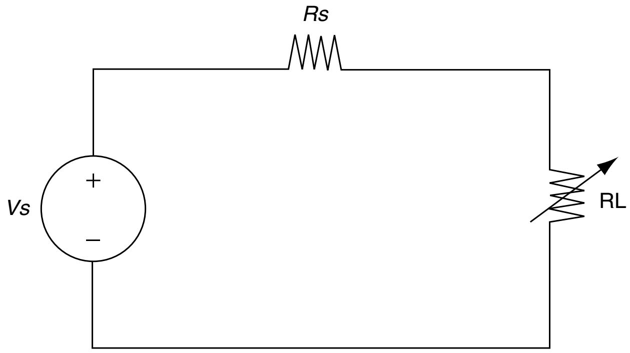


FIGURE 1.19 Circuit with a Variable Load Excited by a Thevenin Source

$$Ri + L\frac{di}{dt} = v_s. \tag{1.20}$$

Because this is a nonhomogeneous differential equation, its solution consists of two parts:

$$i(t) = i_n(t) + i_f(t), \tag{1.21}$$

where $i_n(t)$, the natural response (also called the complementary function) of the circuit, is the solution of the homogeneous differential equation:

$$L\frac{di_n}{dt} + Ri_n = 0. \tag{1.22}$$

The forced response (also called the particular integral) of the circuit, $i_f(t)$, is given by the solution of the nonhomoge-

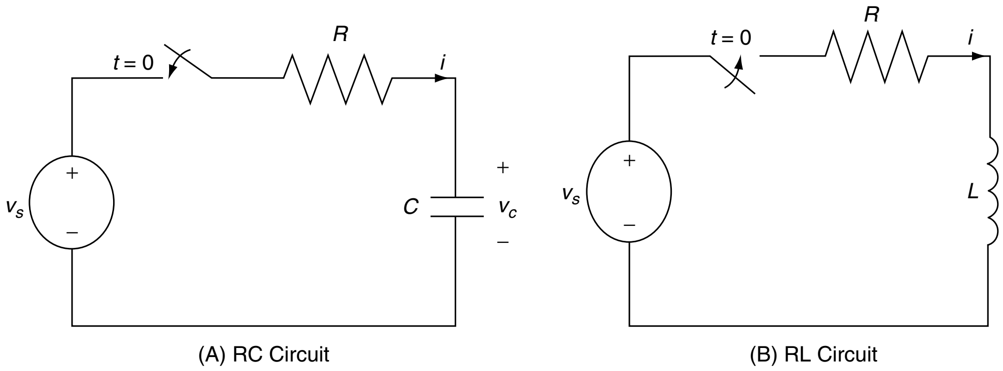

FIGURE 1.20 Circuits with a Single Energy-Storing Element

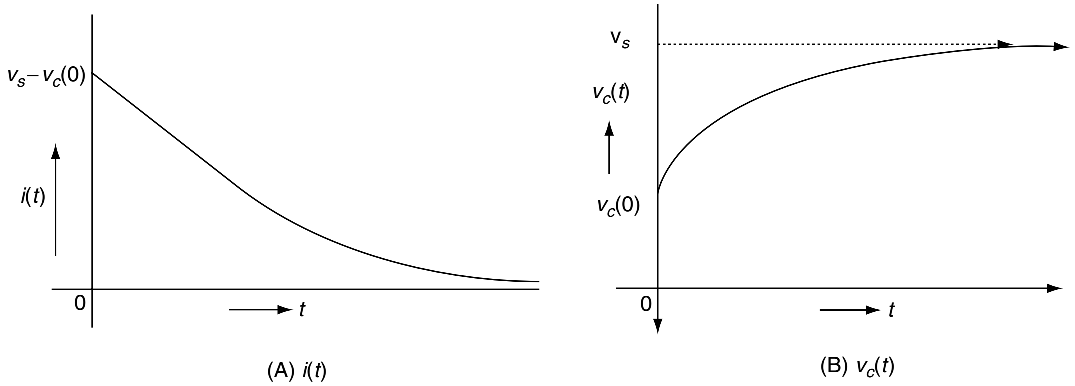

FIGURE 1.21 Response of the Circuit in Figure 1.20(A)

neous differential equation corresponding to the particular forcing function v_s. If v_s is a constant, the forced response in general is also a constant. In this case, the natural and forced responses and the total response are given by:

$$i_n(t) = Ke^{-R/Lt},\ i_f(t) = \frac{v_s}{R},\ \text{and}\ i(t) = Ke^{-(R/L)t} + \frac{v_s}{R}. \tag{1.23}$$

K is found using the initial condition in the inductor $i(0) = I_0$ as $i(0) = K + v_s/R$, and so $K = I_0 - v_s/R$. Substituting for K in the total response yields:

$$i(t) = \left(I_0 - \frac{v_s}{R}\right)e^{-(R/L)t} + \frac{v_s}{R}. \tag{1.24}$$

The current waveform, shown in Figure 1.22, has an exponential characteristic with a time constant of L/R [s].

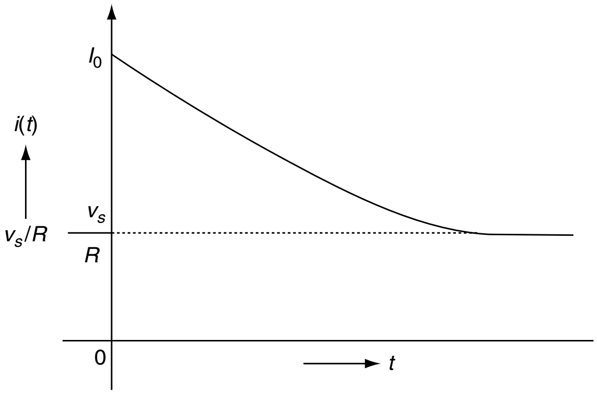

FIGURE 1.22 Response of the Circuit Shown in Figure 1.20(B)

1.6.2 Second-Order Circuits

If the circuit contains two energy-storing elements, L and/or C, the equation connecting voltage or current in the circuit is a second-order differential equation. Consider, for example, the circuit shown in Figure 1.23.

Writing KCL around the loop and substituting $i = Cdv_c/dt$ results in:

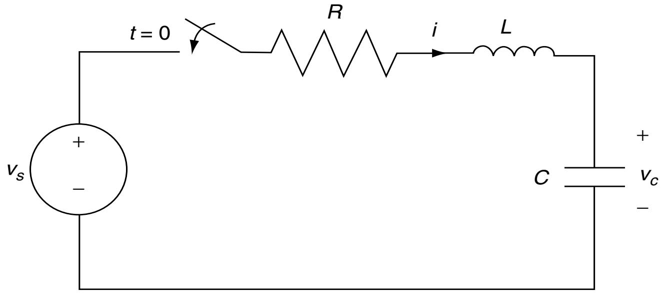

FIGURE 1.23 Circuit with Two Energy-Storing Elements

$$LC\frac{d^2v_c}{dt} + RC\frac{dv_c}{dt} + v_c = v_s. \qquad (1.25)$$

This equation can be solved by either using a Laplace transform or a conventional technique. This section illustrates the use of the conventional technique. Assuming a solution of the form $v_n(t) = Ke^{st}$ for the homogeneous equation yields the characteristic equation as:

$$LCs^2 + RCs + 1 = 0. \qquad (1.26)$$

Solving for s results in the characteristic roots written as:

$$s_{1,2} = -\frac{R}{2L} \pm \sqrt{\left(\frac{R}{2L}\right)^2 - \frac{1}{LC}}. \qquad (1.27)$$

Four cases should be considered:

Case 1: $(R/2L)^2 > (1/LC)$. The result is two real negative roots s_1 and s_2 for which the solution will be an overdamped response of the form:

$$v_n(t) = K_1e^{s_1t} + K_2e^{s_2t}. \qquad (1.28)$$

Case 2: $(R/2L)^2 = (1/LC)$. In this case, the result is a double root at $s_0 = -R/2L$. The natural response is a critically damped response of the form:

$$v_n(t) = (K_1t + K_2)e^{s_0t}. \qquad (1.29)$$

Case 3: $0 < (R/2L)^2 < (1/LC)$. This case yields a pair of complex conjugate roots as:

$$s_{1,2} = -\frac{R}{2L} \pm j\sqrt{\frac{1}{LC} - \left(\frac{R}{2L}\right)^2} = -\sigma \pm j\omega_d. \qquad (1.30)$$

The corresponding natural response is an underdamped oscillatory response of the form:

$$v_n(t) = Ke^{-\sigma t}\cos(\omega_d t + \theta). \qquad (1.31)$$

Case 4: $R/2L = 0$. In this case, a pair of imaginary roots are created as:

$$s_{1,2} = \pm j\sqrt{\frac{1}{LC}} = \pm\, j\omega_0. \qquad (1.32)$$

The corresponding natural response is an undamped oscillation of the form:

$$v_n(t) = K\cos(\omega_0 t + \theta). \qquad (1.33)$$

The forced response can be obtained as $v_f(t) = V_s$. The total solution is obtained as:

$$v_c(t) = v_n(t) + V_s. \qquad (1.34)$$

The unknown coefficients K_1 and K_2 in cases 1 and 2 and K and θ in cases 3 and 4 can be calculated using the initial values on the current in the inductor and the voltage across the capacitor.

Typical responses for the four cases when V_s equals zero are shown in Figure 1.24. For circuits containing energy-dissipating elements, namely resistors, the natural response in general will die down to zero as t goes to infinity. The component of the response that goes to zero as time t goes to infinity is called the **transient response**. The forced response depends on the forcing function. When the forcing function is a constant or a sinusoidal function, the forced response will continue to be present even as t goes to infinity. The component of the total response that continues to exist for all time is called **steady state response**. In the next section, computation of steady state responses for sinusoidal forcing functions is considered.

1.6.3 Higher Order Circuits

When a circuit has more than two energy-storing elements, say n, the analysis of the circuit in general results in a differential equation of order n. The solution of such an equation follows steps similar to the second-order case. The characteristic equation will be of degree n and will have n roots. The natural response will have n exponential terms. Also, the forced response will in general have the same shape as the forcing function. The Laplace transform is normally used to solve such higher order circuits.

1.7 Laplace Transform

In the solution of linear time-invariant differential equations, it was noted that a forcing function of the form K_ie^{st} yields an output of the form K_oe^{st} where s is a complex variable. The function e^{st} is a complex sinusoid of exponentially varying amplitude, often called a damped sinusoid. Because linear equations obey the superposition principle, the solution of a linear differential equation to any forcing function can be found by superposing solutions to component-damped sinusoids if the forcing function is expressed as a sum of damped

FIGURE 1.24 Typical Second-Order Circuit Responses

sinusoids. With this objective in mind, the Laplace transform is defined. The **Laplace transform** decomposes a given time function into an integral of complex-damped sinusoids.

1.7.1 Definition

The Laplace transform of $f(t)$ is defined as:

$$F(s) = \int_{0}^{\infty} f(t)e^{-st}dt. \tag{1.35}$$

The inverse Laplace transform is defined as:

$$f(t) = \frac{1}{2\pi j}\int_{\sigma_0 - j\infty}^{\sigma_0 + j\infty} F(s)e^{st}dt. \tag{1.36}$$

$F(s)$ is called the Laplace transform of $f(t)$, and σ_0 is included in the limits to ensure the convergence of the improper integral. The equation 1.36 shows that $f(t)$ is expressed as a sum (integral) of infinitely many exponential functions of complex frequencies (s) with complex amplitudes (phasors) $\{F(s)\}$. The complex amplitude $F(s)$ at any frequency s is given by the integral in equation 1.35. The Laplace transform, defined as the integral extending from zero to infinity, is called a single-sided Laplace transform against the double-sided Laplace transform whose integral extends from $-\infty$ to $+\infty$. As transient response calculations start from some initial time, the single-sided transforms are sufficient in the time domain analysis of linear electric circuits. Hence, this discussion considers only single-sided Laplace transforms.

1.7.2 Laplace Transforms of Common Functions

Consider

$$f(t) = Ae^{-at} \text{ for } 0 \leq t \leq \infty, \tag{1.37}$$

then

$$F(s) = \int_{0}^{\infty} Ae^{-at}e^{-st}\,dt = \left.\frac{Ae^{-(a+s)t}}{-(a+s)}\right|_{0}^{\infty}$$
$$= \frac{Ae^{-\infty} - Ae^{-0}}{-(a+s)} = \frac{A}{s+a}. \qquad (1.38)$$

In this equation, it is assumed that $\mathrm{Re}(s) - \mathrm{Re}(a)$. In the region in the complex s-plane where s satisfies the condition that $\mathrm{Re}s > \mathrm{Re}a$, the integral converges, and the region is called the **region of convergence of F(s)**. When $a = 0$ and $A = 1$, the above $f(t)$ becomes $u(t)$, the unit step function. Substituting these values in equation 1.38, the Laplace transform of *u(t)* is obtained as $1/s$. In a similar way, letting $s = -j\omega$, the Laplace transform of $Ae^{j\omega t}$ is obtained as $A/(s - j\omega)$. Expressing $\cos(\omega t) = (e^{j\omega t} + e^{-j\omega t})/2$, we get the Laplace transform of $A\cos(\omega t)$ as $A\,s/(s^2 + \omega^2)$. In a similar way, the Laplace transform of $A\sin(\omega t)$ is obtained as $A\,\omega/(s^2 + w^2)$. Transforms for some commonly occurring functions are given in Table 1.4. This table can be used for finding forward as well as inverse transforms of functions.

As mentioned at the beginning of this section, the Laplace transform can be used to solve linear time-invariant differential equations. This will be illustrated next in example 1.7.

Example 1.7. *Consider the second-order differential equation and use the Laplace transform to find a solution*:

$$\frac{d^2f}{dt^2} + 6\frac{df}{dt} + 8f = 4e^{-t} \qquad (1.39)$$

with initial conditions $f(0) = 2$ and $\frac{df}{dt}(0) = 3$.

TABLE 1.4 Laplace Transforms of Common Functions

$f(t)$, for $t \geq 0$	$F(s)$
A	$\frac{A}{s}$
$Ae^{-\sigma t}$	$\frac{A}{s+\sigma}$
$A\,t$	$\frac{A}{s^2}$
$\sin(\omega t)$	$\frac{\omega}{s^2+\omega^2}$
$\cos(\omega t)$	$\frac{s}{s^2+\omega^2}$
$e^{-\sigma t}\cos(\omega t)$	$\frac{s+\sigma}{(s+\sigma)^2+\omega^2}$
$e^{-\sigma t}\sin(\omega t)$	$\frac{\omega}{(s+\sigma)^2+\omega^2}$

Taking the Laplace transform of both sides of the above differential equation produces:

$$s^2F(s) - sf(0) - \frac{df}{dt}(0) + 6(sF(s) - f(0)) + 8F(s)$$
$$= \frac{4}{(s+1)}. \qquad (1.40)$$

Substituting for the initial values, you get:

$$s^2F(s) - 2s - 3 + 6sF(s) - 12 + 8F(s) = \frac{4}{(s+1)}. \qquad (1.41)$$

$$(s^2 + 6s + 8)F(s) = \frac{(2s+15)(s+1)+4}{(s+1)}$$
$$= \frac{(2s^2 + 17s + 19)}{(s+1)}. \qquad (1.42)$$

$$F(s) = \frac{(2s^2 + 17s + 19)}{(s^2 + 6s + 8)(s+1)} = \frac{(2s^2 + 17s + 19)}{(s+2)(s+4)(s+1)}. \qquad (1.43)$$

Applying partial fraction expansion, you get:

$$F(s) = \frac{7/2}{s+2} + \frac{-17/6}{s+4} + \frac{4/3}{s+1}. \qquad (1.44)$$

Taking the inverse Laplace transform using the Table 1.5, you get:

$$f(t) = \frac{-7e^{-2t}}{2} \frac{-17e^{-4t}}{6} + \frac{4e^{-t}}{3} \text{ for } t > 0. \qquad (1.45)$$

It may be noted that the total solution is obtained in a single step while taking the initial conditions along the way.

1.7.3 Solution of Electrical Circuits Using the Laplace Transform

There are two ways to apply the Laplace transform for the solution of electrical circuits. In one method, the differential equations for the circuit are first obtained, and then the differential equations are solved using the Laplace transform. In the second method, the circuit elements are converted into s-domain functions and KCL and KVL are applied to the s-domain circuit to obtain the needed current or voltage in the s-domain. The current or voltage in time domain is obtained using the inverse Laplace transform. The second method is simpler and is illustrated here.

Let the Laplace transform of $\{v(t)\} = V(s)$ and Laplace transform of $\{i(t)\} = I(s)$. Then the s-domain voltage current relations of the R, L, and C elements are obtained as follows. Consider a resistor with the v–i relation:

$$v(t) = R\,i(t). \qquad (1.46)$$

Taking the Laplace transform on both the sides yields:

$$V(s) = R\,I(s). \qquad (1.47)$$

Scaling	$f(at),\ a > 0$	$\frac{1}{a}F(\frac{s}{a})$
Initial value	$f(0^+)$	$\lim_{s\to\infty} sF(s)$
Final value	$f(\infty)$	$\lim_{s\to 0} sF(s)$

Note: The $u(t)$ is the unit step function defined by $u(t) = 0$ for $t < 0$ and $u(t) = 1$ for $t > 0$.

Defining the impedance of an element as $V(s)/I(s) = Z(s)$ produces $Z(s) = R$ for a resistance. For an inductance, $v(t) = L\ di/dt$. Taking the Laplace transform of the relation yields $V(s) = sL\,I(s) - Li(0)$, where $i(0)$ represents the initial current in the inductor and where $Z(s) = sL$ is the impedance of the inductance. For a capacitance, $i(t) = c\ dv/dt$ and $I(s) = sc\ V(s) - cv(0)$, where $v(0)$ represents the initial voltage across the capacitance and where $1/sc$ is the impedance of the capacitance.

Equivalent circuits that correspond to the s-domain relations for R, L, and C are shown in Table 1.6 and are suitable for writing KVL equations (initial condition as a voltage source) as well as for writing KCL equations (initial condition as a current source). With these equivalent circuits, a linear circuit can be converted to an s-domain circuit as shown in the example 1.8.

It is important first to show that the KCL and KVL relations can also be converted into s-domain relations. For example, the KCL relation in s-domain is obtained as follows: At any node, KCL states that:

$$i_1(t) + i_2(t) + i_3(t) + \ldots + i_n(t) = 0. \tag{1.48}$$

By applying Laplace transform on both sides, the result is:

$$I_1(s) + I_2(s) + I_3(s) + \ldots + I_n(s) = 0, \tag{1.49}$$

which is the KCL relation for s-domain currents in a node. In a similar manner, the KVL around a loop can be written in s-domain as:

$$V_1(s) + V_2(s) + \ldots + V_n(s) = 0, \tag{1.50}$$

where $V_1(s), V_2(s), \ldots, V_n(s)$ are the s-domain voltages around the loop. In fact, the various time-domain theorems considered earlier, such as the superposition, Thevenin, and Norton theorems, series and parallel equivalent circuits and voltage and current divisions are also valid in the s-domain. The loop current method and node voltage method can be applied for analysis in s-domain.

> Example 1.8. *Consider the circuit given in Figure 1.25(A) and convert a linear circuit into an s-domain circuit.* You can obtain the s-domain circuit shown in Figure 1.25(B) by replacing each element by its equivalent s-domain element. As noted previously, the differential relations of the elements on application of the Laplace transform have become algebraic relations. Applying KVL around the loop, you can obtain the following equations:
>
> $$2I(s) + 0.2sI(s) - 0.4 + \frac{6}{s}I(s) + \frac{3}{s} = \frac{10}{s}. \tag{1.51}$$
>
> $$(2 + 0.2s + \frac{6}{s})I(s) = \frac{10}{s} - \frac{3}{s} + 0.4 = \frac{7 + 0.4s}{s}. \tag{1.52}$$
>
> $$I(s) = \frac{2s + 35}{s^2 + 10s + 30} = \frac{2(s+5) + 25}{(s+5)^2 + (\sqrt{5})^2}. \tag{1.53}$$
>
> $$i(t) = e^{-5t}\{2\cos(\sqrt{5}t) + 5\sqrt{5}\sin(\sqrt{5}t)\} \quad \text{for } t > 0. \tag{1.54}$$

From 1.51 to 1.54 equations, you can see that the solution using the Laplace transform determines the natural response and forced response at the same time. In addition, the initial conditions are taken into account when the s-domain circuit is set up. A limitation of the Laplace transform is that it can be used only for linear circuits.

1.7.4 Network Functions

For a one-port network, voltage and current are the two variables associated with the input port, also called the driving port. One can define two driving point functions under zero initial conditions as:

$$\text{Driving point impedance } Z(s) = \frac{V(s)}{I(s)}.$$

$$\text{Driving point admittance } Y(s) = \frac{I(s)}{V(s)}.$$

In the case of two-port networks, one of the ports may be considered as an input port with input signal $X(s)$ and the other considered the output port with output signal $Y(s)$. Then the transfer function is defined as:

TABLE 1.6 *s*-Domain Equivalent Circuits for *R*, *I*, and *C* Elements

Time domain	Laplace domain KVL	Laplace domain KCL
 $v(t) = R\,i(t)$	 $V(s) = RI(s)$	 $I(s) = G\,V(s)$
 $v(t) = Ldi/dt$	 $V(s) = (sL)\,I(s) - Li(0+)$	 i(0+)/s (1/sL) [siemens] + I(s) I(s) + V(s) $I(s) = (1/sL)\,V(s) + [i(0+)/s]$
 $i(t) = C\,dv/dt$	 $V(s) = (1/sC)I(s) + (v(0+)/s)$	 Cv(0+) [ampere] sC [siemens] + I(s) I(s) + V(s) $I(s) = (sC)\,V(s) - Cv(0+)$

Note: [A] represents ampere, and [*V*] represents volt.

$$H(s) = \frac{Y(s)}{X(s)}, \text{ under zero initial conditions.}$$

In an electrical network, both $Y(s)$ and $X(s)$ can be either voltage or current variables. Four transfer functions can be defined as:

$$\textbf{Transfer voltage ratio } G_v(s) = \frac{V_2(s)}{V_1(s)},$$

under the condition $I_2(s) = 0$.

$$\textbf{Transfer current ratio } G_i(s) = \frac{I_2(s)}{I_1(s)},$$

under the condition $V_2(s) = 0$.

$$\textbf{Transfer impedance } Z_{21} = \frac{V_2(s)}{I_1(s)},$$

under the condition $I_2(s) = 0$.

$$\textbf{Transfer admittance } Y_{21} = \frac{I_2(s)}{V_1(s)},$$

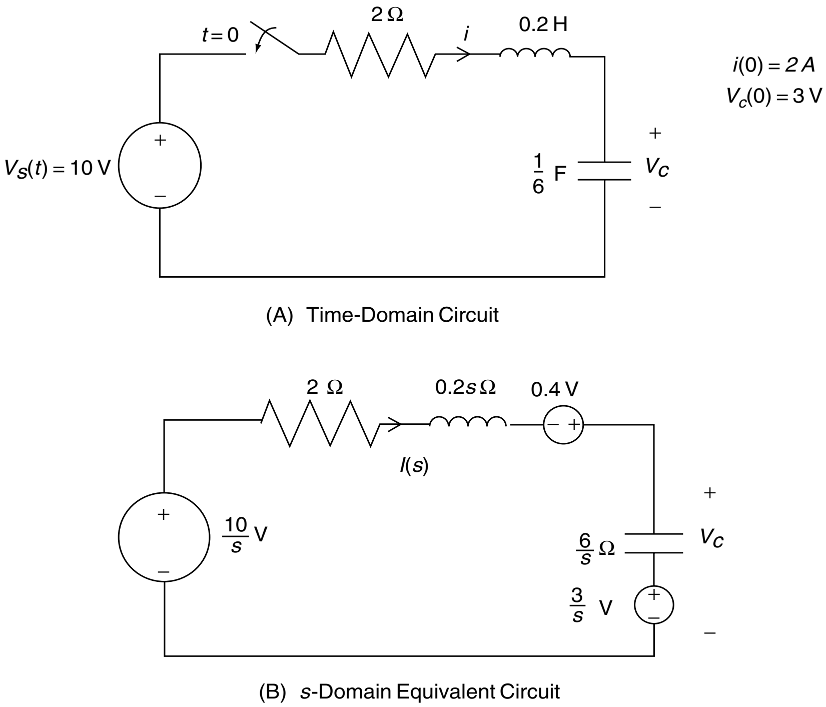
under the condition $V_2(s) = 0$.

1.8 State Variable Analysis

State variable analysis or state space analysis, as it is sometimes called, is a matrix-based approach that is used for analysis of circuits containing time-varying elements as well as nonlinear elements. The state of a circuit or a system is defined as a set of a minimum number of variables associated with the circuit; knowledge of these variables along with the knowledge of the input will enable the prediction of the currents and voltages in all system elements at any future time.

1.8.1 State Variables for Electrical Circuits

As was mentioned earlier, only capacitors and inductors are capable of storing energy in a circuit, and so only the variables associated with them are able to influence the future condition of the circuit. The voltages across the capacitors and the currents through the inductors may serve as state variables. If loops are not solely made up of capacitors and voltage sources, then the voltages across all the capacitors are independent



(A) Time-Domain Circuit

(B) s-Domain Equivalent Circuit

FIGURE 1.25 Circuit for Example 1.8

variables and may be taken as state variables. In a similar way, if there are no sets of inductors and current sources that separate the circuit into two or more parts, then the currents associated with the inductors are independent variables and may be taken as state variables. The following examples assume that all the capacitor voltages and inductor currents are independent variables and will form the set of state variables for the circuit.

1.8.2 Matrix Representation of State Variable Equations

Because matrix techniques are used in state variable analysis, the state variables are commonly expressed as a vector ***x***, and the input source variables are expressed as a vector ***r***. The output variables are denoted as ***y***.

Once the state variables ***x*** are chosen, KVL and KCL are used to determine the derivatives $\dot{x}$ of the state variables and the output variables y in terms of the state variables ***x*** and source variables ***r***. They are expressed as:

$$\begin{aligned}\dot{x} &= Ax + Br.\\ y &= Cx + Dr.\end{aligned} \tag{1.55}$$

The $\dot{x}$ equation is called the **state dynamics equation**, and the y equation is called the **output equation**. A, B, C, and D are appropriately dimensioned coefficient matrices. This set of equations, where the derivative of state variables is expressed as a linear combination of state variables and forcing functions, is said to be in **normal form**.

Example 1.9. *Consider the circuit shown in Figure 1.26 and solve for state variable equations in matrix form.*

Taking v_L and i_C as state variables and applying KVL around loop ABDA, you get:

$$\frac{di_L}{dt} = \frac{1}{L}v_L = \frac{1}{L}(v_a - v_C) = \frac{1}{L}v_a - \frac{1}{L}v_C. \tag{1.56}$$

Similarly, by applying KCL at node B, you get:

$$\frac{dv_C}{dt} = \frac{1}{C}(i_C) = \frac{1}{C}(i_L + i_1). \tag{1.57}$$

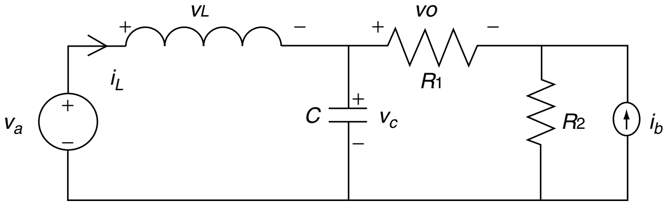


FIGURE 1.26 Circuit for Example 1.9

The current i_1 can be found either by writing node equation at node C or by applying the superposition as:

$$i_1 = \frac{R_2}{R_1 + R_2} i_b - \frac{1}{R_1 + R_2} v_c. \tag{1.58}$$

Substituting for i_1 in equation 1.57, you get:

$$\frac{dv_C}{dt} = \frac{1}{C} i_L + \frac{1}{C(R_1 + R_2)} i_b - \frac{1}{C(R_1 + R_2)} v_c. \tag{1.59}$$

The output v_o can be obtained as $-i_1 R_1$ and can be expressed in terms of state variables and sources by employing equation 1.58 as:

$$v_o = -\frac{R_1 R_2}{R_1 + R_2} i_b + \frac{R_1}{R_1 + R_2} v_c. \tag{1.60}$$

Equations 1.56, 1.59, and 1.60 can be expressed in matrix form as:

$$\begin{aligned} \begin{bmatrix} \dfrac{di_L}{dt} \\ \dfrac{dv_C}{dt} \end{bmatrix} &= \begin{bmatrix} 0 & -\dfrac{1}{L} \\ \dfrac{1}{C} & \dfrac{1}{C(R_1 + R_2)} \end{bmatrix} \begin{bmatrix} i_L \\ v_C \end{bmatrix} \\ &+ \begin{bmatrix} \dfrac{1}{L} & 0 \\ 0 & \dfrac{1}{C(R_1 + R_2)} \end{bmatrix} \begin{bmatrix} v_a \\ i_b \end{bmatrix}. \end{aligned} \tag{1.61}$$

$$\begin{aligned} [v_o] &= \begin{bmatrix} 0 & \dfrac{R_1}{R_1 + R_2} \end{bmatrix} \begin{bmatrix} i_L \\ v_C \end{bmatrix} \\ &+ \begin{bmatrix} 0 & -\dfrac{R_1 R_2}{R_1 + R_2} \end{bmatrix} \begin{bmatrix} v_a \\ i_b \end{bmatrix}. \end{aligned} \tag{1.62}$$

The ordering of the variables in the state variable vector $\boldsymbol{x}$ and the input vector $\boldsymbol{r}$ is arbitrary. Once the ordering is chosen, however, it must remain the same for all the variables in every place of occurrence. In large circuits, topological methods may be employed to systematically select the state variables and write KCL and KVL equations. For want of space, these methods are not described in this discussion. Next, this chapter briefly goes over the method for solving state variable equations.

1.8.3 Solution of State Variable Equations

There are many methods for solving state variable equations: (1) computer-based numerical solution, (2) conventional differential equation time-domain solution, and (3) Laplace transform s-domain solution. This chapter will only present the Laplace transform domain solution.

Consider the state dynamics equation:

$$\dot{x} = Ax + Br. \tag{1.63}$$

Taking the Laplace transform on both sides yields:

$$sX(s) - x(0) = AX(s) + BR(s), \tag{1.64}$$

where $X(s)$ and $R(s)$ are the Laplace transforms of $x(t)$ and $r(t)$, respectively, and $x(0)$ represents the initial conditions.

Rearranging equation 1.64 results in:

$$\begin{aligned} &(sI - A)X(s) = x(0) + BR(s) \\ &X(s) = (sI - A)^{-1}x(0) + (sI - A)^{-1}BR(s). \end{aligned} \tag{1.65}$$

Taking the inverse Laplace transform of $X(s)$ yields:

$$x(t) = \phi(t)x(0) + \phi(t) * Br(t), \tag{1.66}$$

where $\phi(t)$, the inverse Laplace transform of $\{(sI - A)^{-1}\}$, is called the state transition matrix and where * represents the time domain convolution.

Expanding the convolution, $x(t)$ can be written as:

$$x(t) = \phi(t)x(0) + \int_0^t \phi(t - \tau)Br(\tau)d\tau. \tag{1.67}$$

Once $x(t)$ is known, $y(t)$ may be found using the output equation 1.60.

1.9 Alternating Current Steady State Analysis

1.9.1 Sinusoidal Voltages and Currents

Standard forms of writing sinusoidal voltages and currents are:

$$v(t) = V_m \cos(\omega t + \alpha)[\mathrm{V}]. \tag{1.68a}$$

$$i(t) = I_m \cos(\omega t + \beta)[\mathrm{A}]. \tag{1.68b}$$

V_m and I_m are the maximum values of the voltage and current, ω is the frequency of the signal in radians/second, and α and β are called the phase angles of the voltage and current, respectively. V_m, I_m, and ω are positive real values, whereas α and β are real and can be positive or negative. If α is greater than β, the voltage is said to lead the current, or the current to lag the voltage. If α is less than β the voltage is said to lag the current, or the current to lead the voltage. If α equals β, the voltage and current are in phase.

1.9.2 Complex Exponential Function

Define $X_m e^{j(\omega t+\phi)}$ as a complex exponential function. By Euler's theorem,

$$\begin{aligned} e^{j\theta} &= \cos\theta + j\sin\theta. \\ X_m e^{j(\omega t+\phi)} &= X_m[\cos(\omega t+\phi) + j\sin(\omega t+\phi)]. \\ x(t) &= X_m\cos(\omega t+\phi). \\ &= \text{Real}\ [X_m e^{j(\omega t+\phi)}] = \text{Real}\ [(X_m e^{j\phi})e^{j\omega t}]. \end{aligned} \tag{1.69}$$

The term $(X_m e^{j\phi})$ is called the phasor of the sinusoidal function $x(t)$. For linear RLCM circuits, the forced response is sinusoidal at the input frequency. Since the natural response decays exponentially in time, the forced response is also the steady state response.

1.9.3 Phasors in Alternating Current Circuit Analysis

Consider voltage and current waves of the same frequency:

$$v(t) = V_m\cos(\omega t+\alpha)[\text{V}].$$

$$i(t) = I_m\cos(\omega t+\beta)[\text{A}].$$

Alternative representation is by complex exponentials:

$$v(t) = \text{Real}\ [V_m e^{j\alpha}]e^{j\omega t}[\text{V}].$$

$$i(t) = \text{Real}\ [I_m e^{j\beta}]e^{j\omega t}[\text{A}].$$

Phasor voltage and current are defined as:

$$\boldsymbol{V} = V_m e^{j\alpha}[\text{V}]. \tag{1.70a}$$

$$\boldsymbol{I} = I_m e^{j\beta}[\text{A}]. \tag{1.70b}$$

Since a phasor is a complex number, other representations of a complex number can be used to specify the phasor. These are listed in Table 1.7.

Addition of two voltages or two currents of the same frequency is accomplished by adding the corresponding phasors.

1.9.4 Phasor Diagrams

Since a phasor is a complex number, it can be represented on a complex plane as a *vector* in Cartesian coordinates. The length of the vector is the magnitude of the phasor, and the direction is the phase angle. The projection of the vector on the x-axis is the real part of the phasor, and the projection on the y-axis is the imaginary part of the phasor in rectangular form as noted in Figure 1.27. The graphical representation is called the phasor diagram and the vector is called the phasor.

1.9.5 Phasor Voltage–Current Relationships of Circuit Elements

Voltage $v(t)$ and current $i(t)$ are sinusoidal signals at a frequency of ω rad/s, whereas $\boldsymbol{V}$ and $\boldsymbol{I}$ are phasor voltage and current, respectively. The v–i and **V**–**I** relations for R, L, and C elements are given in Table 1.8.

1.9.6 Impedances and Admittances in Alternating Current Circuits

Impedance $\boldsymbol{Z}$ is defined as the ratio of phasor voltage to phasor current at a pair of terminals in a circuit. The unit of impedance is ohms. **Admittance** $\boldsymbol{Y}$ is defined as the ratio of phasor current to phasor voltage at a pair of terminals of a circuit. The unit of admittance is siemens. $\boldsymbol{Z}$ and $\boldsymbol{Y}$ are complex numbers and reciprocals of each other. Note that phasors are also complex numbers, but phasors represent time-varying sinusoids. Impedance and admittance are time invariant and frequency dependent. Table 1.9 shows the impedances and admittances for R, L, and C elements. It may be noted that the phasor impedance for an element is obtained by substituting $s = j\omega$ in the s-domain impedance $Z(s)$ of the corresponding element.

1.9.7 Series Impedances and Parallel Admittances

If n impedances are in series, their equivalent impedance is given by $\boldsymbol{Z_{eq}} = (\boldsymbol{Z_1} + \boldsymbol{Z_2} + \ldots + \boldsymbol{Z_n})$. Similarly, the equivalent admittance of n admittances in parallel is given by $\boldsymbol{Y_{eq}} = (\boldsymbol{Y_1} + \boldsymbol{Y_2} + \ldots + \boldsymbol{Y_n})$.

1.9.8 Alternating Current Circuit Analysis

Before the steady state analysis is made, a given time-domain circuit is replaced by its phasor-domain circuit, also called the **phasor circuit**. The phasor circuit of a given time-domain circuit at a specified frequency is obtained as follows:

- Voltages and currents are replaced by their corresponding phasors.
- Circuit elements are replaced by impedances or admittances at the specified frequency given in Table 1.9.

All circuit analysis techniques are now applicable to the phasor circuit.

1.9.9 Steps in the Analysis of Phasor Circuits

- Select mesh or nodal analysis for solving the phasor circuit.
- Mark phasor mesh currents or phasor nodal voltages.
- Use impedances for mesh analysis and admittances for nodal analysis.
- Write KVL around meshes (loops) or KCL at the nodes.
  KVL around a mesh: The algebraic sum of phasor voltage drops around a mesh is zero.
  KCL at a node: The algebraic sum of phasor currents leaving a node is zero.
- Solve the mesh or nodal equations with complex coefficients and obtain the complex phasor mesh currents or nodal voltages. The solution can be obtained by variable elimination or Cramer's rule. Remember that the arithmetic is complex number arithmetic.

1.9.10 Methods of Alternating Current Circuit Analysis

All methods of circuit analysis are applicable to alternating current (ac) phasor circuits. Phasor voltages and currents are the variables. Impedances and admittances describe the element voltage–current relationships. Some of the methods are described in this section.

Method of superposition: Circuits with multiple sources of the same frequency can be solved by using the mesh or nodal analysis method on the phasor circuit at the source frequency. Alternatively, the principle of superposition in linear circuits can be applied. First, solve the phasor circuit for each independent source separately. Then add the response voltages and currents from each source to get the total response. Since the responses are at the same frequency, phasor addition is valid.

Voltage and current source equivalence in ac circuits:

An ac voltage source in series with an impedance can be replaced across the same terminals by an equivalent ac current source of the same frequency in parallel with an admittance, as shown in Figure 1.28. Similarly, an ac current source in parallel with an admittance can be replaced across the same terminals by an equivalent ac voltage source of the same frequency in series with an impedance.

Current and voltage division in ac circuits:

For two impedances in series:

$$\boldsymbol{V}_1 = (\frac{\boldsymbol{Z}_1}{\boldsymbol{Z}_1 + \boldsymbol{Z}_2})\boldsymbol{V}, \quad \boldsymbol{V}_2 = (\frac{\boldsymbol{Z}_2}{\boldsymbol{Z}_1 + \boldsymbol{Z}_2})\boldsymbol{V}$$

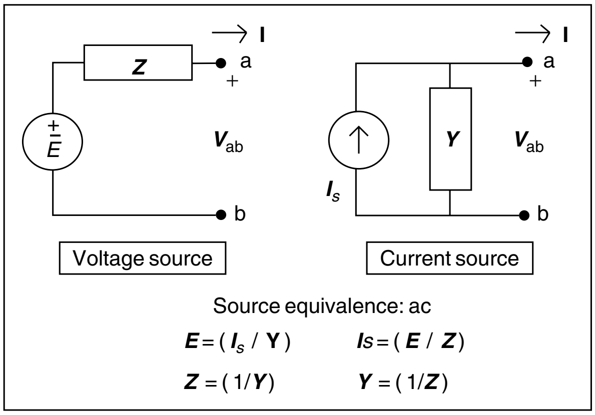

FIGURE 1.28 Source Transformations

For n impedances in series

$$\boldsymbol{V}_1 = \left(\frac{\boldsymbol{Z}_1}{\sum_{i=1}^{n} \boldsymbol{Z}_i}\right)\boldsymbol{V}, \quad \boldsymbol{V}_2 = \left(\frac{\boldsymbol{Z}_2}{\sum_{i=1}^{n} \boldsymbol{Z}_i}\right)\boldsymbol{V}, \ldots, \boldsymbol{V}_n = \left(\frac{\boldsymbol{Z}_n}{\sum_{i=1}^{n} \boldsymbol{Z}_i}\right)\boldsymbol{V}.$$

For two admittances in parallel

$$\boldsymbol{I}_1 = \left(\frac{\boldsymbol{Y}_1}{\boldsymbol{Y}_1 + \boldsymbol{Y}_2}\right)\boldsymbol{I}, \quad \boldsymbol{I}_2 = \left(\frac{\boldsymbol{Y}_2}{\boldsymbol{Y}_1 + \boldsymbol{Y}_2}\right)\boldsymbol{I}$$

For n admittances in parallel:

$$\boldsymbol{I}_1 = \left(\frac{\boldsymbol{Y}_1}{\sum_{i=1}^{n} \boldsymbol{Y}_i}\right)\boldsymbol{I}, \quad \boldsymbol{I}_2 = \left(\frac{\boldsymbol{Y}_2}{\sum_{i=1}^{n} \boldsymbol{Y}_i}\right)\boldsymbol{I}, \ldots, \boldsymbol{I}_n = \left(\frac{\boldsymbol{Y}_n}{\sum_{i=1}^{n} \boldsymbol{Y}_i}\right)\boldsymbol{I}.$$

Thevenin theorem for ac circuits: A phasor circuit across a pair of terminals is equivalent to an ideal phasor voltage source $\boldsymbol{V}_{oc}$ in series with an impedance $\boldsymbol{Z}_{Th}$, where $\boldsymbol{V}_{oc}$ is the open circuit voltage across the terminals and where $\boldsymbol{Z}_{Th}$ is the equivalent impedance of the circuit across the specified terminals.

Norton theorem for ac circuits: A phasor circuit across a pair of terminals is equivalent to an ideal phasor current source $\boldsymbol{I}_{sc}$ in parallel with an admittance $\boldsymbol{Y}_N$, where $\boldsymbol{I}_{sc}$ is the short circuit current across the terminals and where $\boldsymbol{Y}_N$ is the equivalent admittance of the circuit across the terminals.

Thevenin and Norton equivalent circuits of a linear phasor circuit are shown in Figure 1.29.

1.9.11 Frequency Response Characteristics

The voltage gain G_v at a frequency ω of a two-port network is defined as the ratio of the output voltage phasor to the input voltage phasor. In a similar manner, the current gain G_i is defined as the ratio of output current phasor to input current phasor. Because the phasors are complex quantities that depend on frequency, the gains, voltages, and currents are written as $G(j\omega)$, $V(j\omega)$, and $I(j\omega)$. Frequency response is then defined as the variation of the gain as a function of frequency. The above gain functions are also called transfer functions and written as $H(j\omega)$. $H(j\omega)$ is a complex number and can be written in polar form as follows:

$$H(j\omega) = A(\omega)/\phi(\omega) \tag{1.71}$$

where $A(\omega)$ is the gain magnitude function, $|H(j\omega)|$, and $\phi(\omega)$ is the phase function given by the argument of $H(j\omega)$. In addition to the above gain functions, a number of other useful ratios (network functions) among the voltages and currents of two port networks can be defined. These definitions and their nomenclature are given in Figure 1.30.

1.9.12 Bode Diagrams

Bode diagrams are graphical representations of the frequency responses and are used in solving design problems. Magnitude and phase functions are shown on separate graphs using logarithmic frequency scale along the x-axis. Logarithm of the frequency to base 10 is used for the x-axis of a graph. Zero frequency will correspond to negative infinity on the logarithmic scale and will not show on the plots. The x-axis is graduated in $\log_{10}\omega$ and so every decade of frequency (e.g.,...0.001, 0.01, 0.1, 1, 10, 100,...) is equally spaced on the x-axis.

The gain magnitude, represented by decibels defined as $20 \log_{10}[A(\omega)]$, is plotted on the y-axis of magnitude plot. Since $A(\omega)$ dB can be both positive and negative, the y-axis has both positive and negative values. Zero dB corresponds to a magnitude function of unity. The y-axis for the phase function uses a linear scale in radians or degrees. Semilog graph paper makes it convenient to sketch Bode plots.

Bode plots are easily sketched by making asymptotic approximations first. The frequency response function $H(j\omega)$ is a rational function, and the numerator and denominator are factorized into first-order terms and second-order terms with complex roots. The factors are then written in the standard form as follows:

$$\text{First-order terms: } (j\omega + \omega_0) \rightarrow \omega_0\left(1 + j\frac{\omega}{\omega_0}\right).$$

FIGURE 1.30 Frequency Response Functions
Notes: The frequency response ratios are called network functions.
When the input and output are at different terminals, frequency response function is also called a transfer function.

Second-order terms: $[(\omega_0^2 - \omega^2) + j(2\zeta\omega_0\omega)]$

$$\rightarrow \omega_0^2\left[\left(1 - \left(\frac{\omega}{\omega_0}\right)^2\right) + j\left(2\zeta\left(\frac{\omega}{\omega_0}\right)\right)\right].$$

Here ζ is the damping ratio with a value of less than 1. The magnitude and phase Bode diagrams are drawn by adding the individual plots of the first- and second-order terms. Asymptotic plots are first easily sketched by using approximations. For making asymptotic Bode plots, the ratio ω/ω_0 is assumed to be much smaller than one or much larger than one, so the Bode plots become straight line segments called asymptotic approximations. The normalizing frequency ω_0 is called the corner frequency. The asymptotic approximations are corrected at the corner frequencies by calculating the exact value of magnitude and phase functions at the corner frequencies.

The first- and second-order terms can occur in the numerator or denominator of the rational function $H(j\omega)$. Normalized plots for these terms are shown in figures 1.31 and 1.32. Bode diagrams for any function can be made using the normalized plots as building blocks. Figure 1.31 shows the Bode diagrams for a first-order term based on the following equations:

$$\textbf{(i)}\ H(j\omega) = \left(1 + j\frac{\omega}{\omega_0}\right). \quad \textbf{(ii)}\ H(j\omega) = \left(1 + j\frac{\omega}{\omega_0}\right)^{-1}.$$

The magnitude and phase plots of a denominator second-order term with complex roots are given in Figure 1.32. If the term is in the numerator, the figures are flipped about the x-axis, and the sign of the y-axis calibration is reversed.

1.10 Alternating Current Steady State Power

1.10.1 Power and Energy

Power is the rate at which energy E is transferred, such as in this equation:

$$p(t) = \frac{dE}{dt}$$

Energy is measured in Joules [J]. A unit of power is measured in watts [W]: 1W = 1J/s. When energy is transferred at a constant rate, power is constant. In general, energy transferred over time t is the integral of power.

$$E = \int_0^T p(t)dt$$

1.10.2 Power in Electrical Circuits

Power in a two-terminal circuit at any instant is obtained by multiplying the voltage across the terminals by the current through the terminals:

$$p(t) = v(t)i(t). \tag{1.72}$$

If the voltage is in volts [V] and the current in amperes [A], power is in watts. In direct current (dc) circuits under steady state, the voltage $V$and current $I$are constant and power is also constant, given by $P = VI$. In ac circuits under steady state, V

and I are sinusoidal functions of the same frequency. Power in ac circuits is a function of time. For $v(t) = V_m \cos(\omega t + \alpha)$ [V] and $i(t) = I_m \cos(\omega t + \beta)$[A],

$$\begin{aligned} p(t) &= [V_m \cos(\omega t + \alpha)][I_m \cos(\omega t + \beta)] \\ &= 0.5 V_m I_m \{\cos(\alpha - \beta) + \cos(2\omega t + \alpha + \beta)\} \end{aligned} \qquad (1.73)$$

Average power P is defined as the energy transferred per second and can be calculated by integrating $p(t)$ for 1s. Since the voltage and current are periodic signals of the same frequency, the average power is the energy per cycle multiplied by the frequency *f*. Energy per cycle is calculated by integrating *p(t)* over one cycle, that is, one period of the voltage or current wave.

$$\begin{aligned} P &= f\left[\int_0^T p(t)dt\right] = \frac{1}{T}\left[\int_0^T p(t)dt\right] \\ &= \frac{1}{T}\int_0^T 0.5 V_m I_m \{\cos(\alpha - \beta) + \cos(2\omega t + \alpha + \beta)\} dt. \end{aligned}$$

Evaluating the integral yields average power:

$$\mathrm{P} = 0.5 V_m I_m \cos(\alpha - \beta)[\mathrm{W}]. \qquad (1.74)$$

The $p(t)$ is referred to as the **instantaneous power**, and P is the average power or **ac power**. When a sinusoidal voltage of peak value of V_m [V] is applied to a 1Ω resistor, the average power

(B) Phase Plot

FIGURE 1.32 Bode Diagrams of $H(j\omega) = [(\omega_0^2 - \omega^2) + j(2\zeta\omega_0\omega)]^{-1}$

dissipated in the resistor is $0.5\ V_m^2$ [W]. Similarly, when a sinusoidal current of I_m [A] passes through a one ohm resistor, the average power dissipated in the resistor is $0.5\ I_m^2$ [W].

Root mean square (RMS) or effective value of an ac voltage or current is defined as the equivalent dc voltage or current that will dissipate the same amount of power in a $1 - \Omega$ resistor.

$$\begin{aligned} V_{RMS} &= \sqrt{0.5}V_m = 0.707V_m. \\ I_{RMS} &= \sqrt{0.5}V_m = 0.707I_m. \end{aligned} \tag{1.75}$$

For determining whether the power is dissipated (consumed) or supplied (delivered), source or load power conventions are used. In a load, the current flowing into the positive terminal of the voltage is taken in calculating the dissipated power. For a source, the current leaving the positive terminal of the voltage is used for evaluating the supplied power.

1.10.3 Power Calculations in AC Circuits

The average power of a resistance R in an ac circuit is obtained as $0.5\ \mathrm{V_m^2/R}$ [W] or $0.5\,\mathrm{R\ I_m^2}$ [W], with V_m the peak voltage across the resistance and I_m the peak current in the resistance. The average power in an inductor or a capacitor in an ac circuit is zero.

Phasor voltages and currents are used in ac calculations. Average power in ac circuits can be expressed in terms of phasor voltage and current. Using the effective values of V and I for the phasors, the following definitions are given:

Using the notation $\boldsymbol{V} = V\angle\alpha$ [V], $\boldsymbol{I} = I\angle\beta$ [A] and conjugate $\boldsymbol{I}$, denoted by $\boldsymbol{I}^* = \boldsymbol{I}\angle - \beta$ [A], you get:

In the set of equations [W] stands for watts, [VAR] for volt-ampere reactive, and [VA] for voltampere. Average power is also called **active power**, **real power** or simply **power**. Reactive power is also referred to as **imaginary power**. Reactive power is a useful concept in power systems because the system voltage is affected by the reactive power flow. The average power in an inductor or capacitor is zero. By definition, the reactive power taken by an inductor is positive, and the reactive power taken by a capacitor is negative. Complex power representation is useful in calculating the power supplied by the source to a number of loads connected in the system.

Power factor is defined as the ratio of the average power in an ac circuit to the apparent power, which is the product of the voltage and current magnitudes.

$$\text{power factor} = \frac{\text{average power}}{\text{apparent power}} = \frac{P}{S} \tag{1.77}$$

Power factor (PF) has a value between zero and *unity*. The nature of the power factor depends on the relationship between the current and voltage phase angles as:

$(\alpha - \beta) > 0$ PF is lagging.

$(\alpha - \beta) = 0$ PF is unity (UPF).

$(\alpha - \beta) < 0$ PF is leading.

$(\alpha - \beta) = \pi/2$ PF is zero-lagging.

$(\alpha - \beta) = -\pi/2$ PF is zero-leading.

As reactive power $Q = V\,I\,\sin(\alpha - \beta)$,

its sign depends on the nature of PF:
Q is positive for lagging PF.
Q is negative for leading PF.
Q is zero for UPF.

The PF of an inductive load is lagging and that of a capacitive load is leading. A pure inductor has zero-lagging power factor and absorbs positive reactive power. A pure capacitor has zero-leading power factor and absorbs negative reactive power or delivers positive reactive power. Table 1.10 summarizes the expressions for various power quantities in ac circuit elements. Loads are usually specified in terms of P and PF at a rated voltage. Examples are motors and household appliances. Alternatively, the apparent P and PF can be specified.

PF plays an important role in power systems. The product of V and I is called the apparent power. The investment cost of a utility depends on the voltage level and the current carried by the conductors. Higher current needs larger, more expensive conductors. Higher voltage means more insulation costs. The revenue of a utility is generally based on the amount of energy in Kilowatt per hour sold. At low power factors, the revenue is low since power P and energy sold is less. For getting full benefit of investment, the utility would like to sell the highest possible energy, that is, operate at unity power factor all the time. Utilities can have a tariff structure that penalizes the customer for low power factor. Most electromagnetic equipment such as motors have low lagging PF and absorb large reactive powers. By connecting capacitors across the terminals of the motor, part or all of the reactive power absorbed by the motor can be supplied by the capacitors. The reactive power from the supply will be reduced, and the supply PF improved. Cost of the capacitors is balanced against the savings accrued due to PF improvement.

2.1 Introduction

The theory of graphs has played a fundamental role in discovering structural properties of electrical circuits. This should not be surprising because graphs, as the reader shall soon see, are good pictorial representations of circuits and capture all their structural characteristics. This chapter develops most results that form the foundation of graph theoretic study of electrical circuits. A comprehensive treatment of these developments may be found in Swamy and Thulasiraman (1981). All theorems in this chapter are stated without proofs.

The development of graph theory in this chapter is self-contained except for the definitions of standard and elementary results from set theory and matrix theory.

2.2 Basic Concepts and Results

2.2.1 Graphs

A graph $G = (V, E)$ consists of two sets: a finite set $V = (v_1, v_2, \ldots v_n)$ of elements called **vertices** and a finite set $E = (e_1, e_2, \ldots e_n)$ of elements called **edges**. If the edges of G are identified with ordered pairs of vertices, then G is called a **directed** or an **oriented graph**; otherwise, it is called an **undirected** or an **unoriented graph**.

Graphs permit easy pictorial representations. In a pictorial representation, each vertex is represented by a dot, and each edge is represented by a line joining the dots associated with the edge. In directed graphs, an orientation or direction is assigned to each edge. If the edge is associated with the ordered pair (v_i, v_j), then this edge is oriented from v_i to v_j. If an edge e connects vertices v_i and v_j, then it is denoted by $e = (v_i, v_j)$. In a directed graph, (v_i, v_j) refers to an edge directed from v_i to v_j. An undirected graph and a directed graph are shown in Figure 2.1. Unless explicitly stated, the term **graph** may refer to a directed graph or an undirected graph.

The vertices v_i and v_j associated with an edge are called the **end vertices** of the edge. All edges having the same pair of end vertices are called **parallel edges**.

In a directed graph, parallel edges refer to edges connecting the same pair of vertices v_i and v_j the same way from v_i to v_j or from v_j to v_i. For instance, in the graph of Figure 2.1(A), the edges connecting v_1 and v_2 are parallel edges. In the directed graph of Figure 2.1(B), the edges connecting v_3 and v_4 are parallel edges. However, the edges connecting v_1 and v_2 are not parallel edges because they are not oriented in the same way.

If the end vertices of an edge are not distinct, then the edge is called a **self-loop**. The graph of Figure 2.1(A) has one self loop, and the graph of Figure 2.1(B) has two self-loops. An edge is said to be **incident on** its end vertices. In a directed

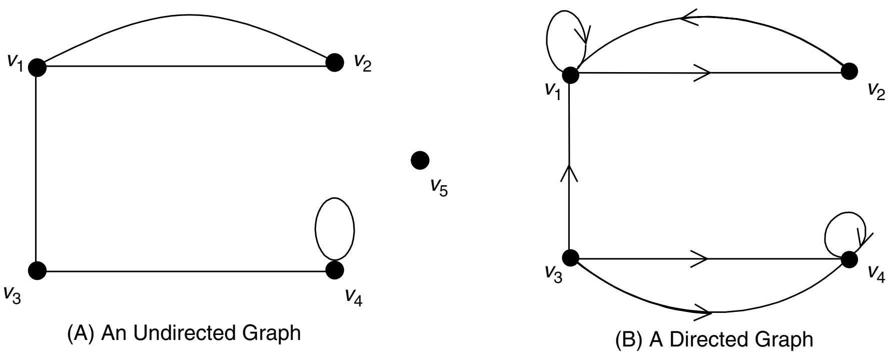

FIGURE 2.1 Graphs: Easy Pictorial Representations

graph, the edge $(v_i,\ v_j)$ is said to be **incident out** of v_i and is said to be **incident into** v_j. Vertices v_i and v_j are adjacent if an edge connects v_i and v_j.

The number of edges incident on a vertex v_i is called the **degree** of v_i and is denoted by $d(v_i)$. In a directed graph, $d_{in}(v_i)$ refers to the number of edges incident into the vertex v_i, and it is called the **in-degree**. In a directed graph, $d_{out}(v_i)$ refers to the number of edges incident out of the vertex v_i or the **out-degree**. If $d(v_i) = 0$, then v_i is said to be an **isolated vertex**. If $d(v_i) = 1$, then v_i is said to be a **pendant vertex**.

A self-loop at a vertex v_i is counted twice while computing $d(v_i)$. As an example in the graph of Figure 2.1(A), $d(v_1) = 3$, $d(v_4) = 3$, and v_5 is an isolated vertex. In the directed graph of Figure 2.1(B), $d_{in}(v_1) = 3$ and $d_{out}(v_1) = 2$.

Note that in a directed graph, for every vertex v_i,

$$d(v_i) = d_{in}(v_i) + d_{out}(v_i).$$

2.2.2 Basic Theorems

Theorem 2.1: (1) The sum of the degrees of the vertices of a graph G is equal to $2\,m$, where m is the number of edges of G, and (2) in a directed graph with m edges, the sum of the in-degrees and the sum of out-degrees are both equal to m.

The following theorem is known to be the first major result in graph theory.

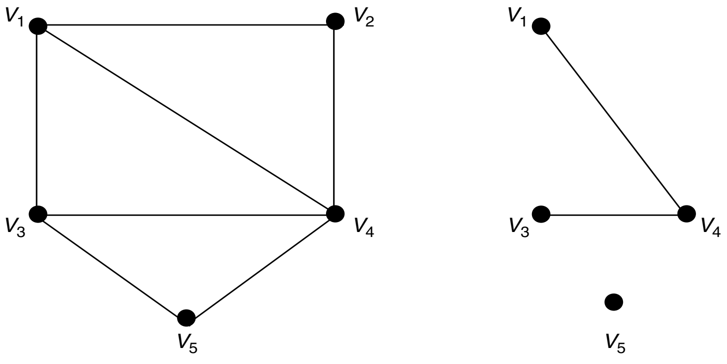
Theorem 2.2: The number of vertices of odd degree in any graph is even.

Consider a graph $G = (V',\ E')$. The graph $G' = (V',\ E')$ is a subgraph of G if $V' \subseteq V$ and $E' \subseteq E$. As an example, a graph G and a subgraph of G are shown in Figure 2.2.

In a graph G, a **path P** connecting vertices v_i and v_j is an alternating sequence of vertices and edges starting at v_i and ending at v_j, with all vertices except v_i and v_j being distinct. In a directed graph, a path P connecting vertices v_i and v_j is called a **directed path** from v_i to v_j if all the edges in P are oriented in the same direction when traversing P from v_i toward v_j.

If a path starts and ends at the same vertex, it is called a **circuit**. In a directed graph, a circuit in which all the edges are oriented in the same direction is called a **directed circuit**. It is often convenient to represent paths and circuits by the sequence of edges representing them.

For example, in the undirected graph of Figure 2.3(A), P: e_1, e_2, e_3, e_4 is a path connecting v_1 and v_5, and C: e_1,



(A) Graph *G*

(B) Subgraph of *G*

FIGURE 2.2 Graphs and Subgraphs

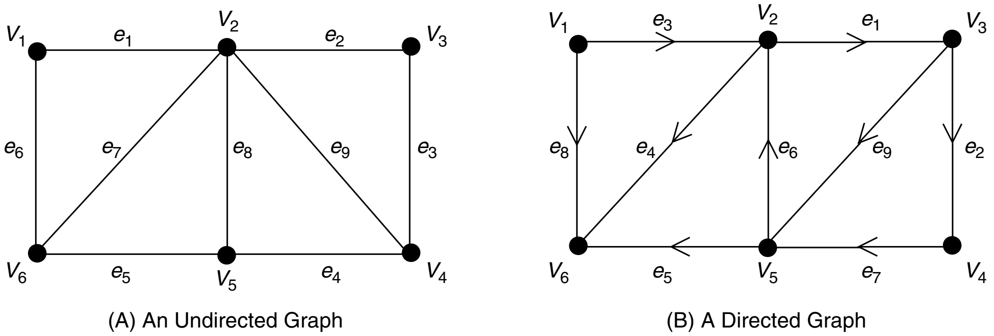


FIGURE 2.3 Graphs Showing Paths

e_2, e_3, e_4, e_5, e_6 is a circuit. In the directed graph of Figure 2.3(B) P: e_1, e_2, e_7, e_5 is a directed path and C: e_1, e_2, e_7, e_6 is a directed circuit. Note that C: e_7, e_5, e_4, e_1, e_2 is a circuit in this directed graph, although it is not a directed circuit. Similarly, P: e_9, e_6, e_3 is a path but not a directed path.

A graph is **connected** if there is a path between every pair of vertices in the graph; otherwise, the graph is not connected. For example, the graph in Figure 2.2(A) is a connected graph, whereas the graph in Figure 2.2(B) is not a connected graph.

A **tree** is a graph that is connected and has no circuits. Consider a connected graph G. A subgraph of G is a **spanning tree** of G if the subgraph is a tree and contains all the vertices of G. A tree and a spanning tree of the graph of Figure 2.4(A) are shown in Figures 2.4(B) and (C), respectively. The edges of a spanning tree T are called the **branches** of T. Given a spanning tree of connected graph G, the **cospanning tree** relative to T is the subgraph of G induced by the edges that are not present in T. For example, the cospanning tree relative to the spanning tree T of Figure 2.4(C) consists of these edges: e_3, e_6, e_7. The edges of a cospanning tree are called **chords**.

It can be easily verified that in a tree, exactly one path connects any two vertices. It should be noted that a tree is minimally connected in the sense that removing any edge from the tree will result in a disconnected graph.

Theorem 2.3: A tree on n vertices has $n-1$ edges.

If a connected graph G has n vertices and m edges, then the **rank** ρ and **nullity** μ of G are defined as follows:

$$\rho(G) = n - 1.$$
$$\mu(G) = m - n + 1.$$

The concepts of rank and nullity have parallels in other branches of mathematics such as matrix theory.

Clearly, if G is connected, then any spanning tree of G has $\rho = n - 1$ branches and

$$\mu = m - n + 1 \text{ chords.}$$

2.2.3 Cuts, Circuits, and Orthogonality

Introduced here are the notions of a cut and a cutset. This section develops certain results that bring out the dual nature of circuits and cutsets.

Consider a connected graph $G = (V,\ E)$ with n vertices and m edges. Let V_1 and V_2 be two mutually disjoint nonempty subsets of V such that $V = V_1 \cup V_2$. Thus V_2 is the complement of V_1 in V and vice versa. V_1 and V_2 are also said to form a partition of V. Then the set of all those edges that have one end vertex in V_1 and the other in V_2 is called a **cut** of G and is denoted by $< V_1,\ V_2 >$. As an example, a graph and a cut $< V_1,\ V_2 >$ of G are shown in Figure 2.5.

The graph G, which results after removing the edges in a cut, will not be connected. A **cutset** S of a connected graph G is a minimal set of edges of G, such that removal of S disconnects G. Thus a cutset is also a cut. Note that the minimality property of a cutset implies that no proper subset of a cutset is a cutset.

Consider a spanning tree T of a connected graph G. Let b denote a branch of T. Removal of branch b disconnects T into two trees, T_1 and T_2. Let V_1 and V_2 denote the vertex sets of T_1 and T_2, respectively. Note that V_1 and V_2 together contain all the vertices of G. It is possible to verify that the cut $< V_1,\ V_2 >$ is a cutset of G and is called the **fundamental cutset** of G with respect to branch b of T. Thus, for a given graph G and a spanning tree T of G, we can construct $n-1$ fundamental cutsets, one for each branch of T. As an example, for the graph shown in Figure 2.5, the fundamental cutsets with respect to the spanning tree $T = [e_1,\ e_2,\ e_6,\ e_8]$ are the following:

Branch e_1: $(e_1,\ e_3,\ e_4)$.

Branch e_2: $(e_2,\ e_3,\ e_4,\ e_5)$.

Branch e_6: $(e_6,\ e_4,\ e_5,\ e_7)$.

Branch e_8: $(e_8,\ e_7)$.

Note that the fundamental cutset with respect to branch b contains b. Furthermore branch b is not present in any other fundamental cutset with respect to T.

FIGURE 2.4 Examples of Tree Graphs

This section next identifies a special class of circuits of a connected graph G. Again let T be a spanning tree of G. Because exactly one path exists between any two vertices of T, adding a chord c to T produces a unique circuit. This circuit is called the **fundamental circuit** of G with respect to chord c of T. Note again that the fundamental circuit with respect to chord c contains c, and that the chord c is not present in any other fundamental circuit with respect to T. As an example, the set of fundamental circuits with respect to the spanning tree $T = (e_1,\ e_2,\ e_6,\ e_8)$ of the graph shown in Figure 2.5. is the following:

Chord e_3: $(e_3,\ e_1,\ e_2)$.
Chord e_4: $(e_4,\ e_1,\ e_2,\ e_6)$.
Chord e_5: $(e_5,\ e_2,\ e_6)$.
Chord e_7: $(e_7,\ e_8,\ e_6)$.

2.2.4 Incidence, Circuit, and Cut Matrices of a Graph

The incidence, circuit and cut matrices are coefficient matrices of Kirchhoff's voltage and current laws that describe an electrical network. This section defines these matrices and presents some properties of these matrices that are useful in studying electrical networks.

Incidence Matrix

Consider a connected directed graph G with n vertices and m edges and with no self-loops. The **all-vertex incidence matrix** $A_c = [a_{ij}]$ of G has n rows, one for each vertex, and m columns, one for each edge. The element a_{ij} of A_c is defined as follows:

$$a_{ij} = \begin{cases} 1, & \text{if } j\text{th edge is incident out of the } i\text{th vertex.} \\ -1, & \text{if } j\text{th edge is incident into the } i\text{th vertex.} \\ 0, & \text{if the } j\text{th edge is not incident on the } i\text{th vertex.} \end{cases}$$

As an example, a graph and its A_c matrix are shown in Figure 2.6.

From the definition of A_c it should be clear that each column of this matrix has exactly two nonzero entries, one $+1$ and one -1, and therefore, any row of A_c can be obtained from the remaining rows. Thus,

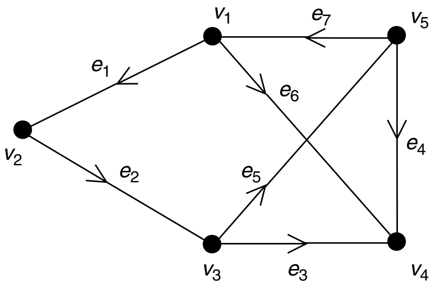

FIGURE 2.6 A Directed Graph

$$\text{rank}(A_c) \leq n - 1.$$

An $(n-1)$ rowed submatrix of A_c is referred to as an **incidence matrix** of *G*. The vertex that corresponds to the row that is not in A_c is called the reference vertex of *A*.

Cut Matrix

Consider a cut $(V_a,\ V_b)$ in a connected directed graph *G* with *n* vertices and *m* edges. Recall that $< V_a,\ V_b >$ consists of all those edges connecting vertices in V_a to V_b. This cut may be assigned an orientation from V_a to V_b or from V_b to V_a. Suppose the orientation of $(V_a,\ V_b)$ is from V_a to V_b. Then the orientation of an edge $(v_i,\ v_j)$ is said to agree with the cut orientation if $v_i \in V_a$, and $v_j \in V_b$.

The **cut matrix** $Q_c = [q_{ij}]$ of *G* has *m* columns, one for each edge and has one row for each cut. The element q_{ij} is defined as follows:

$$q_{ij} = \begin{cases} 1 & \text{if the } j\text{th edge is in the } i\text{th cut and its} \\ & \text{orientation agrees with the cut orientation.} \\ -1 & \text{if the } j\text{th edge is in the } i\text{th cut and its} \\ & \text{orientation does not agree with cut orientation.} \\ 0 & \text{if the } j\text{th edge is not in the } i\text{th cut.} \end{cases}$$

Each row of Q_c is called the **cut vector**. The edges incident on a vertex form a cut. Hence, the matrix A_c is a submatrix of Q_c. Next, another important submatrix of Q_c is identified.

Recall that each branch of a spanning tree T of connected graph G defines a fundamental cutset. The submatrix of Q_c corresponding to the $n-1$ fundamental cutsets defined by T is called the **fundamental cutset matrix** Q_f of G with respect to T.

Let $b_1,\ b_2,\ \ldots, b_{n-1}$ denote the branches of T. Assume that the orientation of a fundamental cutset is chosen to agree with that of the defining branch. Arrange the rows and the columns of Q_f so that the ith column corresponds to the fundamental cutset defined by b_i. Then the matrix Q_f can be displayed in a convenient form as follows:

$$Q_f = [U|Q_{fc}],$$

where U is the unit matrix of order $n-1$, and its columns correspond to the branches of T. As an example, the fundamental cutset matrix of the graph in Figure 2.6 with respect to the spanning tree $T = (e_1,\ e_2,\ e_5,\ e_6)$ is:

$$Q_f = \left[\begin{array}{ccccccc} e_1 & e_2 & e_5 & e_6 & e_3 & e_4 & e_7 \\ 1 & 0 & 0 & 0 & -1 & -1 & -1 \\ 0 & 1 & 0 & 0 & -1 & -1 & -1 \\ 0 & 0 & 1 & 0 & 0 & -1 & -1 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 \end{array}\right]$$

It is clear that the rank of Q_f is $n-1$. Hence,

$$\operatorname{rank}(Q_c) \geq n-1.$$

Circuit Matrix

Consider a circuit C in a connected directed graph G with n vertices and m edges. This circuit can be traversed in one of two directions, clockwise or counterclockwise. The direction chosen for traversing C is called the orientation of C. If an edge $e = (v_i,\ v_j)$ directed from v_i to v_j is in C, and if v_i appears before v_j in traversing C in the direction specified by the orientation of C, then the orientation agrees with the orientation of e.

The **circuit matrix** $B_c = [b_{ij}]$ of G has m columns, one for each edge, and has one row for each circuit in G. The element b_{ij} is defined as follows:

$$b_{ij} = \begin{cases} 1 & \text{if the } j\text{th edge is in the } i\text{th circuit and its} \\ & \text{orientation agrees with the circuit orientation.} \\ -1 & \text{if the } j\text{th edge is in the } i\text{th circuit and its} \\ & \text{orientation does not agree with circuit orientation.} \\ 0 & \text{if the } j\text{th edge is not in the } i\text{th circuit.} \end{cases}$$

The submatrix of B_c corresponding to the fundamental circuits defined by the chords of a spanning tree T is called **fundamental circuit matrix** B_f of G with respect to the spanning tree T.

Let $c_1,\ c_2,\ c_3,\ \ldots, c_{m-n+1}$ denote the chords of T. Arrange the columns and the rows of B_f so that the ith row corresponds to the fundamental circuit defined by the chord c_i and the ith column corresponds to the chord c_i. Then orient the fundamental circuit to agree with the orientation of the defining chord. The result is writing B_f as:

$$B_f = [U|B_{ft}],$$

where U is the unit matrix of order $m-n+1$, and its columns correspond to the chords of T.

As an example, the fundamental circuit matrix of the graph shown in Figure 2.6 with respect to the tree $T = (e_1,\ e_2,\ e_5,\ e_6)$ is given here.

$$B_f = \begin{array}{c} \\ e_3 \\ e_4 \\ e_7 \end{array}\!\!\begin{array}{c} \begin{array}{ccccccc} e_3 & e_4 & e_7 & e_1 & e_2 & e_5 & e_6 \end{array} \\ \left[\begin{array}{ccccccc} 1 & 0 & 0 & 1 & 1 & 0 & -1 \\ 0 & 1 & 0 & 1 & 1 & 1 & -1 \\ 0 & 0 & 1 & 1 & 1 & 1 & 0 \end{array}\right] \end{array}$$

It is clear from this example that the rank of B_f is $m-n+1$. Hence,

$$\operatorname{rank}(B_c) \geq m-n+1.$$

The following results constitute the foundation of the graph-theoretic application to electrical circuit analysis.

Theorem 2.4 (orthogonality relationship): (1) A circuit and a cutset in a connected graph have an even number of common edges; and (2) if a circuit and a cutset in a directed graph have $2k$ common edges, then k of these edges have the same relative orientation in the circuit and the cutset, and the remaining k edges have one orientation in the circuit and the opposite orientation in the cutset.

Theorem 2.5: If the columns of the circuit matrix B_c and the columns of the cut matrix Q_c are arranged in the same edge order, then

$$B_c Q_c^t = 0.$$

Theorem 2.6:

$$\operatorname{rank}(B_c) = m-n+1.$$
$$\operatorname{rank}(Q_c) = n-1.$$

Note that it follows from the above theorem that the rank of the circuit matrix is equal to the nullity of the graph, and the rank of the cut matrix is equal to the rank of the graph. This result, in fact, motivated the definitions of the rank and nullity of a graph.

2.3 Graphs and Electrical Networks

An electrical network is an interconnection of electrical network elements, such as resistances, capacitances, inductances, voltage, and current sources. Each network element is associ-

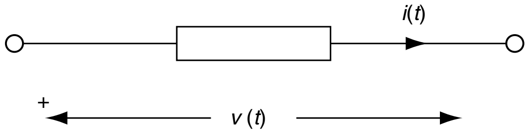

FIGURE 2.7 A Network Element with Reference Convention

(B) Directed Graph Representation of *N*

FIGURE 2.8 Graph Examples of KVL and KCL Equations

ated with two variables: the voltage variable $v(t)$ and the current variable $i(t)$. Reference directions are also assigned to the network elements as shown in Figure 2.7 so that $i(t)$ is positive whenever the current is in the direction of the arrow and so that $v(t)$ is positive whenever the voltage drop in the network element is in the direction of the arrow. Replacing each element and its associated reference direction by a directed edge results in the directed graph representing the network. For example, a simple electrical network and the corresponding directed graph are shown in Figure 2.8.

The physical relationship between the current and voltage variables of network elements is specified by Ohm's law. For voltage and current sources, the voltage and current variables are required to have specified values. The linear dependence among the voltage variables in the network and the linear dependence among the current variables are governed by Kirchhoff's voltage and current laws:

Kirchhoff's voltage law (KVL): The algebraic sum of the voltages around any circuit is equal to zero.

Kirchhoff's current law (KCL): The algebraic sum of the currents flowing out of a node is equal to zero.

As examples, the KVL equation for the circuit 1, 3, 5 and the KCL equation for vertex b in the graph of Figure 2.8 are the following:

$$\begin{array}{ll} \text{Circuit } 1,\ 3,\ 5. & V_1 + V_3 + V_5 = 0 \\ \text{Vertex } b\text{:} & -I_1 + I_2 + I_3 = 0 \end{array}$$

It can be easily seen that KVL and KCL equations for an electrical network N can be conveniently written as:

$$A_c I_e = 0.$$
$$B_c V_e = 0.$$

A_c and B_c are, respectively, the incidence and circuit matrices of the directed graph representing N, I_e, and V_e, respectively, and these are the column vectors of element currents and voltages in N. Because each row in the cut matrix Q_c can be expressed as a linear combination of the rows of the matrix, in the above A_c can be replaced by Q_c. Thus, the result is as follows:

$$\text{KCL: } Q_c I_e = 0.$$
$$\text{KVL: } B_c V_e = 0.$$

Hence, KCL can also be stated as: the algebraic sum of the currents in any cut of N is equal to zero.

If a network N has n vertices and m elements and its graph is connected, then there are only $(n - 1)$ linearly independent cuts and only $(m - n + 1)$ linearly independent circuits. Thus, in writing KVL and KCL equations, only B_f and Q_f, respectively, need to be used. Thus, we have

$$\text{KCL: } Q_f I_e = 0$$
$$\text{KVL: } B_f V_e = 0$$

Note that KCL and KVL equations depend only on the way network elements are interconnected and not on the nature of the network elements. Thus, several results in electrical network theory are essentially graph-theoretic in nature. Some of those results of interest in electrical network analysis are presented in the remainder of this chapter. Note that for these results, a network N and its directed graph representation are both denoted by N.

2.3.1 Loop and Cutset Transformations

Let T be a spanning tree of an electrical network. Let I_c and V_t be the column vectors of chord currents and branch currents with respect to T.

1. **Loop transformation:**

$$I_e = B_f^t I_c.$$

2. **Cutset transformation:**

$$V_e = Q_f^t V_t.$$

If, in the cutset transformation, Q_f is replaced by the incidence matrix A, then we get the **node transformation** given below:

$$V_e = A^t V_n,$$

where the elements in the vector V_n can be interpreted as the voltages of the nodes with respect to the reference node r. (Note: The matrix A does not contain the row corresponding to the node r).

The above transformations have been extensively employed in developing different methods of network analysis. Two of these methods are described in the following section.

2.4 Loop and Cutset Systems of Equations

As observed earlier, the problem of network analysis is to determine the voltages and currents associated with the elements of an electrical network. These voltages and currents can be determined from Kirchhoff's equations and the element voltage–current (v–i) relations given by Ohm's law. However, these equations involve a large number of variables. As can be seen from the loop and cutset transformations, not all these variables are independent. Furthermore, in place of KCL equations, the loop transformation can be used, which involves only chord currents as variables. Similarly, KVL equations can be replaced by the cutset transformation that involves only branch voltage variables. Taking advantage of these transformations enables the establishment of different sytems of network equations known as the loop and cutset systems.

In deriving the loop system, the loop transformation is used in place of KCL in this case, the loop variables (chord currents) serve as independent variables. In deriving the cutset system, the cutset transformation is used in place of KVL, and the cutset variables (tree branch voltages) serve as the independent variables in this case. It is assumed that the electrical network N is connected and that N consists of only resistances, (R), capacitances (C), inductances (L), including mutual inductances, and independent voltage and current sources. It is also assumed that all initial inductor currents and initial capacitor voltages have been replaced by appropriate sources. Further, the voltage and current variables are all Laplace transforms of the complex frequency variable s. In N, there can be no circuit consisting of only independent voltage sources, for if such a circuit of sources were present, then by KVL, there would be a linear relationship among the corresponding voltages; this would violate the independence of the voltage sources. For the same reason, in N, there can be no cutset consisting of only independent current sources. Hence, there exists in N a spanning tree containing all the voltage sources but not current sources. Such a tree is the starting point for the development of both the loop and cutset systems of equations.

Let T be a spanning tree of the given network such that T contains all the voltage sources but no current sources. Partition the element voltage vector V_e and the element current vector I_e as follows:

$$V_e = \begin{bmatrix} V_1 \\ V_2 \\ V_3 \end{bmatrix} \quad \text{and} \quad I_e = \begin{bmatrix} I_1 \\ I_2 \\ I_3 \end{bmatrix}$$

The subscripts 1, 2, and 3 refer to the vectors corresponding to the current sources, RLC elements, and voltage sources, respectively. Let B_f be the fundamental circuit matrix of N, and let Q_f be the fundamental cutset matrix of N with respect to T. The KVL and the KCL equations can then be written as follows:

$$\text{KVL: } B_f V_e = \begin{bmatrix} U & B_{12} & B_{13} \\ 0 & B_{22} & B_{23} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ V_3 \end{bmatrix} = 0.$$

$$\text{KCL: } Q_f I_e = \begin{bmatrix} Q_{11} & Q_{12} & 0 \\ Q_{21} & Q_{22} & U \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \\ I_3 \end{bmatrix} = 0.$$

2.4.1 Loop Method of Network Analysis

Step 1: Solve the following for the vector I_l. Note that I_l is the vector of currents in the nonsource chords of T.

$$Z_l\ I_l = -B_{23} V_3 - B_{22} Z_2 B_{12} I_1, \qquad (2.1)$$

where Z_2 is the impedance matrix of RLC elements and

$$Z_1 = B_{22} Z_2 B_{22}.$$

Equation 2.1 is called the **loop system of equations.**

Step 2: Calculate I_2 using:

$$I_2 = B_{12}I_1 + B_{22}I_l. \tag{2.2}$$

Then

$$V_2 = Z_2 I_2. \tag{2.3}$$

Step 3: Determine V_1 and I_3 using the following:

$$V_1 = -B_{12}V_2 - B_{13}V_3. \tag{2.4}$$

$$I_3 = B_{13}I_1 + B_{23}I_l. \tag{2.5}$$

Note that I_1 and V_3 have specified values because they correspond to current and voltage sources, respectively.

2.4.2 Cutset Method of Network Analysis:

Step 1: Solve the following for the vector V_b. Note that V_b is the vector of voltages in the nonsource branches of T.

$$Y_b\ V_b = -Q_{11}I_1 - Q_{12}Y_2Q_{22}V_b\,, \tag{2.6}$$

where Y_2 is the admittance matrix of *RLC* elements and

$$Y_b = Q_{12}Y_2Q_{12}$$

Equation 2.6 is called the **cutset system of equations.**
Step 2: Calculate V_2 using:

$$V_2 = Q_{12}V_b + Q_{22}V_3. \tag{2.7}$$

Then

$$I_2 = Y_2Y_2. \tag{2.8}$$

Step 3: Determine V_1 and I_3 using the following:

$$V_1 = Q_{21}V_b + Q_{21}V_3 \tag{2.9}$$

$$I_3 = -Q_{21}I_1 - Q_{22}I_2. \tag{2.10}$$

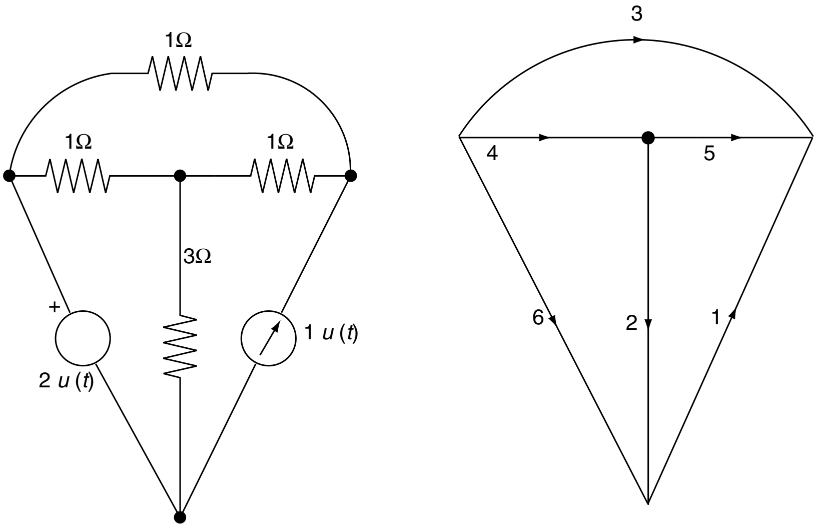
Note that I_1 and V_3 have specified values because they correspond to current and voltage sources.

This completes the cutset method of network analysis.

The following discussion illustrates the loop and cutset methods of analysis on the network shown in Figure 2.9(A). The graph of the network is shown in Figure 2.9(B). The chosen spanning tree T consists of edges 4, 5 and 6. Note that T contains the voltage source and has no current source. The fundamental circuit and the fundamental cutset matrices with respect to T are given below in the required partioned form:

$$B_f = \begin{array}{c} \begin{array}{cccccc} 1 & 2 & 3 & 4 & 5 & 6 \end{array} \\ \begin{bmatrix} 1 & 0 & 0 & -1 & -1 & 1 \\ 1 & 1 & 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & 1 & -1 & 0 \end{bmatrix} \end{array}$$

$$Q_f = \begin{array}{c} \begin{array}{cccccc} 1 & 2 & 3 & 4 & 5 & 6 \end{array} \\ \begin{bmatrix} 1 & -1 & 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 & 1 & 0 \\ -1 & 1 & 0 & 0 & 0 & 1 \end{bmatrix} \end{array}$$



(A) Network (B) Graph

FIGURE 2.9 A Network and Its Graph

From these matrices results the following:

$$\begin{aligned}
B_{12} &= [0 \quad 0 \quad -1 \quad -1] \\
B_{13} &= [1] \\
B_{22} &= \begin{bmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & -1 & -1 \end{bmatrix} \\
B_{23} &= \begin{bmatrix} -1 \\ 0 \end{bmatrix} \\
Q_{11} &= \begin{bmatrix} -1 \\ 0 \end{bmatrix} \\
Q_{12} &= \begin{bmatrix} -1 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix} \\
Q_{21} &= [-1] \\
Q_{22} &= [1 \quad 0 \quad 0 \quad 0].
\end{aligned}$$

The following also results:

$$\begin{aligned}
Z_2 &= \begin{bmatrix} 3 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \\
Y_2 &= \begin{bmatrix} 1/3 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \\
v_6 &= 2\,\mathrm{V} \\
i_1 &= 1\mathrm{A}
\end{aligned}$$

Loop Method

Edges 2 and 3 are nonsource chords. So,

$$I_l = \begin{bmatrix} i_2 \\ i_3 \end{bmatrix}$$

and substituting

$$\begin{aligned}
Z_l &= B_{22} Z_2 B_{22}^t \\
&= \begin{bmatrix} 4 & -1 \\ -1 & 3 \end{bmatrix}
\end{aligned}$$

in equation 2.1 yields the following loop system of equations:

$$\begin{bmatrix} 4 & -1 \\ -1 & 3 \end{bmatrix} \begin{bmatrix} i_2 \\ i_3 \end{bmatrix} = \begin{bmatrix} 3 \\ -2 \end{bmatrix}$$

Solving for i_2 and i_3 yields:

$$I_l = \begin{bmatrix} i_2 \\ i_3 \end{bmatrix} = 1/11 \begin{bmatrix} 7 \\ -5 \end{bmatrix}$$

Using equation 2.2 results in:

$$I_2 = \begin{bmatrix} i_2 \\ i_3 \\ i_4 \\ i_5 \end{bmatrix} = 1/11 \begin{bmatrix} 7 \\ -5 \\ 1 \\ -6 \end{bmatrix}$$

Then using $V_2 = Z_2 I_2$ yields:

$$V_2 = \begin{bmatrix} v_2 \\ v_3 \\ v_4 \\ v_5 \end{bmatrix} = 1/11 \begin{bmatrix} 21 \\ -5 \\ 1 \\ -6 \end{bmatrix}$$

Finally, equations 2.4 and 2.5 yield the following:

$$\begin{aligned}
V_1 &= [v_1] = -27/11. \\
I_3 &= [i_6] = 4/11
\end{aligned}$$

Cutset Method

Edges 4 and 5 are the nonsource branches. So,

$$V_b = \begin{bmatrix} v_4 \\ v_5 \end{bmatrix}$$

and substituting

$$Y_b = \begin{bmatrix} 7/3 & 1 \\ 1 & 2 \end{bmatrix}$$

in equation 2.6 yields the following cutset system of equations:

$$Y_b V_b = \begin{bmatrix} 7/3 & 1 \\ 1 & 2 \end{bmatrix} \begin{bmatrix} v_4 \\ v_5 \end{bmatrix} = \begin{bmatrix} -1/3 \\ -1 \end{bmatrix}$$

Solving for V_b yields:

$$V_b = \begin{bmatrix} v_4 \\ v_5 \end{bmatrix} = 1/11 \begin{bmatrix} 1 \\ -6 \end{bmatrix}$$

From equation 2.7, the result is:

$$V_2 = \begin{bmatrix} v_2 \\ v_3 \\ v_4 \\ v_5 \end{bmatrix} = 1/11 \begin{bmatrix} 21 \\ -5 \\ 1 \\ -6 \end{bmatrix}$$

Then using $I_2 = Y_2 V_2$ yields:

$$I_2 = \begin{bmatrix} i_2 \\ i_3 \\ i_4 \\ i_5 \end{bmatrix} = 1/11 \begin{bmatrix} 7 \\ -5 \\ 1 \\ -6 \end{bmatrix}$$

Finally, using equations 2.9 and 2.10, the end results are:

$$V_1 = [v_1] = -27/11$$
$$I_3 = [i_6] = 4/11$$

This completes the illustration of the loop and cutset methods of circuit analysis.

Node Equations

Suppose a network N has no independent voltage sources. A convenient description of N with the node voltages as independent variables can be obtained as follows.

Let A be the incidence matrix of N with vertex v_r as reference. Let A be partitioned as $A = [A_{11}, A_{12}]$, where the columns of A_{11} and A_{12} correspond, respectively, to the RLC elements and current sources. If I_1 and I_2 denote the column vectors of RLC element currents and current source currents, then KCL equations for N become:

$$A_{11} I_1 = -A_{12} I_2.$$

By Ohm's law:

$$I_1 = Y_1 V_1,$$

where V_1 is the column vector of voltages of RLC elements and Y_1 is the corresponding admittance matrix. Furthermore, by the node transformation yields:

$$V_1 = A_{11}^t V_n,$$

where V_n is the column vector of node voltages. So the result from the KCL equations is the following:

$$(A_{11} Y_1 A_{11}^t) V_n = -A_{12} I_2.$$

The above equations are called **node equations**. The matrix $A_{11} Y_1 A_{11}^t$ is called the **node admittance matrix** of N.

2.5 Summary

This chapter has presented an introduction to certain basic results in graph theory and their application in the analysis of electrical circuits. For a more comprehensive treatment of other developments in circuit theory that are primarily of a graph-theoretic nature, refer to works by Swamy and Thulasiraman (1981) and Chen (1972). A publication by Seshu and Reed (1961) is an early work that first discussed many of the fundamental results presented in this chapter. A review by Watandabe and Shinoda (1999) is the most recent reference summarizing the graph theoretic contributions from Japanese circuit theory researchers.

3.1 Introduction

Hand analysis of large circuits, especially if they contain nonlinear elements, can be tedious and prone to error. In such cases, computer-aided design (CAD) is necessary to speed up the analysis procedure and to obtain accurate results. This chapter describes the algorithms used in CAD programs. Such programs are available from commercial companies, such as *Mentor Graphics*, *Cadence*, and *Avant*!

Typically, CAD programs are based on formulating the equations using matrix methods, and the equations are then solved using numerical methods. For ease in programming, methods that are general and straightforward are preferred. This chapter assumes that the reader is familiar with methods for solving a set of simultaneous linear equations.

3.2 Modified Nodal Analysis

The first step in circuit analysis is formulation of equations. This section modifies the nodal analysis method described in Chapter 1 of this book's Section 1 to include different types of elements in the formulation. Recall that in nodal analysis, Kirchhoff's current law (KCL) is used to write equations at each node in terms of the nodal voltages and element values. The equations are written for one node at a time, and the node voltages are unknown variables. In CAD, it is useful to consider one element at a time and to develop the matrix equations on this basis. Assume that the nodes in a circuit are labeled by consecutive integers from 1 to N such that there are the N nodal voltages in the circuit. The reference node is usually labeled zero. This presentation uses the lowercase letters j, k, l, and m to denote nodes in the circuit. Voltages will be denoted by V and branch currents by I. Consider a linear resistor R connected between nodes j and k as in Figure 3.1.

This element will affect the KCL equations at nodes j and k, and the contributions will be:

$$\text{KCL at Node } j\text{:} \ldots + GV_j - GV_k \ldots = 0.$$
$$\text{KCL at Node } k\text{:} \ldots - GV_j + GV_k \ldots = 0.$$

The V_j and V_k are the nodal voltages at the two nodes $V = V_j - V_k$ and $G = 1/R$, and the ellipses $(\ldots)$ denote contributions from other elements connected to that node. Thus, the entries in the nodal admittance matrix due to the resistor are in four locations:

$$\begin{array}{r c} & \begin{array}{cc} \text{Col.} & \text{Col.} \\ V_j & V_k \end{array} \\ \begin{array}{r} \text{Row } j\text{:} \\ \text{Row } k\text{:} \end{array} & \begin{bmatrix} G & -G \\ -G & G \end{bmatrix} \end{array}$$

Row and Col. denote the row and the column in the matrix, respectively. If one end of the resistor, for example node k, is connected to the reference or ground node, then the

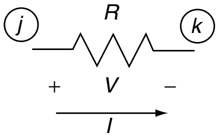

FIGURE 3.1 Linear Resistor

corresponding column and row are not present in the admittance matrix, and there is only one entry in the matrix at location (*j*, *j*). The above is called the **circuit stamp** for the element and can be used for all elements that can be written in admittance form (i.e., the current through the element can be written in terms of nodal voltages and the element value).

Next, consider an independent voltage source for which the current through it cannot be written in terms of nodal voltages, such as in Figure 3.2.

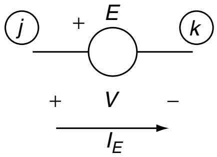

FIGURE 3.2 Independent Voltage Source

In this case, the KCL equations at nodes *j* and *k* are listed as:

$$\begin{aligned}&\text{KCL at node } j\text{:} \ldots + I_E \ldots = 0.\\&\text{KCL at node } k\text{:} \ldots - I_E \ldots = 0.\end{aligned} \tag{3.1}$$

The current I_E is included in the formulation. This increases the number of unknown variables by one. Hence, another equation is needed so that the number of unknowns and the number of equations are the same and can be solved. The additional equation for the voltage source is the following:

$$V_j - V_k = E. \tag{3.2}$$

The circuit stamp for this element includes both equations 3.1 and 3.2 and becomes:

$$\begin{array}{r c} & \begin{array}{ccc} \text{Col.} & \text{Col.} & \text{Col.} \\ V_j & V_k & I_E \end{array} \quad \text{RHS} \\ \begin{array}{r} \text{Row } j\text{:} \\ \text{Row } k\text{:} \\ \text{Row } I_E\text{:} \end{array} & \left[\begin{array}{ccc} & & 1 \\ & & -1 \\ 1 & -1 & \end{array}\right] \quad \left[\begin{array}{c} \\ \\ E \end{array}\right] \end{array}$$

Row I_E denotes the additional equation 3.2 added to nodal analysis, and Col. I_E is the additional column in matrix due to the current through the voltage source. The vector RHS denotes the right-hand side and contains known values of sources. This method is called **modified nodal analysis (MNA)** because of the modifications made to nodal analysis to allow different types of elements in the formulation. The circuit stamps for other common elements are given in Table 3.1 and can be found in CAD books. In this table, rows labeled with lowercase letters *j*, *k*, *l*, and *m* represent KCL equations at that node, and V_j, V_k, V_l, and V_m represent nodal voltages at the corresponding nodes. All rows and columns labeled by a current *I* represent additional rows and columns required for MNA.

As examples, the MNA equations for the linear circuit are in Figure 3.3.

Scanning of the circuit shows that it has three nodal voltages and that it needs three branch currents for MNA formulation. The branch currents are required, one each, for the voltage source, the inductor in impedance form, and the VVT. The total number of variables is six and can be computed before the matrices are formulated. The MNA equations are as follows:

$$\begin{bmatrix} G & -G & 0 & 1 & 0 & 0 \\ -G & G & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & -\mu & 1 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \\ V_3 \\ I_E \\ I_L \\ I_{VVT} \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & C & -C & 0 & 0 & 0 \\ 0 & -C & C & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -L & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \frac{d}{dt} \begin{bmatrix} V_1 \\ V_2 \\ V_3 \\ I_E \\ I_L \\ I_{VVT} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{bmatrix} E, \ \boldsymbol{v}(0) = \begin{bmatrix} V_1(0) \\ V_2(0) \\ V_3(0) \\ I_E(0) \\ I_L(0) \\ I_{VVT}(0) \end{bmatrix}$$

The first three rows represent KCL equations at the three nodes. The last three rows represent the characteristic equations from the independent voltage source, inductor in impedance form, and VVT, respectively. The equations for linear time-invariant circuits are in the form:

$$\boldsymbol{G}\boldsymbol{v}(t) + \boldsymbol{C}\frac{d}{dt}\boldsymbol{v}(t) = \boldsymbol{d}u(t) \text{ and } \boldsymbol{v}(0) = \boldsymbol{v}_0, \tag{3.3}$$

where all conductances and constants arising in the formulation are stored in the matrix ***G*** and all capacitor and inductor values are stored in the matrix ***C***. In addition, the connection of the input source to the circuit is in **d**, the vector of nodal voltages and some branch currents needed for MNA is $\boldsymbol{v}(t)$, and the initial condition vector is $\boldsymbol{v}_0$.

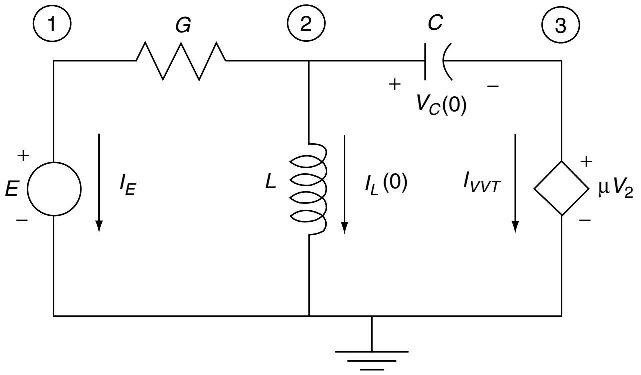

FIGURE 3.3 Linear Circuit Example

For sinusoidal steady state response of a linear time invariant circuit, the input is:

$$u(t) = e^{j\omega t}$$

Here, the initial conditions $\boldsymbol{v}_0$ are ignored, and phasor analysis is used for computing the results. In this case, equation 3.3 becomes:

$$(\boldsymbol{G} + j\omega \boldsymbol{C})\boldsymbol{V}(j\omega) = \boldsymbol{d}, \tag{3.4}$$

where $\boldsymbol{V}(j\omega)$ is the phasor representation of $\boldsymbol{v}(t)$. The matrix equation 3.4 is a set of simultaneous linear equations and are solved numerically for $\boldsymbol{V}(j\omega)$. The solution, in general, is a complex quantity with magnitude $|\boldsymbol{V}(j\omega)|$ and phase angle $\angle \boldsymbol{V}(j\omega)$:

$$\boldsymbol{V}(j\omega) = |\boldsymbol{V}(j\omega)| \angle \boldsymbol{V}(j\omega).$$

The magnitude is also plotted in decibels [dB] and computed as:

$$|\boldsymbol{V}(j\omega)|_{\text{dB}} = 20 \ \log |\boldsymbol{V}(j\omega)|.$$

Using the values $L = 1$ H, $G = 1$ S, $C = 1$ F, $\mu = 0.5$, the magnitude of V_2 is plotted in Figure 3.4.

3.3 Formulation of MNA Equations of Nonlinear Circuits

Formulation of MNA equations of nonlinear circuits follows the same steps as equation formulation for linear circuits. Consider the circuit in Figure 3.5 with a nonlinear resistor defined by $I_R = g(V_R) = 0.001(V_R)^3$ and a nonlinear capacitor defined by $Q_C = q(V_C) = 0.001(V_C)^3$. The current through the capacitor is given by $I_C = (d/dt)Q_C$. Both the nonlinear elements are called voltage-controlled elements because the current through the resistor and charge on the capacitor are nonlinear functions of the voltage across the individual elements. Let the input be a DC source $\text{E}(t) = 1$ V.

The MNA equations for the circuit in Figure 3.5 are the following:

$$\begin{aligned} \frac{V_1 - V_2}{1000} + I_E = 0 = f_1. \\ \frac{V_2 - V_1}{1000} + \frac{(V_2)^3}{1000} + \frac{d}{dt}Q_C(V_2) = 0 = f_2. \\ V_1 - E = 0 = f_3. \end{aligned} \tag{3.5}$$

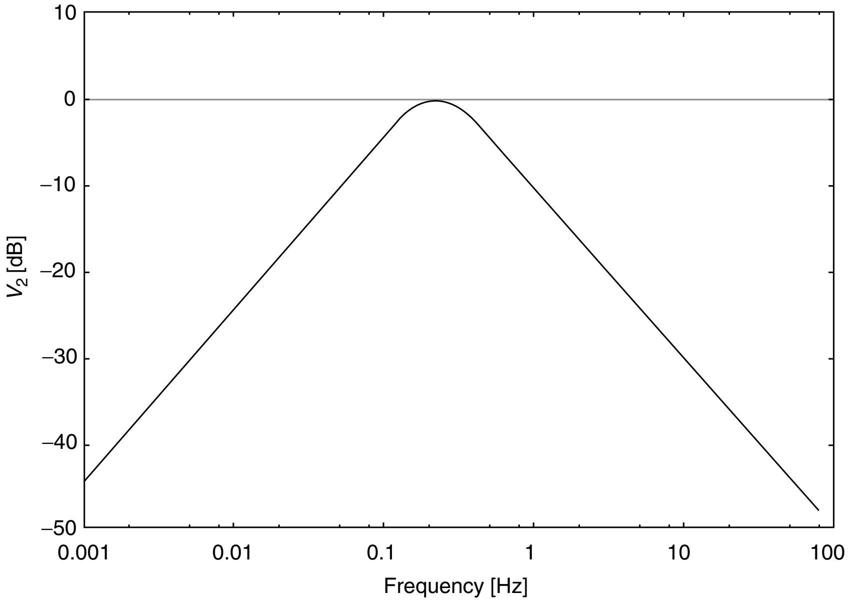

FIGURE 3.4 Frequency Response of a Linear Circuit

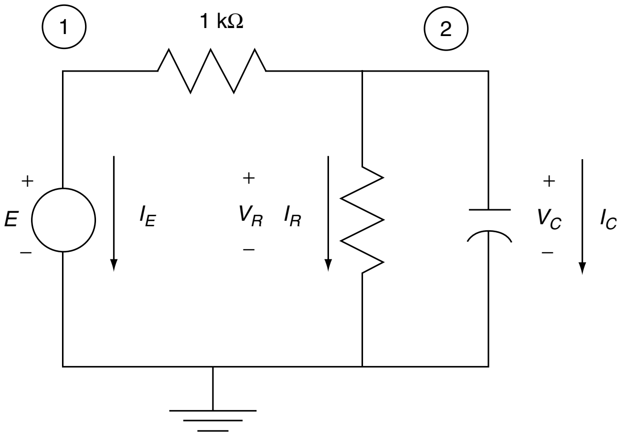

FIGURE 3.5 Nonlinear Circuit

The first two equations are the KCL equations at nodes 1 and 2 respectively, and the last equation is the characteristic equation for the voltage source. In general, all the equations are nonlinear and are collectively written in the form

$$\boldsymbol{f}(\dot{\boldsymbol{v}},\ \boldsymbol{v},\ t) = \begin{vmatrix} f_1(\dot{\boldsymbol{v}},\ \boldsymbol{v},\ t) \\ f_2(\dot{\boldsymbol{v}},\ \boldsymbol{v},\ t) \\ f_3(\dot{\boldsymbol{v}},\ \boldsymbol{v},\ t) \end{vmatrix} = \boldsymbol{0}, \tag{3.6}$$

where the unknown vector and initial conditions are the following:

$$\boldsymbol{v} = \begin{bmatrix} V_1 \\ V_2 \\ I_E \end{bmatrix} \text{and } \boldsymbol{v}(0) = \boldsymbol{v}_0.$$

3.4 A Direct Current Solution of Nonlinear Circuits

For a direct current (dc) solution of nonlinear circuits, the derivatives of the network variables and time are set to zero, and equation 3.6 reduces to:

$$\boldsymbol{f}(\boldsymbol{0},\ \boldsymbol{v},\ 0) = \boldsymbol{x}(\boldsymbol{v}) = \boldsymbol{0}.$$

For example, the equations for the circuit in Figure 3.5 are the following:

$$\boldsymbol{x}(\boldsymbol{v}) = \begin{bmatrix} x_1(V_1,\ V_2,\ I_E) \\ x_2(V_1,\ V_2,\ I_E) \\ x_3(V_1,\ V_2,\ I_E) \end{bmatrix} = \begin{bmatrix} \dfrac{V_1 - V_2}{1000} + I_E \\ \dfrac{V_2 - V_1}{1000} + 0.001(V_2)^3 \\ V_1 - E \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} = \boldsymbol{0}. \tag{3.7}$$

The nonlinear equation 3.7 is solved numerically using an iterative method called the Newton–Raphson (NR) method. Let $\boldsymbol{v}^0$ denote the initial guess and $\boldsymbol{v}^i$ the result of the ith iteration for the solution of equation 3.7. The calculation of the next iteration value $\boldsymbol{v}^{i+1}$ is attempted such that $\boldsymbol{x}(\boldsymbol{v}^{i+1}) \approx \boldsymbol{0}$. Expanding $\boldsymbol{x}(\boldsymbol{v}^{i+1})$ in a Taylor series around the point $\boldsymbol{v}^i$ gives Equation 3.8.

Equation 3.8 shows that only the first two terms in the series have been used and other higher order terms have been ignored. Equation 3.8 can be rewritten in the form:

$$\boldsymbol{J}^i \Delta \boldsymbol{v}^i = -\boldsymbol{x}(\boldsymbol{v}^i), \tag{3.9}$$

where

$$\boldsymbol{J}^i = \begin{bmatrix} \dfrac{\partial x_1}{\partial V_1} & \dfrac{\partial x_1}{\partial V_2} & \dfrac{\partial x_1}{\partial I_E} \\ \dfrac{\partial x_2}{\partial V_1} & \dfrac{\partial x_2}{\partial V_2} & \dfrac{\partial x_2}{\partial I_E} \\ \dfrac{\partial x_3}{\partial V_1} & \dfrac{\partial x_2}{\partial V_2} & \dfrac{\partial x_3}{\partial I_E} \end{bmatrix} = \begin{bmatrix} \dfrac{1}{1000} & \dfrac{-1}{1000} & 1 \\ \dfrac{-1}{1000} & \dfrac{1 + 3(V_2^i)^2}{1000} & 0 \\ 1 & 0 & 0 \end{bmatrix}$$

$$\Delta \boldsymbol{v}^i = \begin{bmatrix} V_1^{i+1} - V_1^i \\ V_2^{i+1} - V_2^i \\ I_E^{i+1} - I_E^i \end{bmatrix},$$

and $\boldsymbol{J}^i$ is called the Jacobian of the system, and $\Delta \boldsymbol{v}^i$ is the change in the solution at the ith iteration. From the solution of equation 3.9, $\Delta \boldsymbol{v}^i$ is obtained and $\boldsymbol{v}^{i+1} = \boldsymbol{v}^i + \Delta \boldsymbol{v}^i$ is computed. Note that equation 3.9 is a linear system of equations, and the Jacobian can be created using circuit stamps, as done

$$\boldsymbol{x}\,(\boldsymbol{v}^{i+1}) \approx \begin{bmatrix} x_1(\boldsymbol{v}^i) + \dfrac{\partial x_1}{\partial V_1}(V_1^{i+1} - V_1^i) + \dfrac{\partial x_1}{\partial V_2}(V_2^{i+1} - V_2^i) + \dfrac{\partial x_1}{\partial I_E}(I_E^{i+1} - I_E^i) \\ x_2(\boldsymbol{v}^i) + \dfrac{\partial x_2}{\partial V_1}(V_1^{i+1} - V_1^i) + \dfrac{\partial x_2}{\partial V_2}(V_2^{i+1} - V_2^i) + \dfrac{\partial x_2}{\partial I_E}(I_E^{i+1} - I_E^i) \\ x_3(\boldsymbol{v}^i) + \dfrac{\partial x_3}{\partial V_1}(V_1^{i+1} - V_1^i) + \dfrac{\partial x_3}{\partial V_2}(V_2^{i+1} - V_2^i) + \dfrac{\partial x_3}{\partial I_E}(I_E^{i+1} - I_E^i) \end{bmatrix} \approx \boldsymbol{0} \tag{3.8}$$

previously for linear circuits. The MNA circuit stamp for a nonlinear voltage-controlled resistor $I_R = g(V_R)$, shown in Figure 3.1, is as follows:

$$\begin{array}{rcc} & \begin{array}{cc} \text{Col.} & \text{Col.} \\ V_j & V_k \end{array} & \text{RHS} \\ \begin{array}{r} \text{Row } j: \\ \\ \text{Row } k: \end{array} & \begin{bmatrix} \dfrac{\partial g}{\partial V_j} & -\dfrac{\partial g}{\partial V_k} \\ -\dfrac{\partial g}{\partial V_j} & \dfrac{\partial g}{\partial V_k} \end{bmatrix} & \begin{bmatrix} -g(V_R^i) \\ \\ g(V_R^i) \end{bmatrix} \end{array}$$

The $V_R = V_j - V_k$ and the linear resistor are special cases of the nonlinear resistor. The difference from MNA formulation of linear circuits is that, for nonlinear circuits, there exists an entry in RHS for all elements. For a current-controlled nonlinear resistor in the form $V_R = r(I_R)$, the impedance form of MNA formulation is used, and the current through the resistor I_R is added to the vector of the unknowns. The additional equation is $V_j - V_k - r(I_R) = 0$.

The Newton–Raphson method is summarized in the following steps:

1. Set the iteration count $i = 0$, and estimate the initial guess of $\boldsymbol{v}^0$.
2. Calculate the Jacobian $\boldsymbol{J}^i$ and right-hand side of equation 3.9, which is $-\boldsymbol{x}(\boldsymbol{v}^i)$.
3. Solve equation 3.9 for $\Delta\boldsymbol{v}^i$.
4. Update the solution vector $\boldsymbol{v}^{i+1} = \boldsymbol{v}^i + \Delta\boldsymbol{v}^i$.
5. Calculate the error in the solution as the norm of the vector $\|\boldsymbol{x}(\boldsymbol{v}^{i+1})\|$. A common method is to use the norm defined as $L_2 = \|\boldsymbol{x}(\boldsymbol{v}^{i+1})\|_2 = \sqrt{\Sigma_j (x_j)^2}$. If the error is small then stop, or instead set $i = i + 1$ and go to step 2.

Under fairly general conditions, it can be shown that if the initial guess is close to the solution, then the Newton–Raphson method converges quadratically to the solution. For the circuit in Figure 3.6, if the initial guess $\boldsymbol{v}^0 = [0 \quad 0 \quad 0]^T$ is used, then the iterations for nodal voltage V_2 are given in Table 3.2.

Note that the last column in the table shows that the right-hand side of equation 3.9 approaches zero with each iteration, indicating that the final value is being reached and the iterations can be stopped when the value is sufficiently close to zero. Also note that with each iteration, the change in the solution is becoming smaller, indicating that one is getting closer to the exact solution. Since the circuit is nonlinear, the Jacobian must be computed for each iteration and is usually the most expensive portion of the entire solution method. If a better initial guess is made, such as $\boldsymbol{v}^0 = [1.0 \quad 0.7 \ -0.003]^T$, then the NR method will converge to the final value in fewer iterations.

The algorithm just described is the basic Newton–Raphson method that works well in most, but not all, cases. Modifications to this method as well as to other methods for solving nonlinear equations can be found in references listed at the end of this chapter.

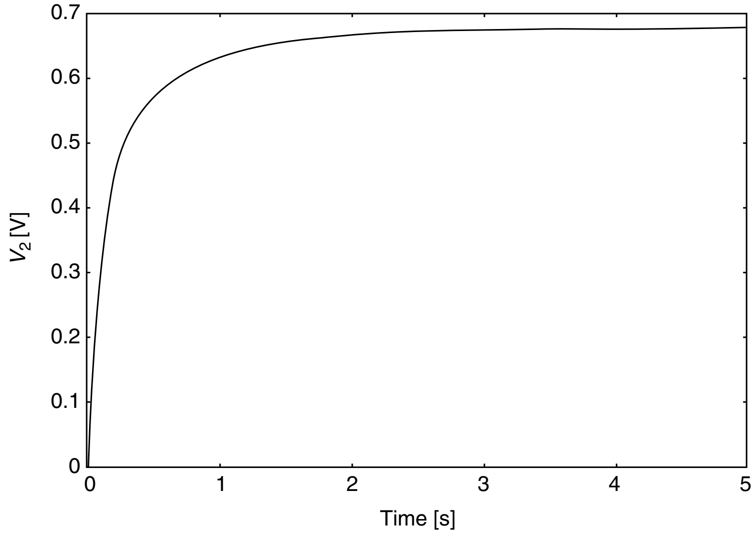

FIGURE 3.6 Time Response of a Nonlinear Circuit

3.5 Transient Analysis of Nonlinear Circuits

Another very useful analysis is the time response of nonlinear circuits. This requires the solution of the differential equation 3.6, and once again numerical methods are used. Usually the solution of the network at time $t = 0$ is known, and the response is calculated after a time step of h at $t + h$. All numerical solution methods replace the time derivative in equation 3.6 with a suitable approximation, and then the resulting equations are solved. Expanding the solution in a Taylor series, the following is obtained:

$$\boldsymbol{v}(t+h) = \boldsymbol{v}(t) + h\frac{d}{dt}\boldsymbol{v}(t) + \ldots \text{ higher order terms.}$$

Assuming that the time step h is small and ignoring the higher order terms as being small, the method called the Euler forward method is used. The method approximates the derivative with:

$$\dot{\boldsymbol{v}}(t) = \frac{d}{dt}\boldsymbol{v}(t) \approx \frac{\boldsymbol{v}(t+h) - \boldsymbol{v}(t)}{h}. \qquad (3.10)$$

Substituting equation 3.10 in equation 3.6 yields:

$$\boldsymbol{f}\left(\frac{\boldsymbol{v}(t+h) - \boldsymbol{v}(t)}{h},\ \boldsymbol{v}(t),\ t\right) = 0 = \boldsymbol{x}(\boldsymbol{v}(t+h)),$$

which is a nonlinear equation with the unknown value $\boldsymbol{v}(t+h)$. It can be written in the form $\boldsymbol{x}(\boldsymbol{v}(t+h)) = 0$ and solved using the Newton–Raphson method given previously. Experience has shown that this method works well with small step sizes; however, large step sizes give results that diverge from the true solution of the network. Such methods are called unstable and are generally not used in integration of differential equations. A better solution method is to use the Euler backward method for which the derivative is approximated by a Taylor series expansion around the time point $\boldsymbol{v}(t+h)$:

$$\boldsymbol{v}(t) = \boldsymbol{v}(t+h) + (-h)\frac{d}{dt}\boldsymbol{v}(t+h) + \ldots \text{ higher order terms.}$$

This equation can be rewritten in the form:

$$\dot{\boldsymbol{v}}(t+h) = \frac{d}{dt}\boldsymbol{v}(t+h) \approx \frac{\boldsymbol{v}(t+h) - \boldsymbol{v}(t)}{h}. \qquad (3.11)$$

Substituting equation 3.11 in equation 3.6 results in:

$$\boldsymbol{f}\left(\frac{\boldsymbol{v}(t+h) - \boldsymbol{v}(t)}{h},\ \boldsymbol{v}(t+h),\ t+h\right) = 0 = \boldsymbol{x}(\boldsymbol{v}(t+h)), \quad (3.12)$$

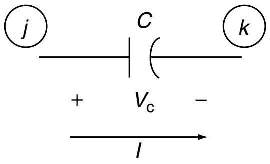
which is a nonlinear equation in the variable $\boldsymbol{v}(t+h)$ and is solved using the Newton–Raphson method. The last step is called the discretization of the differential equation, and this step changes it into an algebraic equation. For example, substituting equation 3.11 in equation 3.5 results in:

$$\begin{bmatrix} \dfrac{V_1(t+h) - V_2(t+h)}{1000} + I_E(t+h) \\ \dfrac{V_2(t+h) - V_1(t+h)}{1000} + \dfrac{(V_2(t+h))^3}{1000} + \dfrac{Q_C(V_2(t+h)) - Q_C(V_2(t))}{h} \\ V_1(t+h) - E(t+h) \end{bmatrix} = \mathbf{0},$$

where the Jacobian will be:

$$\boldsymbol{J}^i = \begin{bmatrix} \dfrac{1}{1000} & \dfrac{-1}{1000} & 1 \\ \dfrac{-1}{1000} & \dfrac{1+3(V_2^i)^2}{1000} + \dfrac{3(V_2^i)^2}{1000h} & 0 \\ 1 & 0 & 0 \end{bmatrix}$$

The explicit dependence on time has been dropped for simplicity. The Jacobian can be created using circuit stamps for the nonlinear elements as done in the case of dc solution of nonlinear circuits. For a nonlinear voltage-controlled capacitor, such as:



defined by the equation $Q_C = q(V_C) = 0.001(V_C)^3$ where $V_C = V_j - V_k$, the circuit stamp is obtained by writing KCL equations at nodes j and k:

$$\text{KCL at node } j\text{:} \ldots + \frac{d}{dt}Q_C(t+h) \ldots = 0.$$

$$\text{KCL at node } k\text{:} \ldots - \frac{d}{dt}Q_C(t+h) \ldots = 0.$$

Using the Euler backward method, the differentials are discretized by:

$$\text{KCL at node } j\text{:} \ldots + \frac{Q_C(t+h) - Q_C(t)}{h} \ldots = 0.$$

$$\text{KCL at node } k\text{:} \ldots - \frac{Q_C(t+h) - Q_C(t)}{h} \ldots = 0.$$

The Jacobian and RHS entries become:

$$\begin{array}{lcc}
 & \begin{array}{cc}\text{Col.} & \text{Col.}\\ V_j & V_k\end{array} & RHS \\
\begin{array}{l}\text{Row } j\text{:}\\[2ex] \text{Row } k\text{:}\end{array} & \begin{bmatrix} \frac{1}{h}\frac{\partial Q_C}{\partial V_j} & -\frac{1}{h}\frac{\partial Q_C}{\partial V_k} \\ -\frac{1}{h}\frac{\partial Q_C}{\partial V_j} & \frac{1}{h}\frac{\partial Q_C}{\partial V_k} \end{bmatrix} & \begin{bmatrix} \frac{-Q_C(V_C^i(t+h)) - Q_C(V_C(t))}{h} \\ \frac{Q_C(V_C^i(t+h)) - Q_C(V_C(t))}{h} \end{bmatrix}
\end{array} \qquad (3.13)$$

Note that in deriving equation 3.13, the use of the chain rule of differentiation and then discretizing $(d/dt)V_C$ has been avoided:

$$\frac{d}{dt}Q_C = \frac{d}{dV_C}Q_C\frac{d}{dt}V_C.$$

The value of $(d/dt)V_C$ has also been discretized. Discretization applied directly to the charge of the capacitor (and flux in case of inductors) leads to better results that maintain charge (and flux) conservation in the numerical solution of electrical circuits. Additional details can be found in work by Kundert (1995).

For the circuit in Figure 3.5, let the capacitor be initially discharged such that $V_2(0) = 0$ and the correct initial condition vector is $\boldsymbol{v}(0) = [1.0\ 0.0 - 0.001]^T$. For this circuit, it is expected that the capacitor will charge up from 0 V to a finite value with time. All nodal voltages in the circuit will remain less than the source voltage of 1 V. If step $h = 0.1$ s is taken, and the initial guess is $\boldsymbol{v}^0(h) = \boldsymbol{v}(0)$, the Newton–Raphson iteration results will be obtained as shown in Table 3.3.

Once the solution at $t = 0.1$ s is obtained, the values from the circuit conditions at that time are used, another time step is taken, and the response at $t = 2h = 0.2$ s is calculated. This procedure is repeated until the end time of interest is reached for computing the response. Although the circuit has a continuous response, the numerical methods are used to compute the response at discrete instants of time. It is expected that if small time steps are taken, then no interesting features of the response will be missed. Note that at each time step, the Newton–Raphson method is used to solve a set of nonlinear equations. Moreover, since the circuit is nonlinear, the Jacobian has to be recomputed at each iteration and each time step. The complete time domain response of the circuit is given in Figure 3.6. The final value $V_2 = 0.6823$ V is reached at about $t = 8$ s. Note that the final value is the same as that obtained in the dc solution above.

TABLE 3.3 Newton–Raphson Iterations for $t = 0$ and $h = 0.1$ s

Iteration **i**	V_2^{i+1}	ΔV_2^i
0	1.0000	1.0000
1	0.6765	−0.3235
2	0.4851	−0.1914
3	0.4006	−0.0845
4	0.3835	−0.0171
5	0.3828	−0.0007

Choosing a large step size $h = 10$ s and calculating the time response will give the results $V_2(10) = 0.6697$ V, $V_2(20) = 0.6816$ V, $V_2(30) = 0.6823$ V, ... Note that even though the result at $t = 10$ s is not accurate, the error does not grow with each time step and the correct value is reached after a few more steps. Such time domain integration methods are called stable and are preferred over the Euler Forward method that may not give correct results for large time steps.

Finally, this section discusses some issues concerning the use of numerical methods for the solution of differential equations and gives some recommendations for obtaining correct results:

1. The discretization equation 3.11 is an approximation, since only the first two terms in the Taylor series expansion are included. As a result of this approximation, the numerically computed results contain an error at each time step, called the local truncation error (LTE). In general, the smaller the time step used, the smaller will be the LTE. The normal expectation is that if the error is reduced at each time step, then the overall error in the numerical results will also be small.
2. This discussion concerning the LTE suggests that if a discretization formula is used that matches more than two terms in the Taylor series expansion, then more accurate results will be obtained. This is also correct, provided the same step size is used for both discretization methods, or alternatively the second method will allow larger step sizes for a given error.
3. This discussion also suggests that it is not necessary to use the same time step when determining the time domain solution of a circuit over a long period of time. It is possible to change the time step during the computation based on error and accuracy requirements.
4. The Newton–Raphson method is used at each time step to solve a set of nonlinear equations. For this method, a good initial guess gives the solution in fewer iterations. Such formulae, called predictor formulae, are available and reduce the overall computation needed for the solution.
5. The issue of stability of the response with large step sizes has already been mentioned. A stable integration method is preferred. Stable methods ensure that the error at each time step does not accumulate over time and reasonably accurate results are obtained.

Additional reasons for these recommendations, as well as other integration methods for time domain solution of nonlinear circuits, can be found in the references at the end of this chapter.

Synthesis of Networks

4.1 Introduction

Synthesis of electrical networks is an area of electrical engineering in which one attempts to find the network from given specifications. In most cases, this is applied to filters constructed with various elements.

This chapter begins with a few words about history. Before the second world war, the main communication products were radios working with amplitude modulation. Stations transmitted on various frequencies, and it was necessary to get only the desired one and suppress all the others. This led to the development of various filters. Two men contributed fundamentally to the filter design theory: Darlington, from the United States, and Cauer, from Germany.

As time went by, it was discovered that inductor capacitor (LC) filters were not suitable for many applications, especially in low frequency regions where inductors are large and heavy. An idea occurred: replace the inductors by active networks composed of amplifiers with feedback by means of resistors and/or capacitors. This was the era of active networks, approximately in the 1960s to 1980s of the 20th century.

Technological advances and miniaturization led to integrated circuits, with the attempt to get complete filters on a chip. Here it turned out that using resistors was not convenient, and a new idea emerged of switched capacitor networks. In these networks, the resistors are replaced by rapidly switched capacitors that act approximately as resistors. In such networks, we have only capacitors and transistors work as amplifiers or switches. Capacitors and transistors are suitable for integration.

New developments continue to find their ways. This Chapter limits explanations mostly to LC filters. Switched capacitor networks and later theoretical developments are too complex to cover in this short contribution.

Returning now to filter synthesis, this discussion must first clarify the appropriate theoretical tools. Filters are linear devices that allow the use of linear network theories. Specifications of filters are almost always given as frequency domain responses, which leads to the use of Laplace transform. This chapter assumes that the reader is at least somewhat familiar with the concept of the transformation because the discussion deals with the complex plane, the complex variable s, frequency domain responses, poles, and zeros. A sufficient amount of information is given so that a reader can refresh his or her knowledge.

4.2 Elementary Networks

Filters can be built with passive elements that do not need any power supply to retain their properties and with active elements that work only when electrical power is supplied from a battery or from a power supply.

The passive elements are inductors (L), capacitors (C), and resistors (R). Resistance of the resistor is measured in ohms. Its inverse value is a conductance, $G = 1/R$. For inductors and capacitors, we use the Laplace transform; in such a case, we speak about impedances of these elements: $Z_L = sL$ and $Z_C = 1/sC$. The inverse of the impedance is the admittance, $Y_C = sC$ and $Y_L = 1/sL$. The subscripts used here are for clarification only and are usually not used. Symbols for these elements are in Figure 4.1. Such networks have two terminals, sometimes called a port. Notice the voltage signs and positive directions of the currents. This is an important convention because it is also valid for independent voltage and current sources, shown in Figure 4.2. We use the letter E for the independent voltage source and the letter J for the independent current source to distinguish them from voltages and currents anywhere inside the network.

From the above description of a one-port network, we can refer to the concept of a two-port network, usually drawn so that the input port is on the left and the output port is on the right. We can introduce a general symbol for the two-port as shown in Figure 4.3. Notice that in such a case we speak about the input voltage across the left one-port, V_1, and the output voltage across the right one-port, V_2. The plus sign is on top and minus sign is at the bottom. We also indicate the currents I_1 and I_2 as shown. Notice how the currents flow into the two-port and how they leave it. It is very important to know these directions.

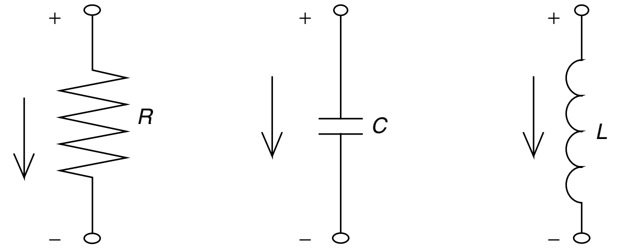

FIGURE 4.1 Symbols for a Resistor, Capacitor, and Inductor

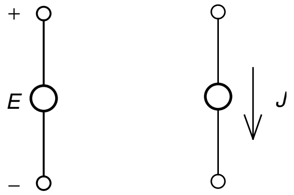

FIGURE 4.2 Symbols for Independent Voltage (E) and Independent Current (J) Source

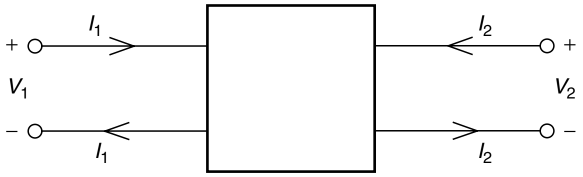

FIGURE 4.3 Symbol for a Two-Port

There exist four elementary two-ports, shown in Figure 4.4. They are the most simplified forms of amplifiers. The voltage-controlled voltage source, *VV*, has its output controlled by the input voltage:

$$V_2 = \mu V_1. \tag{4.1}$$

The μ is a dimensionless constant. Another elementary two-port is a voltage-controlled current source, *VC*, described by the equation:

$$I_2 = gV_1, \tag{4.2}$$

where g is transconductance and has the dimension of a conductance. The third elementary two-port is the current-controlled voltage source, *CV*, defined by:

$$V_2 = rI_1, \tag{4.3}$$

where r represents transresistance and has the dimension of a resistor. The last such two-port is a current-controlled current source, *CC*, defined by:

$$I_2 = \alpha I_1, \tag{4.4}$$

where α is a dimensionless constant.

Any number of elements can be variously connected; if we consider on such a network an input port and an output port, we will have a general two-port. This two-port has four variables, V_1, V_2, I_1, and I_2, as in Figure 4.3. Any two can be selected as independent variables, and the other two will be dependent variables. For instance, we can consider both currents as independent variables, which will make the voltages dependent variables. To couple them in a most general form, we can write the following:

$$\begin{aligned} V_1 &= z_{11}I_1 + z_{12}I_2. \\ V_2 &= z_{21}I_1 + z_{22}I_2. \end{aligned} \tag{4.5}$$

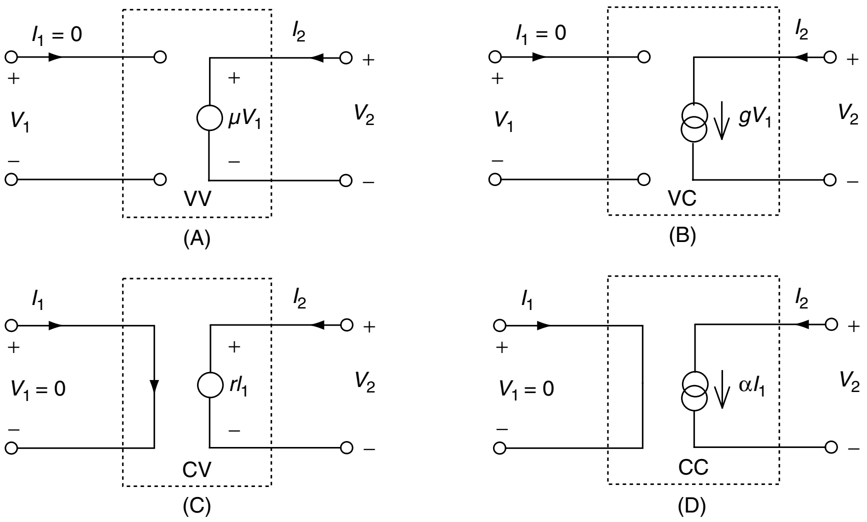

FIGURE 4.4 Simplest Two-Ports

In equation 4.5, the z_{ij} have dimensions of impedances, and we speak about the impedance description of the network. The equations are usually cast into a matrix equation:

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} z_{11} & z_{12} \\ z_{11} & z_{22} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} \tag{4.6}$$

Another way of expressing the dependences is to select the voltages as independent variables and the currents as dependent variables and present them in the form of two equations:

$$\begin{aligned} I_1 &= y_{11}V_1 + y_{12}V_2. \\ I_2 &= y_{21}V_1 + y_{22}V_2. \end{aligned} \tag{4.7}$$

This is an admittance description of a two-port, and in matrix form it is:

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \begin{bmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} \tag{4.8}$$

There exist additional possibilities on how to couple the variables. They can be found in any textbook on network theory.

For demonstration, we use the network in Figure 4.5 and derive its z_{ij} parameters. We attach a voltage source V_1 on the left and nothing on the right. This means that $I_2 = 0$, and the voltage V_2 appears in the middle of the network as indicated. We see that $V_1 = (Z_1 + Z_3)I_1$ and $z_{11} = V_1/I_1 = Z_1 + Z_3$. In addition, since the voltage in the middle of the network is V_2, we can write $V_2 = I_1 Z_3$ and $z_{21} = V_2/I_1 = Z_3$. In the next step, we place the voltage source on the right and proceed similarly. The result is:

$$\begin{bmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{bmatrix} = \begin{bmatrix} Z_1 + Z_3 & Z_3 \\ Z_3 & Z_2 + Z_3 \end{bmatrix} \tag{4.9}$$

In the next example, we consider the connection of a two-port to a loading resistor, as sketched in Figure 4.6. We wish to find the input impedance of the combination. After we connect them, as indicated by the dashed line, there is the same voltage, V_2, across the second port and across the resistor. The current flowing into the resistor will be $-I_2$ and thus $V_2 = -I_2 R$. Inserting into the second equation of the set (4.5), we obtain this equation:

$$I_2 = \frac{-z_{21}}{R + z_{22}} I_1.$$

Replacing I_2 in the first equation by this result, we get:

$$Z_{in} = V_1/I_1 = \frac{z_{11}R + z_{11}z_{22} - z_{12}z_{21}}{R + z_{22}}. \tag{4.10}$$

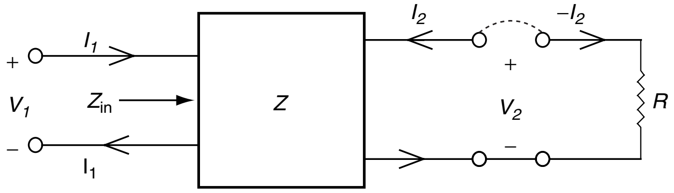

FIGURE 4.6 Obtaining Input Impedance of a Two Port Loaded by a Resistor

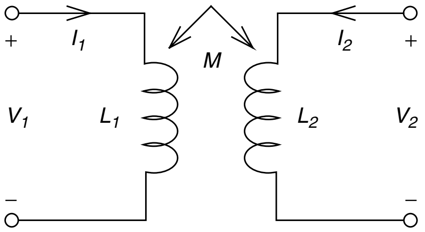

FIGURE 4.7 Symbol for a Technical Transducer

We will conclude this section by introducing two more two-ports, namely the ideal and the technical transformer[5]. The ideal transformer, often used in the synthesis theory, is described by the equations:

$$\begin{aligned} V_2 &= nV_1. \\ I_2 &= -\frac{1}{n}I_1. \end{aligned} \tag{4.11}$$

We note that we cannot put equation 4.11 into any of the two matrix forms that we introduced (impedance or admittance form). A technical transformer is realized by magnetically coupled coils. The device is described by the equations:

$$\begin{aligned} V_1 &= sL_1I_1 + sMI_2. \\ V_2 &= sMI_1 + sL_2I_2 \end{aligned}. \tag{4.12}$$

The L_1 and L_2 are the primary and secondary inductances, and M is the mutual inductance. These variables can be expressed in the impedance form as:

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} sL_1 & sM \\ sM & sL_2 \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} \tag{4.13}$$

Figure 4.7 Shows the technical transformer.

4.3 Network Functions

In the second section, we introduced two-port networks with their input and output variables. We now introduce the concept of networks with only one source and one output. As an example, take the network in Figure 4.8. The output voltage is:

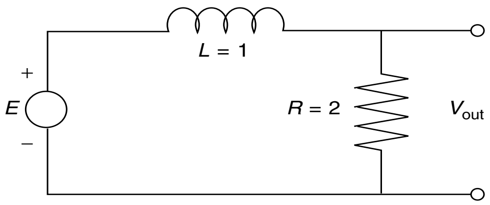

FIGURE 4.8 Introducing a Network Function

$$V_{\text{out}} = \frac{2}{s+2}E, \tag{4.14}$$

where E is any independent signal voltage. If we do not consider a specific signal but rather divide the equation by E, we get the voltage transfer function:

$$T_V = \frac{V_{\text{out}}}{E} = \frac{2}{s+2}. \tag{4.15}$$

This is one of the possible network functions. Had we chosen a larger network, the ratio would be in the form:

$$T_V = \frac{V_{\text{out}}}{E} = \frac{N(s)}{D(s)}, \tag{4.16}$$

where $N(s)$ and $D(s)$ are polynomials in the variable s.

One network may have many network functions. The number depends on where we apply the independent source, which source we select, and where we take the output. To be able to define the network function, we must satisfy two conditions: (1) the network is linear, and (2) there are zero initial conditions on capacitors and inductors.

If these conditions are satisfied, then we define a general network function as the ratio:

$$\text{Network function} = \frac{\text{output}}{\text{input}}. \tag{4.17}$$

Depending on the type of independent input source (voltage or current) and the type of the output (voltage or current), we can define the following network functions:

1. Voltage transfer is $T_V = \dfrac{V_{\text{out}}}{E}$.
2. Current transfer is $T_I = \dfrac{I_{\text{out}}}{J}$.
3. Transfer impedance is $Z_{TR} = \dfrac{V_{\text{out}}}{J}$.
4. Transfer admittance is $Y_{TR} = \dfrac{I_{\text{out}}}{E}$.
5. Input impedance is $Z_{in} = \dfrac{V_{\text{in}}}{J}$.
6. Input admittance is $Y_{in} = \dfrac{I_{\text{in}}}{E}$.

The input impedance is the inverse of the input admittance, but this is not true for the transfer impedances and admittances.

As an example, we take the network in Figure 4.9. Using nodal analysis, we can write the equations:

$$V_1(G_1 + G_2 + sC) - G_2V_2 = J.$$

$$-G_2V_1 + (G_2 + 1/sL)V_2 = 0.$$

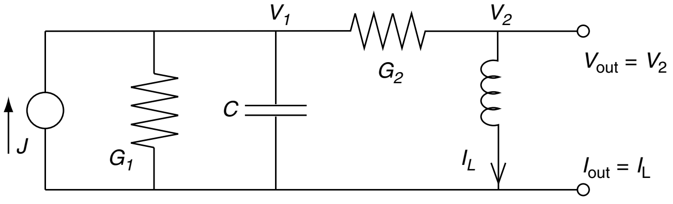

FIGURE 4.9 Finding Two Network Functions of One Network

They can also be written in matrix form:

$$\begin{bmatrix} (G_1 + G_2 + sC) & -G_2 \\ -G_2 & (G_2 + 1/sL) \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} J \\ 0 \end{bmatrix}$$

The denominator of the transfer function is the determinant of the system matrix:

$$D = sCG_2 + (G_1G_2 + C/L) + (G_1 + G_2)/sL.$$

Using Cramer's rule, we obtain:

$$V_{\text{out}} = \frac{G_2 J}{D}.$$

Since $I_{\text{out}} = V_{\text{out}}/sL$, we also get

$$I_{\text{out}} = (G_2/sL)/D.$$

We remove the complicated fractions by multiplying the numerator and the denominator by sL, with the result:

$$Z_{TR} = \frac{sLG_2}{s^2LCG_2 + s(LG_1G_2 + C) + G_1 + G_2}.$$

$$T_I = \frac{G_2}{s^2LCG_2 + s(LG_1G_2 + C) + G_1 + G_2}.$$

This example demonstrated that the network functions are ratios of polynomials in the variable s. If the elements are given by their numerical values, we can find roots of such polynomials. Roots of the numerator polynomial are called **zeros**, and roots of the denominator are called **poles**. From mathematics, we know that a polynomial has many zeros just as the highest power of the s variable. In the above example, the denominator is a polynomial of second degree, and the network has two poles. Since the numerator in this example is only a constant, the network will not have any (finite) zeros.

In general, the poles (or zeros) can be real or can appear in complex conjugate pairs. We can draw them in the complex plane, and we can use crosses to mark the poles and use small circles to mark the zeros. Figure 4.10 shows the pole-zero plot of a network with one real and two complex conjugate poles and with two purely imaginary zeros.

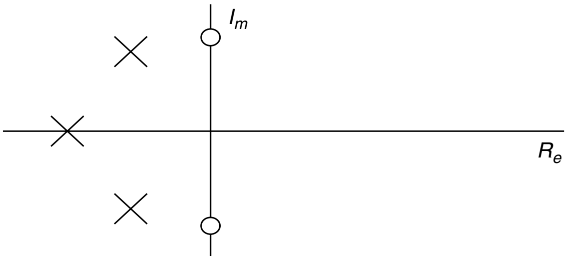

FIGURE 4.10 Pole and Zero Positions of Some Low-Pass Filter

4.4 Frequency Domain Responses

Let us now consider any one of the above network functions and denote it by the letter F. The function will be the ratio of two polynomials in the variables s, $N(s)$, and $D(s)$. If we use a root-finding method, we can also get the poles, p_i, and zeros, z_i. As a result, for a general network function, we can use one of the two following forms:

$$F(s) = \frac{N(s)}{D(s)} = K\frac{\prod(s - z_i)}{\prod(s - p_j)}. \tag{4.18}$$

To obtain various network responses, we substitute

$$s = j\omega. \tag{4.19}$$

$$\omega = 2\pi f = \frac{2\pi}{T}. \tag{4.20}$$

In equations 4.19 and 4.20, f is the frequency of the signal we applied, and $f = 1/T$. Using one frequency and substituting it into equation 4.18, we obtain one complex number with a real and imaginary part:

$$F = x + jy = \text{R}e^{j\phi} \tag{4.21}$$

Here

$$R = \sqrt{x^2 + y^2} \tag{4.22}$$

and

$$\tan\phi = \frac{y}{x}. \tag{4.23}$$

This is sketched in Figure 4.11.

If we evaluate the absolute value or the angles for many frequencies and plot the frequency on the horizontal axis and the resulting values on the vertical axis, we obtain the amplitude and the phase responses of the network.

Calculation of the frequency responses is always done by a computer. We assume that the reader knows how this calculation is done, but we show the responses for the filter in Figure 4.12.

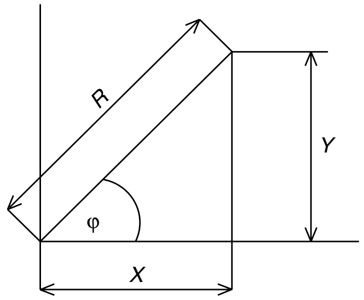

FIGURE 4.11 Finding the Absolute Value and Phase in Complex Plane

We have several possibilities for plotting them: the horizontal axis can be linear or logarithmic, the amplitude responses can be in absolute values, $|F_i| = |F(j\omega_i)|$, or $|F_{i_1\text{dB}}| = 20 \log |F_i|$ (in decibels, which is a logarithmic scale). The four possible plots of the same responses are in Figures 4.13(A) through 4.13(D). Clearly, selecting a correct scale and plot is very important for proper presentation and understanding.

The phase responses can also be plotted, but we have a couple of problems: the tangent function is periodic, and the plots experience jumps. For this reason, the phase response is rarely plotted, and we prefer to use the group delay, defined by:

$$\tau = -\frac{d\phi}{d\omega}. \tag{4.24}$$

Plot of the group delay for the filter in Figure 4.12 is in Figure 4.14. We see that the amplitude response approximates fairly well a constant in the passband, but the group delay has a large peak. Not every program has a built-in evaluation of the group delay, but there is a remedy: every computer has a polynomial root-finding routine. We can calculate the poles and zeros and use the second formula in equation 4.18. Let there be M zeros

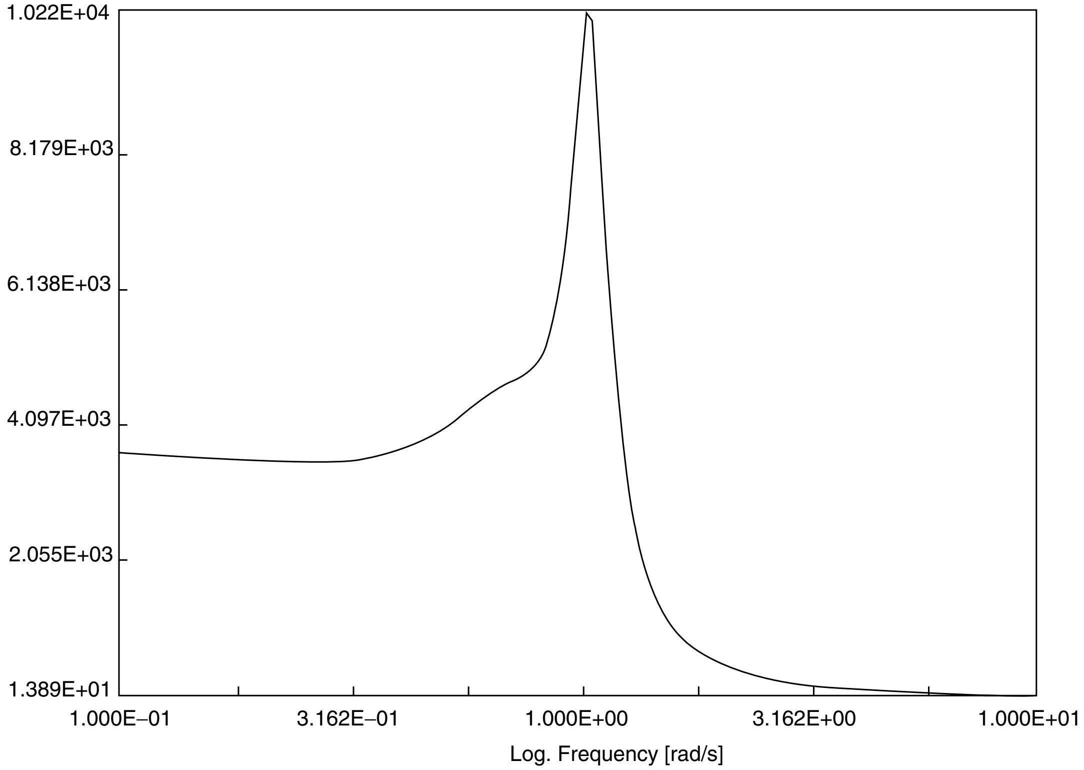

FIGURE 4.14 LC Filter, Group Delay of V_4, in ms, Logarithmic Frequency Scale

$z_i = \alpha_i + \beta_i$ and N poles $p_i = \gamma_i + \delta_i$. Substituting $s = j\omega$ and taking the absolute value, we arrive at the formula:

$$|F| = K\left[\frac{\prod_{i=1}^{M}[\alpha_i^2 + (\omega - \beta_i)^2]}{\prod_{i=1}^{N}[\gamma_i^2 + (\omega - \delta_i)^2]}\right]^{1/2} \tag{4.25}$$

The phase response will be as follows:

$$\Phi = \sum_{i=1}^{M} \arctan\frac{\beta_i - \omega}{\alpha_i} - \sum_{i=1}^{N} \arctan\frac{\delta_i - \omega}{\gamma_i}. \tag{4.26}$$

Differentiating equation 4.26 with respect to ω_o provides the formula for the group delay:

$$\tau(\omega) = \sum_{i=1}^{M}\frac{\alpha_i}{\alpha_i^2 + (\omega - \beta_i)^2} - \sum_{i=1}^{N}\frac{\gamma_i}{\gamma_i^2 + (\omega - \delta)^2}. \tag{4.27}$$

All formulas are easily programmed and plotted.

4.5 Normalization and Scaling

Normalization is one of the most useful concepts in linear networks. It allows us to reduce one frequency and the network impedance to unit values without losing any information. Consider first the scaling of impedances. If we increase (decrease) the impedance of every element of a filter described by its voltage or current transfer function, the input–output relationship should not change. It is thus customary to apply scaling, which reduces one (any) resistor to the value of 1. We can also scale the frequency so that the cutoff frequency of a low-pass filter or the center frequency of a band-pass filter is reduced to 1 rad/s.

To derive the necessary formulas, we will denote the scaled values by the subscript s and leave the values to be used for realization without subscript. Impedance scaling means that the impedance of every network element must be scaled by the same constant, k. This immediately leads to $R_s = R/k$. For frequency normalization, we introduce the formula:

$$\omega_s = \frac{\omega}{\omega_0}, \tag{4.28}$$

where ω_0 is a constant by which we wish to scale the frequency. Now consider the impedance of a scaled inductor by writing:

$$Z_{L,s} = j\omega\frac{L}{k} = j\frac{\omega}{\omega_0}\frac{\omega_0 L}{k} = j\omega_s(\frac{\omega_0 L}{k}).$$

Similarly, for a capacitor we obtain:

$$Z_{C,s} = \frac{1}{j\omega Ck} = \frac{1}{j\frac{\omega}{\omega_0}(\omega_0 Ck)} = \frac{1}{j\omega_S C_S}.$$

The results can be collected in the following formulas:

$$\begin{aligned} R_S &= \frac{R}{k}, \quad G_S = Gk. \\ L_S &= \frac{L\omega_0}{k}. \\ C_S &= C\omega_0 k. \end{aligned} \tag{4.29}$$

If the network has amplifiers, then:

- VV and CC remain unchanged;
- VC transconductance g is multiplied by k; and
- CV transresistance r is divided by k.

The scaling makes it possible to provide numerous tables of filters, all normalized so that one resistor is equal to 1 Ω and some frequency is normalized to $\omega_S = 1$. From such tables, the reader selects a suitable filter and modifies the values to suit the frequency band and impedance level.

4.6 Approximations for Low-Pass Filters

Before we go into the details of the approximations, we first pose a question: what kind of properties should a lowpass filter have to transfer, without distortion, a certain frequency band and suppress completely all other frequencies. The thought comes immediately to mind that all components should be amplified equally. This is true but not sufficient. In addition, the phase response must be a straight line; thus, the group delay must be a constant for all frequencies of interest. The conditions are sketched in Figure 4.15. We will see that this is impossible to achieve and that we have to accept some approximations when comparing with Figures 4.13(A) through 4.13(D) and Figure 4.14.

A lowpass filter, as indicated by the name, passes some frequency band starting from zero frequency and suppresses higher frequencies. One type of low-pass filter, called the polynomial filter, is described by transfer functions having a general form:

$$T(s) = K\frac{1}{\text{polynomial in } s}. \tag{4.30}$$

The polynomial must have all its roots (poles of the filter) in the left half of the complex plane to make the filter stable.

One such filter was suggested by Butterworth (Schaumann, 1990). He wanted to determine what the coefficients were of the polynomial in equation 4.30 to get a maximally flat amplitude low-pass transfer at $\omega = 0$. To make the problem unique, he also requested that the output of the filter at $\omega = 1$ should be 3 dB less than at $\omega = 0$.

We will not go into detail about how the polynomials were and are found; the steps are in any book on filters. Instead, we show the responses in Figure 4.16 for orders $n = 2$ to 10. We have used a logarithmic horizontal scale, and the responses start at $\omega = 0.1$. As we see, the approximation of a constant at low frequencies is reasonable for a high n, but the group delay

turns out to have a peak at approximately $\omega = 1$, and the peak grows with the order n.

The poles of the normalized Butterworth (or maximally flat) filter lie on a circle with a radius $r = 1$. Figure 4.17 shows the situation for $n = 3$ and $n = 4$. Extension to higher degrees is easy to extrapolate from these two figures: all odd powers will have one real pole, and all even powers will have only complex conjugate poles. The poles of a few filters are in Table 4.1.

Another well-known types of polynomial filters include the Chebychev filters; they use special polynomials discovered by Russian scientist Chebychev. They are also described by the general Formula 4.30, but the requirements are different. In the passband, the amplitude response oscillates between two limits, like in Figure 4.18. The ripple is normally expressed in decibels. At $\omega = 1$, the response always drops by the amount of specified ripple, as in the figure. Compared with the maximally flat filters, Chebychev filters have better attenuation outside the passband and approximate a constant better in the frequency band from 0 to 1. Table 4.1 gives pole positions of Chebychev filters with 0.5 dB ripple.

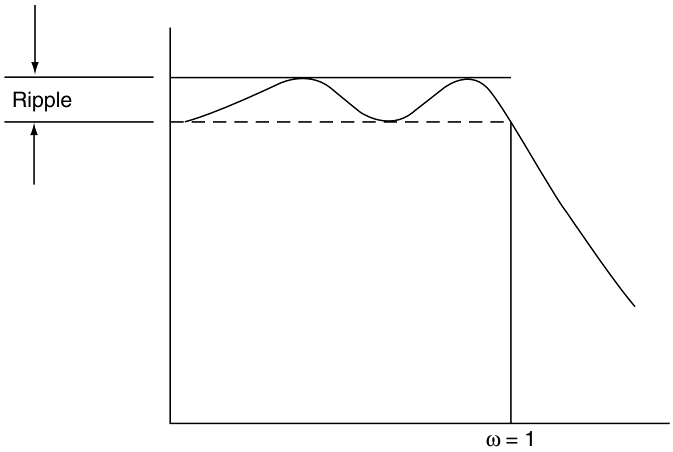

FIGURE 4.18 Amplitude Response of a Chebycher Filter

If the requirements on the suppression of signals outside the passband are more severe, polynomial filters are not sufficient. Much better results are obtained with filters having transfer zeros placed on the imaginary axis. Because a pair of imaginary axis complex conjugate zeros is expressed by terms $(s + j\omega_i)(s - j\omega_i) = s^2 + \omega_i^2$, the transfer function will have the form:

$$T(s) = K \frac{\prod (s^2 + \omega_i^2)}{\text{polynomial in } s}. \tag{4.31}$$

A sketch of the pole-zero plot of some such lowpass filter was shown in Figure 4.10. As always, the roots of the polynomial must be in the left half of the plane. There are many possibilities for selecting the zeros and poles, all beyond the scope of this presentation. Fortunately, there exist numerous tables of filters in literature. Best known are the Cauer-parameter filters with equiripple responses in the passband and with equal minimal suppressions in the stopband. We have analyzed one such filter: see Figure 4.12 and its amplitude responses in Figures 4.13(A) through 4.13(D).

Before closing this section, we provide a general network for low-pass filters described by Formula 4.30. The elements are like those in Figure 4.19. Depending on the order of the filter, the last element before the load resistor will be either an inductor in series or a capacitor in parallel. We can have filters with different values of the resistors and also a design with only one resistor, R_L, but that does not change the general structure of the filter. Table 4.2 gives element values for normalized Butterworth filters with $R_E = R_L = 1$.

4.7 Transformations of Inductor Capacitor Low-Pass Filters

We spoke about low-pass filters and normalization previously because many normalized LC low-pass filters can be found in

the literature, such as in Zverev (1976). One selects a suitable scaled filter and transforms it to the desired frequency and impedance level.

There are, however, additional possibilities for inductor capacitor (LC) low-pass filters. They can be transformed into band-pass, high-pass, or band-stop filters. We introduce these filters now.

4.7.1 Low-Pass into a High-Pass Filter

Consider the transformation:

$$z = \frac{\omega_0}{s}, \tag{4.32}$$

where z describes the complex frequency variable of the original scaled low-pass filter, possibly taken from tables, and s is the variable of the network to be realized. The meaning of ω_0 will become clear later. Multiply both sides of equation 4.32 by L. On the left is the impedance of an inductor. Simple arithmetic operations lead to:

$$zL = \frac{\omega_0 L}{s} = \frac{1}{s/\omega_0 L} = \frac{1}{sC'},$$

where on the right is an impedance of a capacitor with the value $C' = 1/\omega_0 L$. Considering multiplication of equation 4.32 by C, we get:

$$zC = \frac{\omega_0 C}{s} = \frac{1}{s/\omega_0 C} = \frac{1}{sL'}.$$

On the left is the admittance of a capacitor, and on the right is the admittance of an inductor: $L' = 1/\omega_0 C$. The transformation changes each capacitor into an inductor and vice versa; the filter is transformed into a high-pass.

We must still understand the meaning of ω_0. When evaluating the frequency domain responses, we always substitute $s = j\omega$. The frequency of interest is the cutoff frequency of the original low-pass filter, $z = j$. Inserting into equation 4.32, we get $-\omega_0 = \omega$. The sign only means that negative frequencies, existing in mathematics but not in reality, transform into positive frequencies and vice versa. The low-pass cutoff frequency of $\omega_s = 1$ transforms into the highpass cutoff frequency ω_0.

4.7.2 Low-Pass into a Band-Pass Filter

Consider next the transformation:

$$z = \frac{s}{\Delta} + \frac{\omega_0^2}{s\Delta} = \frac{s^2 + \omega_0^2}{s\Delta}. \tag{4.33}$$

In equation 4.33, z belongs to the original low-pass normalized filter. Multiply both sides by L to represent the impedance of an inductor in the z variable:

$$zL = \frac{sL}{\Delta} + \frac{\omega_0^2 L}{s\Delta} = \frac{sL}{\Delta} + \frac{1}{s\Delta/\omega_0^2 L} = sL' + \frac{1}{sC'}.$$

This means that the original inductor impedance was transformed into a series connection of two impedances. One of the elements is an inductor $L'_{ser} = L/\Delta$ and the other is a capacitor $C'_{ser} = \Delta/\omega_0^2 L$. Proceeding similarly for the admittance of a capacitor, we get:

$$zC = \frac{sC}{\Delta} + \frac{\omega_0^2 C}{s\Delta} = s\frac{C}{\Delta} + \frac{1}{s\Delta/\omega_0^2 C} = sC' + \frac{1}{sL'}.$$

The admittance of the capacitor is changed into the sum of two admittances, indicating a parallel connection. One of the elements is a capacitor $C'_{par} = C/\Delta$, and the other is an inductor

$$L'_{par} = \Delta/\omega_0^2 C.$$

To find additional properties of the transformation, we first form the product:

$$L'_{ser}C'_{ser} = L'_{par}C'_{par} = \frac{1}{\omega_0^2}.$$

This equation shows that the resonant frequencies of the parallel and series tuned circuits are the same, ω_0. Next, multiply equation 4.33 by the denominator to get:

$$s^2 - sz\Delta + \omega_0^2 = 0.$$

This is a quadratic equation with two solutions:

$$s_{1,2} = \frac{z\Delta}{2} \pm \sqrt{\frac{z^2\Delta^2}{4} - \omega_0^2}.$$

Now consider special points of the original filter. For $z = 0$, we get

$$s_{1,2}(z = 0) = \pm j\omega_0.$$

Zero frequency of the original filter is transformed into $\pm\omega_0$ point on the imaginary axis. Taking next the cutoff frequency of the low-pass filter, $z = \pm j$, we get four points:

$$s_{1,2,3,4} = \pm\frac{j\Delta}{2} \pm j\sqrt{\omega_0^2 + \frac{\Delta^2}{4}}.$$

Only two of these points will be on the positive imaginary axis:

$$j\omega_1 = j\frac{\Delta}{2} + j\sqrt{\omega_0^2 + \frac{\Delta^2}{4}}.$$

$$j\omega_2 = -j\frac{\Delta}{2} + j\sqrt{\omega_0^2 + \frac{\Delta^2}{4}}.$$

Their difference is the following:

$$\omega_1 - \omega_2 = \Delta. \qquad (4.34)$$

Their product is:

$$\omega_1\omega_2 = \omega_0^2. \qquad (4.35)$$

Thus, ω_0 is the (geometric) center of the two frequencies, and Δ is the passband of the transformed filter.

4.7.3 Low-Pass into a Band-Stop Filter

Consider a transformation similar to equation 4.33:

$$\frac{1}{z} = \frac{s}{\Delta} + \frac{\omega_0^2}{s\Delta} = \frac{s^2 + \omega_0^2}{s\Delta}. \qquad (4.36)$$

It transforms a low-pass into a band-stop. All the above steps remain valid, and only the elements will be transformed differently. Divide both sides by L to get:

$$\frac{1}{zL} = \frac{s}{\Delta L} + \frac{\omega_0^2}{s\Delta L}.$$

On the left is an admittance, and on the right is the sum of two admittances, indicating that the elements will be in parallel: $C'_{par} = 1/\Delta L$ and $L'_{par} = \Delta L/\omega_0^2$. A similar division by C will result in:

$$\frac{1}{zC} = \frac{s}{\Delta C} + \frac{\omega_0^2}{s\Delta C}$$

On the left side is an impedance, and on the right side is the sum of two impedances, indicating that the elements will be in series $L'_{ser} = 1/\Delta C$ and $C'_{ser} = \Delta C/\omega_0^2$. All three transformations are summarized in Figure 4.20 for easy understanding. As an example, we will take the third order maximally flat filter from Table 4.2 and its realization in Figure 4.21(A). We then transform it into a band-pass filter with center frequency $\omega_0 = 1$ rad/s and with the bandwidth $\Delta = 0.1$ rad/s. The transformed band-pass filter is in Figure 4.21(B) and its amplitude response in Figure 4.22. Using equations from section 4.5, the band-pass filter can be transformed to any impedance level and any center frequency with a bandwidth equal to one tenth of the center frequency.

4.8 Realizability of Functions

Synthesis is a process in which we have a given function, and we try to find a network whose properties will be described by that function. In most cases, we try to do so for a voltage transfer function. The first question that comes into mind is whether any function can be realized as a network composed of passive elements: capacitors, inductors, resistors, and transformers. Rather obviously, the answer is no.

To make the problem treatable, we must start with a simple network function and establish conditions that the function must satisfy. The simplest network function is an impedance (or admittance) but since one is the inverse of the other, we can restrict ourselves to only one of them: the impedance. A large amount of work went into establishing the necessary and sufficient conditions for an impedance function composed of

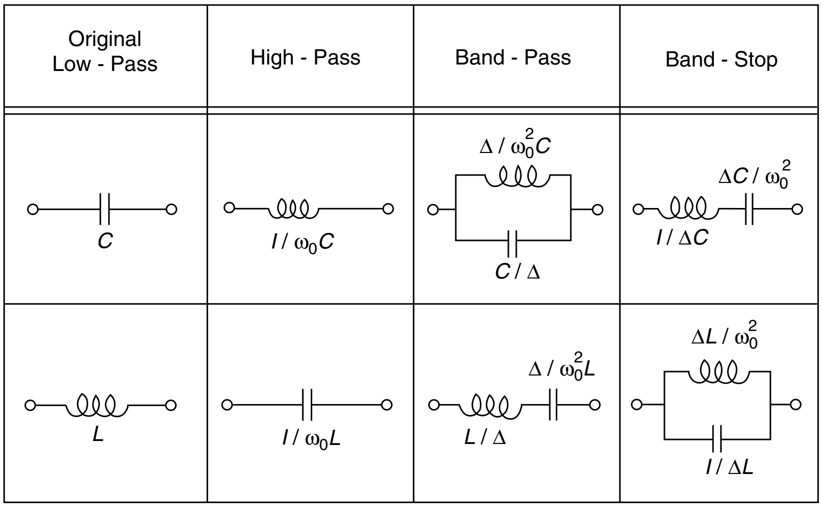

FIGURE 4.20 Transformations of Low-Pass Filters

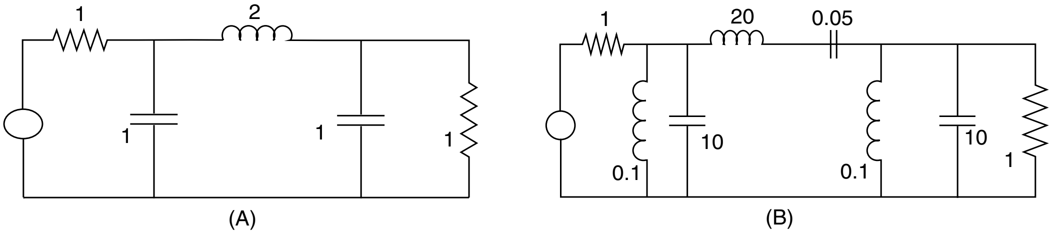

FIGURE 4.21 Transformation of a Butterworth Low-Pass Filter into a Band-Pass

L, C, and *R* elements, possibly with an ideal transformer. We will explain the conditions as a set of rules without trying to establish the reasons for these rules.

A rational function in the variable s can be realized as an impedance (admittance) if it satisfies the following rules:

1. The degree of the numerator and denominator may differ by at most one.
2. $Z(s)$ may not have any poles or zeros in the right half of the plane.
3. Poles and zeros in the left half of the plane may be multiple.
4. Poles on the imaginary axis must be simple and must have positive residues.
5. The function must satisfy the condition:

$$Re\, Z(s) \geq 0 \text{ if } Re\, s \geq 0. \tag{4.37}$$

The first condition is easy to establish by inspection. The second condition is a standard requirement for stability. Because the impedance and the admittance are the inverse of each other, the same must apply for the zeros. Stability is not destroyed by multiple poles in the left half plane, as stated in point 3. Point 4 would call for partial fraction expansion of the function. Unfortunately, all these steps are only necessary but not sufficient. The only necessary and sufficient condition is point 5, which is difficult to test.

All of this information may seem very discouraging, but, fortunately, synthesis of completely arbitrary impedances is almost never needed. In most cases, we need to realize LC impedances (admittances), and the rules are considerably simplified here. Again, without trying to provide a proof, let us state that any LC impedance can be realized in the form of the circuit in Figure 4.23(A) and any LC admittance in the form of the network in Figure 4.23(B).

Consider the network Figure 4.23(A). The tuned circuits have the impedance:

$$Z_i = \frac{1}{C_i} \frac{s}{s^2 + 1/L_i C_i}. \tag{4.38}$$

We usually define:

$$k_i = \frac{1}{2C_i}. \tag{4.39}$$

$$\omega_i^2 = \frac{1}{L_i C_i}. \tag{4.40}$$

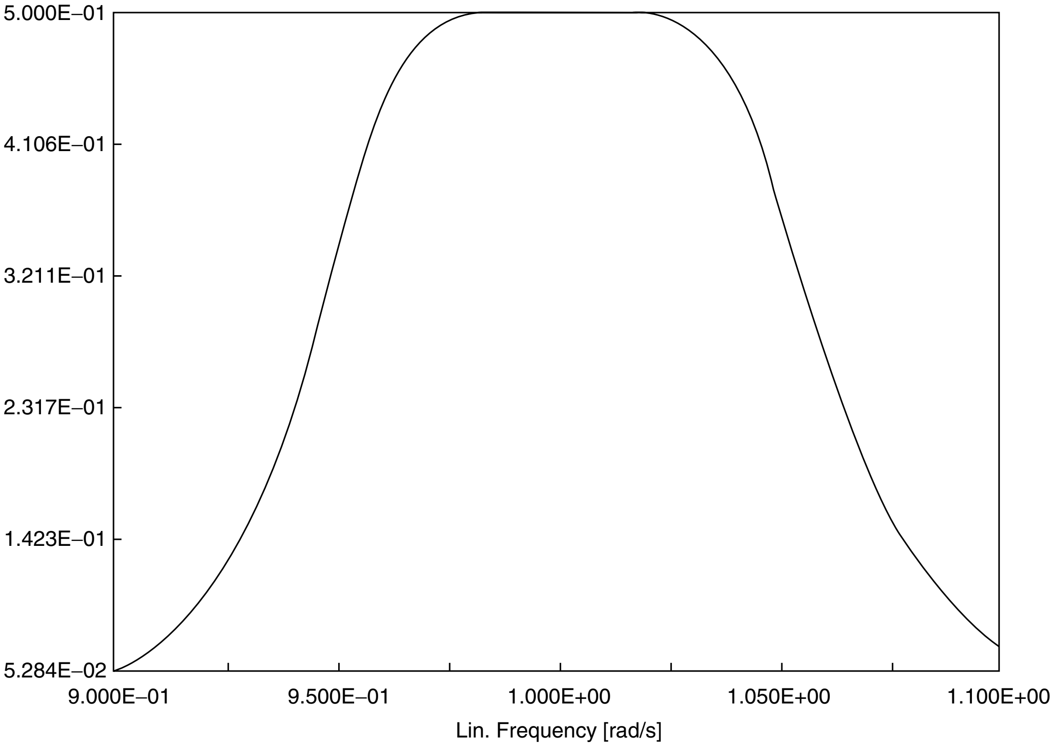

FIGURE 4.22 Amplitude Response of the Band-Pass Filter in Figure 4.21

The variable k_i represents the residues of the poles on the imaginary axis, $p_i = \pm j\omega_i$, and ω_i is the resonant frequency of the circuit. This gives us the possibility of writing a general LC impedance in the form:

$$Z_{LC} = sL + \frac{1}{sC} + \sum \frac{2k_i s}{s^2 + \omega_i^2}. \tag{4.41}$$

Any of the components in equation 4.41 may be missing. A similar expression could be derived for the network in Figure 4.23(B). We could now use a computer, plot various impedances, and study the results. We will summarize them for you:

1. Z_{LC} or Y_{LC} have only simple poles on the imaginary axis.
2. The residues of the poles are positive.
3. The zeros and poles on the imaginary axis must alternate.
4. Z_{LC} or Y_{LC} are expressed as a ratio of an even and an odd polynomial.
5. A pole or a zero may appear at the origin or at infinity, but the alternating nature of the poles and zeros must be preserved.

These results can be summarized by the simple sketches in Figure 4.24.

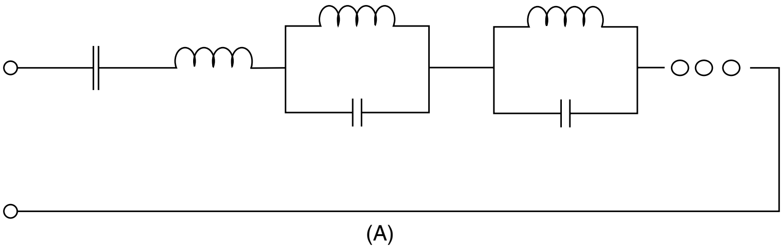
Synthesis of filters is usually based on the two-port theory. Using overall expressions for the whole filter, we separate the LC two-port from the loading resistors and apply synthesis to find the elements of the LC two-port. Again, as could be expected, some restrictions apply for the overall network, but the conditions are much more relaxed than for the impedances. A voltage or current transfer function can be realized as an LC two-port with loading resistors if the following statements are true:

1. The degree of the numerator, M, and denominator, N, satisfy $M \leq N$.
2. Zeros are usually on the imaginary axis, but theoretically they can be anywhere.
3. Poles must be in the left half of the plane.

Networks composed of passive elements always have $z_{12} = z_{21}$. In addition, z_{11} and z_{22} will have the same poles as $z_{12} = z_{21}$. Both z_{11} and z_{22} can have additional poles (called private poles), as we will show later. If the network components are only L and C, then z_{11} and z_{22} must satisfy the conditions on LC impedances discussed previously.

We now indicate the simplest method to extract the LC two-port from the network function. Consider the network in Figure 4.25. We wish to find the transfer impedance V_2/I_1. To do so, we need the second equation from the equation set 4.5,

$$V_2 = z_{21}I_1 + z_{22}I_2. \tag{4.42}$$



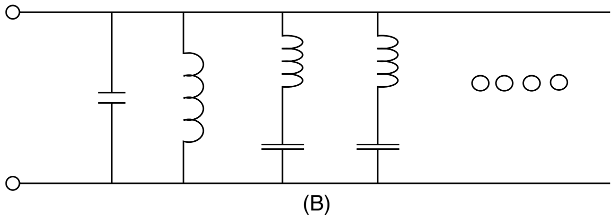


FIGURE 4.23 A General Form of an LC: (A) Impedance and (B) Admittance

After the indicated connection, we have:

$$-I_2 = \frac{V_2}{R}.$$

Inserting into equation 4.42 and eliminating I_2, we obtain:

$$Z_{TR} = \frac{V_2}{I_1} = \frac{z_{21}}{1 + z_{22}/R}. \qquad (4.43)$$

As we explained in section 4.5, we can simplify the expression by normalizing the impedance level to $R = 1$. Now consider a function having the form:

$$f = \frac{g}{m + n}, \qquad (4.44)$$

where m collects all the even terms of the denominator and n collects all the odd terms. All roots of the denominator must be in the left half of the plane. We can rewrite equation 4.44 in one of the two forms:

$$f = \frac{g/m}{1 + m/n}. \qquad (4.45)$$

or

$$f = \frac{g/m}{1 + n/m}. \qquad (4.46)$$

The ratios in the denominator, n/m or m/n, satisfy the conditions imposed on z_{22} of an LC network. The problem is reduced to the synthesis of z_{22}, taking into account the properties of z_{21}. We will describe such synthesis in section 4.10.

We have chosen this primitive case for demonstration only. Practical synthesis steps usually require voltage transfer with a loading resistor and with an input resistor. The steps that extract properties of the LC two-port are more complicated but are available in books focusing on synthesis of filters.

4.9 Synthesis of LC One-Ports

For LC impedances or admittances, we stated the rules that the function is represented by the ratio of an even and odd polynomial and the poles and zeros must interchange, be simple, and have positive residues. To find the partial fractions, we must use a root-finding routine and actually get the zeros and poles first. To calculate the residues of the poles, we use the following formulas:

$$\text{Pole at the origin:} \quad k_0 = sZ(s)|_{s=0}. \tag{4.47}$$

$$\text{Pole at infinity:} \quad k_\infty = \frac{Z(s)}{s}|_{s=\infty}. \tag{4.48}$$

$$\text{Two poles at } \pm j\omega_i\text{: } 2k = \frac{s^2+\omega_i^2}{p} Z(s)|_{s^2=-\omega_i^2}. \tag{4.49}$$

In formulas 4.47 through 4.49, it is first necessary to cancel the additional terms against equal terms in $Z(s)$ and then substitute the indicated values for s. Suppose now that we consider an admittance in the form:

$$Y(s) = k_\infty s + \frac{k_0}{s} + \sum_{i=1}^{n} \frac{2k_i s}{s^2+\omega_i^2}. \tag{4.50}$$

The first term is $C = k_\infty$, and the second is $L = 1/k_0$. The remaining terms can be written as:

$$Y_i(s) = \frac{2k_i s}{s^2+\omega_i^2} = \frac{1}{s/2k_i + \omega_i^2/2k_i s}, \tag{4.51}$$

where

$$L_i = \frac{1}{2k_i}. \tag{4.52}$$

$$C_i = \frac{2k_i}{\omega_i^2}. \tag{4.53}$$

The admittance realized this way was shown in Figure 4.23(B). Should we consider the function in equation 4.50 as an impedance, similar steps would lead to the network in Figure 4.23(A). These networks have the name Foster canonical forms. Another method, originally due to Cauer, gives impedances or admittances in the form of a ladder. As an example, consider the impedance:

$$Z = \frac{s^4+10s^2+9}{s^3+4s} = \frac{(s^2+1)(s^2+9)}{s(s^2+4)}. \tag{4.54}$$

Subtract from equation 4.54 an impedance sL (a pole at infinity). This gives the following:

$$Z_2 = \frac{s^4+10s^2+9}{s^3+4s} - sL = \frac{s^4(1-L)+s^2(10-4L)+9}{s^3+4s}.$$

We could now select L to be anywhere between zero and one, but if we select $L = 1$, the function simplifies to:

$$Z_2 = \frac{6s^2+9}{s^3+4s}.$$

The subtraction means that we have realized the first element in series, $L = 1$, and removed a pole at infinity. The remaining function can now be inverted to:

$$Y_2 = \frac{s^3+4s}{6s^2+9}.$$

This equation has a pole at infinity. We can continue by subtracting from it the admittance of a capacitor:

$$Y_3 = Y_2 - sC = \frac{s^3(1-6C)+s(4-9C)}{6s^2+9}.$$

If we select $C = 1/6$, we remove again a pole at infinity and realize a capacitor in parallel, $C = 1/6$, with the result:

$$Y_3 = \frac{5s/2}{6s^2+9}.$$

Y_3 can be inverted again:

$$Z_3 = \frac{12s}{5} + \frac{18}{5s}.$$

The first element is an inductor $L = 12/5$, the second a capacitor $C = 5/18$, both connected in series. The resulting network is in Figure 4.26.

The above expansion started from the highest powers. There exists another possibility by starting from the lowest power. Rewrite the impedance from 4.54 in the form:

$$Z = \frac{9+10s^2+s^4}{4s+s^3}. \tag{4.55}$$

and subtract $1/sC$, a pole at the origin:

$$Z_2 = Z - \frac{1}{sC} = \frac{(9-4/C)+s^2(10-1/C)+s^4}{4s+s^3}.$$

If we select $C = 4/9$ as a capacitor in series, the first term disappears, and we remove the pole at $s = 0$ to get:

$$Z_2 = \frac{31s/4+s^3}{4+s^2}.$$

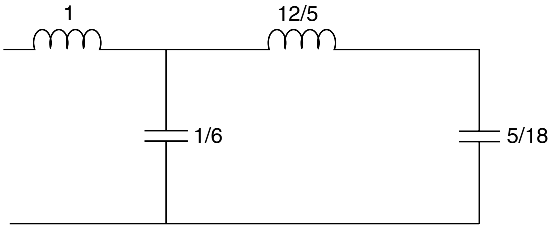

FIGURE 4.26 Synthesis of Equation 4.54 by Extracting Poles at Infinity

The remainder can be inverted and the admittance of an inductor subtracted again:

$$Y_3 = Y_2 - \frac{1}{sL} = \frac{(4 - 31/4L) + s^2(1 - 1/L)}{\frac{31}{4}s + s^3}.$$

The choice $L = 31/16$, connected in parallel, removes the first term and another pole at the origin. The process can be continued, with the resulting network shown in Figure 4.27. It is not necessary to continue one type of the expansion to the end. It is always possible, at any step, to rewrite the remaining function like we did going from equations 4.54 to 4.55 and continue. In addition, we need not remove one of the terms completely. All this indicates that synthesis of LC impedances or admittances is far from a unique procedure.

Let us return to equation 4.54, where we subtracted $L = 1$; we subtract now only $L = 0.5$. The result will be as follows:

$$Z_2 = \frac{0.5s^4 + 8s^2 + 9}{s^3 + 4s} = \frac{0.5(s^2 + 1.22)(s^2 + 14.78)}{s^3 + 4s}. \quad (4.56)$$

We see that the partial removal did not simplify the function but shifted zeros of the original function into new positions. Normally, if no other conditions are imposed, we would always remove the full value because then the resulting number of elements is minimal. Partial removal is used in the synthesis of two-port networks, as is shown later in this chapter.

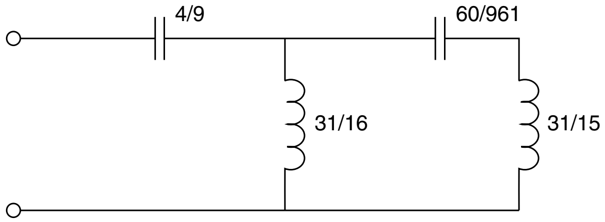

FIGURE 4.27 Synthesis of Equation 4.55 by Extracting Poles at Zero

4.10 Synthesis of LC Two-Port Networks

4.10.1 Transfer Zeros at Infinity

In this section, we indicate synthesis steps of two-ports. It is a fairly complicated procedure, and we will try to explain directly with examples.

An LC two-port is described by its impedance or admittance parameters, equations 4.5 or 4.7. We will use the impedance parameters and assume that the functions have been decomposed into partial fractions. Because for passive networks $z_{12} = z_{21}$, we need (for full description only):

$$z_{11} = \frac{k_0^{(11)}}{s} + \sum \frac{2k_i^{(11)}s}{s^2 + \omega_i^2} + k_\infty^{(11)}s$$

possibly plus some LC impedance.

$$z_{22} = \frac{k_0^{(22)}}{s} + \sum \frac{2k_i^{(22)}s}{s^2 + \omega_i^2} + k_\infty^{(22)}s$$

possibly plus some LC impedance.

$$z_{12}(= z_{21}) = \frac{k_0^{(12)}}{s} + \sum \frac{2k_i^{(12)}s}{s^2 + \omega_i^2} + k_\infty^{(12)}s.$$

The words *possibly in addition LC impedance* indicate that additional terms may exist in z_{11} and/or z_{22}. These are called private impedances and do not influence z_{12}. They would appear as in Figure 4.28(A) for impedance parameters and as in Figure 4.28(B) for admittance parameters. After their removal, all z_{ij} must have the same poles, the residues of z_{11} and z_{22} must be positive, and residues of z_{12} may be positive or negative.

Before we start with the synthesis example, let us state that a removal of an element, which is supposed to influence z_{12} (or y_{12}), must be connected as in Figure 4.29(A) or 4.29(B). Let us now have the following two functions:

$$z_{11} = s + \frac{9}{4s} + \frac{15}{4}\frac{s}{s^2 + 4}.$$
$$z_{12} = \frac{1}{4s} + \frac{-s/4}{s^2 + 4} = \frac{1}{s(s^2 + 4)}. \quad (4.57)$$

The first term in z_{11} is a private impedance (the pole at infinity does not appear in z_{12}) and can be removed as an inductor $L = 1$ in series. The remaining functions are these:

$$z_{11}^* = Z_1 = \frac{9}{4s} + \frac{15}{4}\frac{s}{s^2 + 4} = \frac{6s^2 + 9}{s(s^2 + 4)}.$$

$$z_{12} = \frac{1}{s(s^2 + 4)}.$$

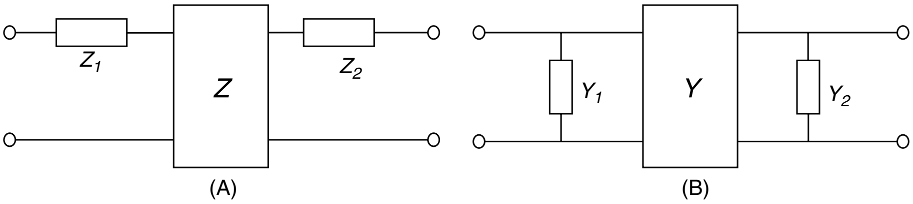

FIGURE 4.28 Removing Private (A) Impedances and (B) Admittances

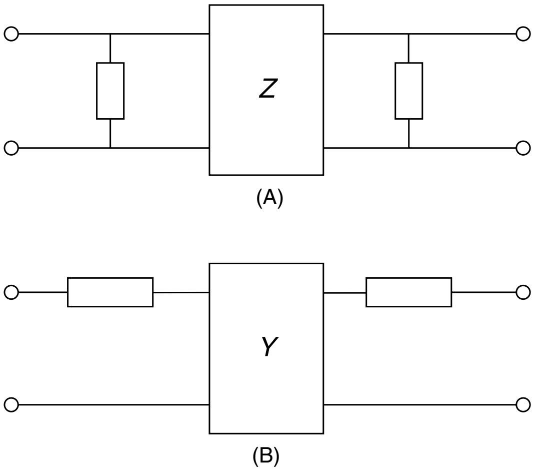

FIGURE 4.29 Removals Affecting Transfer Immittances and Connection of the Last Element for (A) Impedance Description and (B) Admittance Description

The poles of both functions are the same, z_{12} has only a constant in the numerator, and three powers of s are in the denominator. If we insert infinity for any s in the denominator, the function will become zero, and we say that z_{12} has three zeros at infinity. As was shown in the previous section, we cannot remove zeros as elements, but we can remove them as poles of inverted functions. Subtracting the admittance sC from $Y_1 = 1/Z_1$ leads to:

$$Y_2 = \frac{s^3+4s}{6s^2+9} - sC = \frac{s^3(1-6C)+s(4-9C)}{6s^2+9}$$

Selecting $C = 1/6$ (realized as a capacitor in parallel) reduces the admittance to

$$Y_2 = \frac{5s}{12s^2+18}.$$

and takes care of one of the transfer zeros of z_{12}. The remaining function, Y_2, has a zero at infinity. We can invert and remove a pole at infinity from:

$$Z_3 = \frac{1}{Y_2} - sL = \frac{s^3(12-5L)+18}{5s}.$$

We realize $L = 12/5$ as an inductor in series. This has taken care of the second transfer zero of z_{12}. The remaining function is $Z_4 = 18/5\,s$. By inverting it, we have $Y_4 = 5\,s/18$ and remove the last transfer zero as a pole at infinity by connecting a capacitor $C = 5/18$ in parallel. The whole network is in Figure 4.30. Let us now check our result logically. Inductors in series obstruct transfer of high frequencies and capacitors in parallel represent short circuits at high frequencies. Hence, each of the capacitors in parallel and the middle inductor in series will indeed help in suppressing high frequencies and create together three zeros at infinity.

We have used the above more complicated procedure to prepare the reader for synthesis of two-ports with finite transfer zeros. We could have achieved the same by dividing the numerator by the denominator in each of the steps. In fact, if the reader knows expansions into continued fractions, he or she should try it on $1/Z_1$. It is the fastest way for the removal of transfer zeros at infinity.

4.10.2 Transfer Zeros on the Imaginary Axis

As we have demonstrated in equation 4.56, partial removal does not reduce the degree of the function but shifts the zeros to different places. This feature is used in the synthesis. We will indicate the method in an example. Consider:

$$\begin{aligned} z_{11} &= \frac{(s^2+2)(s^2+6)}{s(s^2+3)} = \frac{s^4+8s^2+12}{s(s^2+3)} = s + \frac{4}{s} + \frac{s}{s^2+3}. \\ z_{12} &= \frac{(s^2+1)(s^2+6)}{s(s^2+3)} = s + \frac{4}{3s} + \frac{2s}{3(s^2+3)}. \end{aligned} \tag{4.58}$$

The transfer impedance has transfer zeros at $s = \pm j1$ and $s = \pm j2$. Both z_{11} and z_{12} have the same poles. There are no private poles in z_{11}; the functions are ratios of even and odd polynomials, zeros, and poles of z_{11} interchange. Thus, all the conditions for realizability are satisfied.

In the first step, we wish to take into consideration the transfer zero at $j1$. We substitute this value into z_{11} to obtain:

$$z_{11}(j1) = \frac{5}{2j}. \tag{4.59}$$

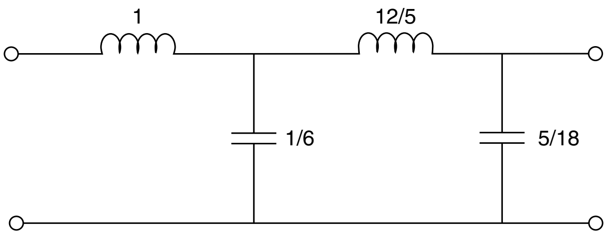

FIGURE 4.30 Synthesis of Equation 4.57

Equation 4.59 behaves as a capacitance; at $\omega_1 = 1$, we have $5/2j = 1/j\omega_1 C = 1/j1C$ from which $C = 2/5$. The capacitance and z_{11} have a pole at the origin, and we subtract:

$$Z_2 = z_{11} - \frac{5}{2s} = \frac{s^4 + 11s^2/2 + 9/2}{s(s^2+3)}. \tag{4.60}$$

The intention is to get the numerator polynomial with zeros at $s = \pm j1$. We can now divide the numerator of equation 4.60 by the term $s^2 + 1$ and obtain the decomposition:

$$Z_2 = \frac{(s^2+1)(s^2+9/2)}{s(s^2+3)}. \tag{4.61}$$

Notice the neat trick we used to shift the zeros by first evaluating equation 4.59. Using the above steps, we have realized the left capacitor in Figure 4.31. Z_2 now has the same number of zeros as the transfer function. We remove them as poles of the inverted function:

$$Y_2 = \frac{s(s^2+3)}{(s^2+1)(s^2+9/2)}. \tag{4.62}$$

To be removed is an admittance of a series-tuned circuit of the form $2k_i s/(s^2 + \omega_i^2)$. This is done by the formula 4.49:

$$2k_1 = \frac{(s^2+1)}{s}\frac{s(s^2+3)}{(s^2+1)(s^2+9/2)}\Big|_{s^2=-1} = \frac{4}{7}. \tag{4.63}$$

The element values of the tuned circuit are:

$$Y_{tc} = \frac{4s/7}{s^2+1} = \frac{1}{7s/4 + 7/4s},$$

with the result $L = 7/4$ and $C = 4/7$. The series tuned circuit, connected in parallel, is on the left of Figure 4.31. In the next step, we remove the expression for the tuned circuit from Y_2:

$$Y_3 = \frac{s(s^2+3)}{(s^2+1)(s^2+9/2)} - \frac{4s/7}{s^2+1} = \frac{3s}{7(s^2+9/2)}. \tag{4.64}$$

Then we return to the impedance:

$$Z_3 = \frac{7}{3}\frac{s^2+9/2}{s}.$$

There is another transfer zero to be removed, $s = j2$. The procedure is repeated by first evaluating $Z_3(j2) = 7/j12$. It behaves as a capacitance equal to $7/j12 = 7/j\omega_2 C_2 = 7/j2C_2$ with the result $C_2 = 6/7$. The impedance corresponding to the capacitance has a pole at the origin, and Z_3 has the same pole, so a partial removal of the pole is possible:

$$Z_4 = Z_3 - \frac{1}{sC_2} = \frac{7(s^2+9/2)}{3s} - \frac{7}{6s} = \frac{7(s^2+4)}{3s}.$$

Because now Z_4 has a zero at the proper place, we can remove it as a pole of a tuned circuit:

$$Y_4 = \frac{3s}{7s^2+28},$$

with the result $L = 7/3$ and $C = 3/28$, see Figure 4.31.

4.11 All-Pass Networks

In filter design, we place the transfer zeros almost always on the imaginary axis because this secures largest suppression of the signal in the stopband. In most cases, a low-pass filter should have approximately constant transfer of low frequencies and rapid suppression of frequencies beyond the specified passband. This may result in almost constant transfer of the desired frequencies, but the group delay response is then far from ideal. We have analyzed one such filter, Figure 4.12, with its amplitude responses in Figure 4.13(A) through Figure 4.13D and with the group delay in Figure 4.14.

In special cases, it may be necessary to compensate for the nonideal group delay response, and this can be done with all-pass networks. They modify only the group delay and pass all frequencies without attenuation.

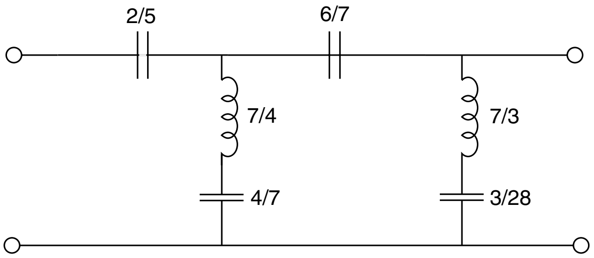

FIGURE 4.31 Synthesis of Equation 4.58

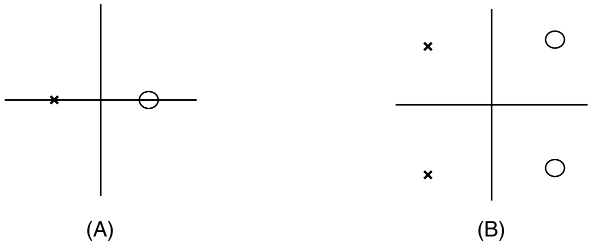

FIGURE 4.32 Possible Pole-Zero Positions for All-Pass Networks

Consider the symmetrical pole and zero positions sketched in Figure 4.32(A) and Figure 4.32(B) and the formulas for amplitude and group delay responses, equations 4.25 and 4.27. Symmetrical positions of both axes make $\alpha_i = -\gamma_i$ and $\beta_i = \delta_i$. When these are inserted into equation 4.25, the numerator cancels against the denominator and the expression in large brackets becomes equal to one. Inserted into equation 4.27, the two terms add and:

$$\tau_{\text{all-pass}} = 2\sum_{i=1}^{M} \frac{\alpha_i}{\alpha_i^2 + (\omega - \beta_i)^2}. \tag{4.65}$$

For further study, we will use the two-port theory and the impedance parameters. Consider the network in Figure 4.33, and remove the dotted resistor. Without it, we have two voltage dividers:

$$V_2 = V_B - V_A = \frac{Z_1 - Z_2}{Z_1 + Z_2} V_1.$$

The current flowing from the source into the two branches will be:

$$I_1 = \frac{2V_1}{Z_1 + Z_2}$$

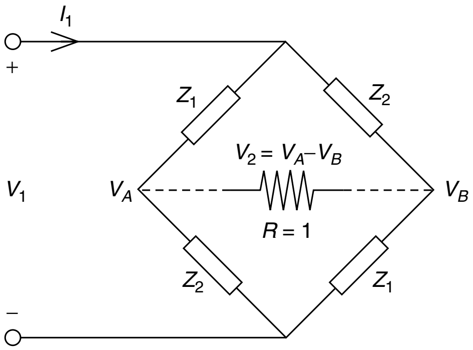

FIGURE 4.33 Deriving Properties of an All-Pass Network

and the entries of the two-port impedance matrix are:

$$Z = \begin{bmatrix} \dfrac{Z_2 + Z_1}{2} & \dfrac{Z_2 - Z_1}{2} \\ \dfrac{Z_2 - Z_1}{2} & \dfrac{Z_2 + Z_1}{2} \end{bmatrix} \tag{4.66}$$

If we connect the dotted resistor, the situation changes:

$$Z_{TR} = \frac{z_{21}}{1 + z_{22}}, \tag{4.67}$$

derived already in equation 4.43, and the input impedance becomes:

$$Z_{in} = \frac{z_{11} + z_{11}z_{22} - z_{12}z_{21}}{1 + z_{22}}, \tag{4.68}$$

obtained in equation 4.10. Let us now impose the condition:

$$Z_1 Z_2 = 1. \tag{4.69}$$

It changes the matrix of equation 4.66 into:

$$Z = \begin{bmatrix} \dfrac{1 + Z_1^2}{2Z_1} & \dfrac{1 - Z_1^2}{2Z_1} \\ \dfrac{1 - Z_1^2}{2Z_1} & \dfrac{1 + Z_1^2}{2Z_1} \end{bmatrix} \tag{4.70}$$

Inserting these entries into equation 4.68, we get, after a few simple algebraic steps, the surprising result:

$$Z_{\text{in}} = 1. \tag{4.71}$$

The input impedance of the combination is equal to the loading resistor, irrespective of what the value of Z_1, as long as we maintain the condition that $Z_2 = 1/Z_1$. Inserting this condition into equation 4.67 results in:

$$Z_{TR} = \frac{1 - Z_1}{1 + Z_1}. \tag{4.72}$$

Let us now take the special case $Z_1 = sL$. The transfer impedance becomes $Z_{TR} = (1 - sL)/(1 + sL)$, and we get the design parameters shown in Figure 4.34. The figure uses an accepted practice to draw only two of the impedances and to indicate the presence of the other two by dashed lines.

Suppose we take for Z_1 a parallel tuned circuit with elements L and C. In such a case,

$$Z_1 = \frac{sL}{s^2LC + 1}. \tag{4.73}$$

Inserting into equation 4.72, we get:

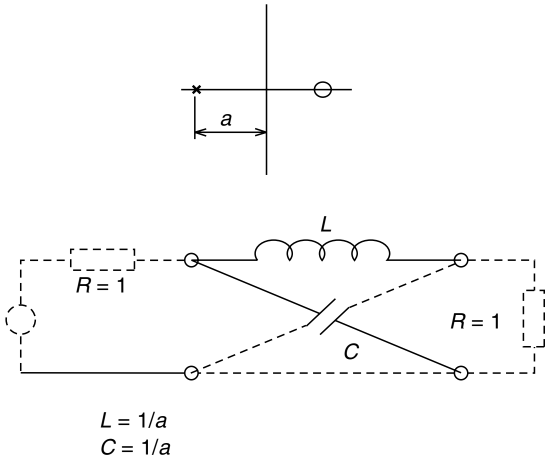

FIGURE 4.34 Position of One All-Pass Pole-Zero and Network Realization

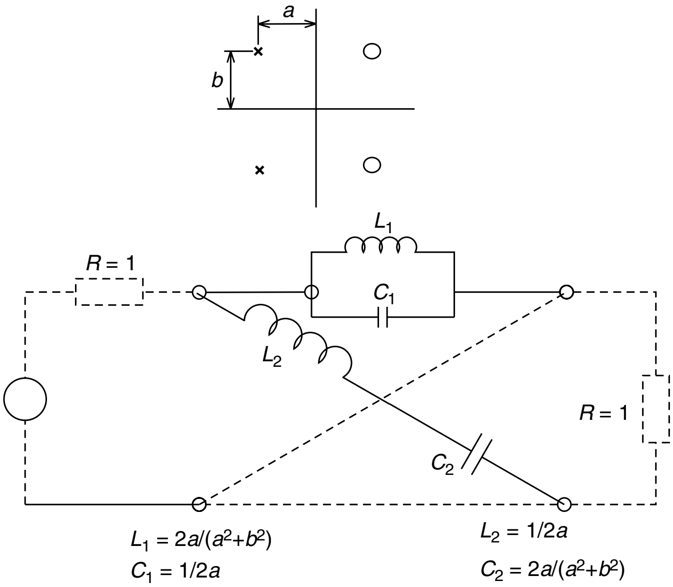

FIGURE 4.35 Positions of Two All-Pass Pole-Zero and Network Realization

$$Z_{TR} = \frac{s^2 - s/C + 1/LC}{s^2 + s/C + 1/LC}. \tag{4.74}$$

Comparing the denominator with

$$(s + a + jb)(s + a - jb) = s^2 + 2as + (a^2 + b^2),$$

we conclude that $C = 1/2a$ and $L = 2a/(a^2 + b^2)$. The network and its design values are in Figure 4.35. Remember that the loading resistor was normalized to unit value, and for other values of R, we must also scale impedances of these elements.

The above networks have one considerable disadvantage: the output is taken between two nodes and not with respect to ground. Connection to filters would have to be done through a transformer. All-pass networks with input and output taken with respect to ground also exist but require a transformer in the all-pass.

4.12 Summary

We have presented simplified steps for the synthesis of LC filters. The intention was to provide enough information for a general understanding and for encouraging the reading of more advanced books. The material should be sufficient for practical situations when tables of filters can be used. We have intentionally skipped synthesis of RC networks. The theory is available but is almost never used for designs, and is in many respects similar to what has been presented. Synthesis of RC networks can be found in specialized books. All references except Mitra (1969), which is an early text concerning active network synthesis, are classic texts about passive network synthesis.

5.1 Introduction

Nonlinearity plays a crucial role in many systems and qualitatively affects their behavior. For example, most circuits emanating from the designs of integrated electronic circuits and systems are nonlinear. It is not an overstatement to say that the majority of interesting electronic circuits and systems are nonlinear.

Circuit nonlinearity is often a desirable design feature. Many electronic circuits are designed to employ the nonlinear behavior of their components. The nonlinearity of the circuits' elements is exploited to provide functionality that could not be achieved with linear circuit elements. For example, nonlinear circuit elements are essential building blocks in many well-known electronic circuits, such as bistable circuits, flip-flops, static shift registers, static RAM cells, latch circuits, oscillators, and Schmitt triggers: they all require nonlinear elements to function properly. The global behavior of these circuits differs from the behavior of amplifiers or logic gates in a fundamental way: they must possess multiple, yet isolated, direct current (dc) operating points (also called equilibrium points). This is possible only if a nonlinear element (such as a transistor) is employed.

A **nonlinear circuit** or a **network** (a circuit with a relatively large number of components) consists of at least one nonlinear element, not counting the voltage and current independent sources. A circuit element is called nonlinear if its constitutive relationship between its voltage (established across) and its current (flowing through) is a nonlinear function or a nonlinear relation. All physical circuits are nonlinear. When analyzing circuits, we often simplify the behavior of circuit elements and model them as linear elements. This simplifies the model of the circuit to a linear system, which is then described by a set of linear equations that are easier to solve. In many cases, this simplification is not possible and the nonlinear elements govern the behavior of the circuit. In such cases, approximation to a linear circuit is possible only over a limited range of circuit variables (voltages and currents), over a limited range of circuit parameters (resistance, capacitance, or inductance), or over a limited range of environmental conditions (temperature, humidity, or aging) that may affect the behavior of the circuit. If global behavior of a circuit is sought, linearization is often not possible and the designer has to deal with the circuit's nonlinear behavior (Chua *et al.*, 1987; Hasler and Neirynck, 1986; Mathis, 1987; Willson, 1975).

As in the case of a **linear circuit**, Kirchhoff's voltage and current laws and Telegen's theorem are valid for nonlinear circuits. They deal only with a circuit's topology (the manner in which the circuit elements are connected together). Kirchhoff's voltage and current laws express linear relationships between a circuit's voltages or currents. The nonlinear relationships between circuit variables stem from the elements' constitutive relationships. As a result, the equations governing the behavior of a nonlinear circuit are nonlinear. In cases where a direct current response of the circuit is sought, the governing equations are nonlinear algebraic equations. In cases where transient behavior of a circuit is examined, the governing equations are nonlinear differential-algebraic equations.

Analysis of nonlinear circuits is more difficult than the analysis of linear circuits. Various tools have been used to understand and capture nonlinear circuit behavior. Some approaches employ quantitative (numerical) techniques and the use of circuit simulators for finding the distribution of a circuit's currents and voltages for a variety of waveforms supplied by sources. Other tools employ qualitative analyses methods, such as those dealing with the theory for establishing the number of dc operating points a circuit may possess or dealing with the analysis of stability of a circuit's operating point.

5.2 Models of Physical Circuit Elements

Circuit elements are models of physical components. Every physical component is nonlinear. The models that capture behavior of these components over a wide range of values of voltages and currents are nonlinear. To some degree of simplification, circuit elements may be modeled as linear elements that allow for an easier analysis and prediction of a circuit's behavior. These linear models are convenient simplifications that are often valid only over a limited range of the element's voltages and currents.

Another simplification that is often used when seeking to calculate the distribution of circuit's voltages and currents, is a piecewise-linear approximation of the nonlinear element's characteristics. The piecewise-linear approximation represents a nonlinear function with a set of nonoverlapping linear segments closely resembling the nonlinear characteristic. For example, this approach is used when calculating circuit voltages and currents for rather simple nonlinear electronic circuits or when applying certain computer-aided software design tools.

Nonlinear circuit elements may be classified based on their constitutive relationships (resistive and dynamical) and based on the number of the element's terminals.

5.2.1 Two-Terminal Nonlinear Resistive Elements

The most common two-terminal nonlinear element is a **nonlinear resistor**. Its constitutive relationship is:

$$f(i,\ v) = 0, \tag{5.1}$$

where *f* is a nonlinear mapping. In special cases, the mapping can be expressed as:

$$i = g(v), \tag{5.2}$$

when it is called a voltage-controlled resistor or:

$$v = h(i), \tag{5.3}$$

when it is a current-controlled resistor.

Examples of nonlinear characteristics of nonlinear two-terminal resistors are shown in Figure 5.1(A). Nonlinear resistors commonly used in electronic circuits are diodes: exponential, zener, and tunnel (Esaki) diodes. They are built from semiconductor materials and are often used in the design of electronic circuits along with linear elements that provide appropriate biasing for the nonlinear components. A circuit symbol for an exponential diode and its characteristic are given in Figure 5.1(B). The diode model is often simplified and the current flowing through the diode in the **reverse biased region** is assumed to be zero. Further simplification leads to a model of a switch: the diode is either *on* (voltage across the diode terminals is zero) or *off* (current flowing through the diode is zero). These simplified diode models are also nonlinear. Three such characteristics are shown in Figure 5.1(B). The zener diode, shown in Figure 5.1(C), is another commonly used electrical component. Tunnel diodes have more complex nonlinear characteristic, as shown in Figure 5.1(D). This nonlinear element is qualitatively different from exponential diodes. It permits multiple values of voltages across the diode for the same value of current flowing through it. Its characteristic has a region where its derivative (differential resistance) is negative. Silicon-controlled rectifier, used in many switching circuits, is a two-terminal nonlinear element with a similar behavior. It is a current-controlled resistor that permits multiple values of currents flowing through it for the same value of voltage across its terminals. A symbol for the silicon-controlled rectifier and its current-controlled characteristic are shown in Figure 5.1(E).

Two simple nonlinear elements, called **nullator** and **norator**, have been introduced mainly for theoretical analysis of nonlinear circuits. The nullator is a two-terminal element defined by the constitutive relations:

$$v = i = 0. \tag{5.4}$$

The current and voltage of a norator are not subject to any constraints. Combinations of nullators and norators have been used to model multiterminal nonlinear elements, such as transistors and operational amplifiers.

Voltage- and current-independent sources are also considered to belong to the family of nonlinear resistors. In contrast to the described nonlinear resistors, which are all passive for the choice of their characteristics presented here, voltage and current independent sources are active circuit elements.

5.2.2 Two-Terminal Nonlinear Dynamical Elements

Nonlinear resistors have a common characteristic that their constitutive relationships are described by nonlinear algebraic equations. **Dynamical nonlinear elements**, such as nonlinear inductors and capacitors, are described by nonlinear differential equations. The constitutive relation of a nonlinear capacitor is:

$$f(v,\ q) = 0, \tag{5.5}$$

where the charge q and the current i are related by:

$$i = \frac{dq}{dt}. \tag{5.6}$$

The constitutive relation for a nonlinear inductor is:

$$f(\phi,\ i) = 0, \tag{5.7}$$

where the flux ϕ and the voltage v are related by:

$$v = \frac{d\phi}{dt}. \tag{5.8}$$

A generalization of the nonlinear resistor that has memory, called a **memristor**, is a one-port element defined by a constitutive relationship:

$$f(\phi, q) = 0, \tag{5.9}$$

where the flux ϕ and charge q are defined in the usual sense. In special cases, the element may model a nonlinear resistor, capacitor, or inductor.

5.2.3 Three-Terminal Nonlinear Resistive Elements

A three-terminal nonlinear circuit element commonly used in the design of electronic circuits is a bipolar junction transistor (Ebers and Moll, 1954; Getreu, 1976). It is a current-controlled nonlinear element used in the design of various integrated circuits. It is used in circuit designs that

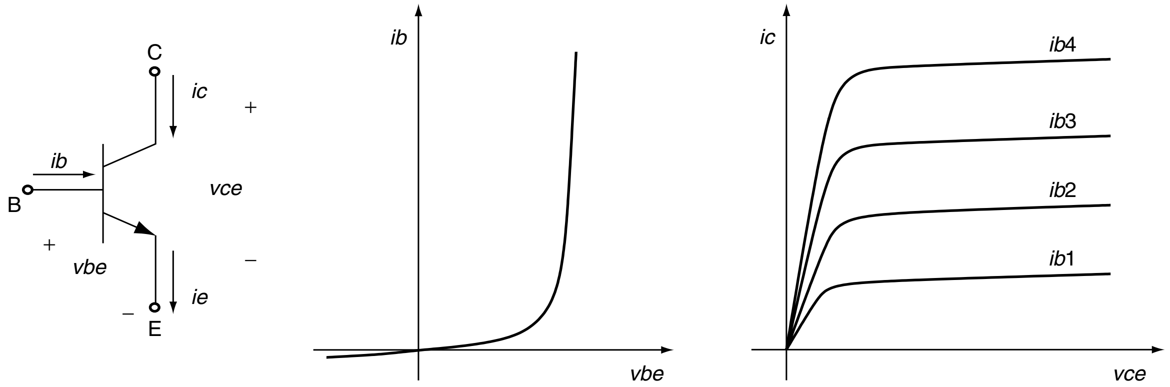

FIGURE 5.2 Three-Terminal Nonlinear Resistive Element: A Circuit Symbol and Characteristics of an *n–p–n* Bipolar Junction Transistor

rely on the linear region of the element's characteristic (logic gates and arithmetic circuits) to designs that rely on the element's nonlinear behavior (flip-flops, static memory cells, and Schmitt triggers). A circuit symbol of the bipolar junction transistor and its simplified characteristics are shown in Figure 5.2. The large-signal behavior of a bipolar junction transistor is usually specified graphically by a pair of graphs with families of curves. A variety of field-effect transistors (the most popular being a metal-oxide semiconductor) are voltage-controlled nonlinear elements used in a similar design fashion as the bipolar junction transistors (Massobrio and Antognetti, 1993).

5.2.4 Multiterminal Nonlinear Resistive Elements

A commonly used multiterminal circuit element is an **operational amplifier** (op-amp). It is usually built from linear resistors and bipolar junction or filed-effect transistors. The behavior of an operational amplifier is often simplified and its circuit is modeled as a linear multiterminal element. Over the limited range of the op-amp input voltage, the relationship between the op-amp input and output voltages is assumed to be linear. The nonlinearity of the op-amp circuit elements is employed in such a way that the behavior of the op-amp can be approximated with a simple linear characteristic. Nevertheless, even in the case of such simplification, the saturation of the op-amp characteristic for larger values of input voltages needs to be taken into account. This makes the op-amp a nonlinear element. The op-amp circuit symbol and its simplified characteristic are shown in Figure 5.3.

5.2.5 Qualitative Properties of Circuit Elements

Two simple albeit fundamental attributes of circuit elements are **passivity** and **no-gain**. They have both proven useful in applying certain modern mathematical techniques for analyzing and solving nonlinear circuit equations. A circuit element is passive if it absorbs power (i.e., if at any operating point, the net power delivered to the element is nonnegative). A nonlinear resistor is passive if for any pair (v, i) of voltage and current, its constitutive relationship satisfies:

$$vi \geq 0. \tag{10}$$

Otherwise, the element is active. Hence, a nonlinear resistor is passive if its characteristic lies in the first and third quadrant. A circuit is passive if all its elements are passive.

A multiterminal element is a **no-gain** element if every connected circuit containing that element, positive resistors, and independent sources possesses the no-gain property. A circuit possesses the no-gain property if, for each solution to the dc network equations, the magnitude of the voltage between any pair of nodes is not greater than the sum of the magnitudes of the voltages appearing across the network's independent sources. In addition, the magnitude of the current flowing through any element of the network must not be greater than the sum of the magnitudes of the currents flowing through the network's independent sources. For example, when considering a multiterminal's large-signal dc behavior, Ebers-Moll modeled bipolar junction transistors, filed-effect transistors, silicon-controlled rectifiers, and many other three-terminal devices are passive and incapable of producing voltage or current gains (Gopinath and Mitra, 1971; Willson, 1975).

Clearly, the no-gain criterion is more restrictive than passive. That is, passivity always follows as a consequence of no-gain, although it is quite possible to cite examples (e.g., the ideal transformer) of passive components capable of providing voltage or current gains.

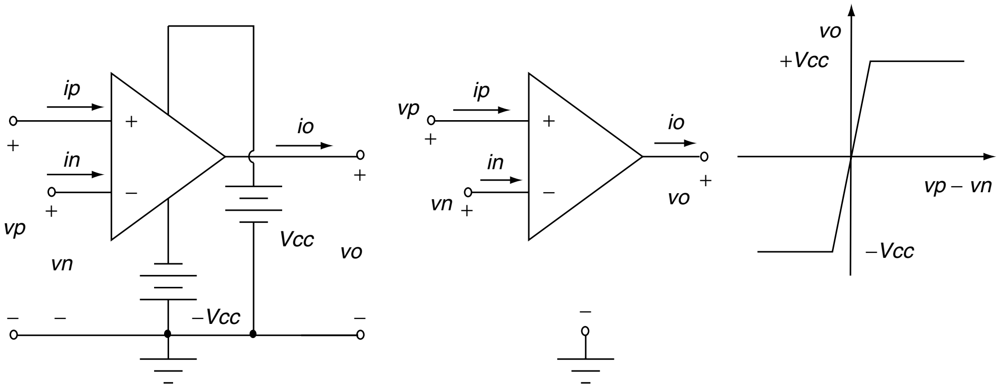

FIGURE 5.3 Multiterminal Nonlinear Circuit Element: An Op-Amp with Five Terminals, its Simplified Circuit Symbol, and an Ideal Characteristic

5.3 Voltages and Currents in Nonlinear Circuits

Circuit voltages and **currents** are solutions to nonlinear differential-algebraic equations that describe circuit behavior. Of particular interest are circuit equilibrium points, which are solutions to associated nonlinear algebraic equations. Hence, circuit equilibrium points are related to dc operating points of a resistive circuit with all capacitors and inductors removed. If capacitor voltages and inductor currents are chosen as state variables, there is a one-to-one correspondence between the circuit's equilibrium points and dc operating points (Chva *et al.*, 1987).

Analyzing nonlinear circuits is often difficult. Only a few simple circuits are adequately described by equations that have a closed form solution. Contrary to linear circuits, which consist of linear elements only (excluding the independent current and voltage sources), nonlinear circuits may possess multiple solutions or may not possess a solution at all (Willson, 1994). A trivial example is a circuit consisting of a current source and an exponential diode, where the value of the dc current supplied by the current source is more negative than the asymptotic value of the current permitted by the diode characteristic when the diode is reverse-biased. It is also possible to construct circuits employing the Ebers-Moll modeled (Ebers and Moll, 1954) bipolar junction transistors whose dc equations may have no solution (Willson, 1995).

5.3.1 Graphical Method for Analysis of Simple Nonlinear Circuits

Voltages and currents in circuits containing only a few nonlinear circuit elements may be found using graphical methods for solving nonlinear equations that describe the behavior of the circuit. A simple nonlinear circuit consisting of a constant voltage source, a linear resistor, and an exponential diode is shown in Figure 5.4. Circuit equations can be solved using a graphical method. The solution is the circuit's dc operating point, found as the intersection of the diode characteristics and the "load line." The load line is obtained by applying Kirchhoff's voltage law to the single circuit's loop.

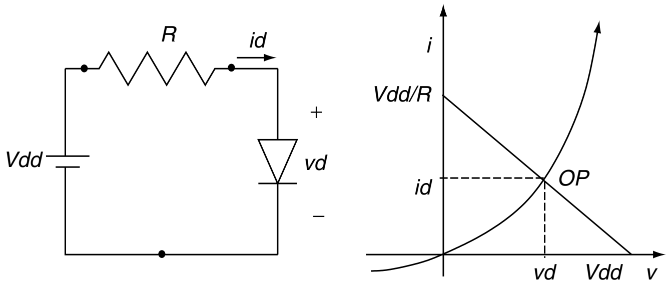

FIGURE 5.4 Simple Nonlinear Circuit and a Graphical Approach for Finding its DC Operating Point (OP): The circuit's load line is obtained by applying Kirchhoff's voltage law. The intersection of diode's exponential characteristic and the load line provides the circuit's dc operating point.

Another simple nonlinear circuit, shown in Figure 5.5, is used to rectify a sinusoidal signal. If the diode is ideal, the sinusoidal signal propagates unaltered and the current flowing through the diode is an ideally rectified sinusoidal signal. The circuit's steady-state response can be found graphically. The diode is *off* below the value $v_s(t) = V_{dd}$. For values $v_s(t) \geq V_{dd}$ the diode is *on*. Hence,

$$i_d(t) = 0 \text{ for } v_s(t) \leq V_{dd}.$$
$$i_d(t) = \frac{v_s(t) - V_{dd}}{R} \text{ for } v_s(t) > V_{dd}. \tag{5.11}$$

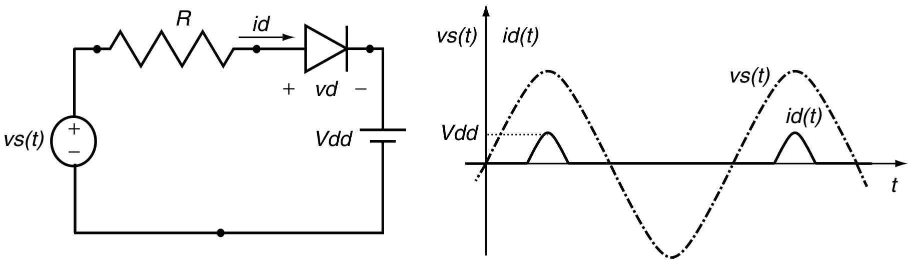

FIGURE 5.5 A Simple Rectifier Circuit with an Ideal Diode: The steady-state solution can be found graphically.

5.3.2 Computer-Aided Tools for Analysis of Nonlinear Circuits

In most cases, a computer program is used to numerically solve nonlinear differential-algebraic circuit equations. The most popular circuits analysis program is SPICE (Massobrio and Antognetti, 1993; Quarles *et al.*, 1994; Vladimirescu, 1994). The original **SPICE code** has been modified and enhanced in numerous electronic design automation tools that employ computer programs to analyze complex integrated circuits containing thousands of nonlinear elements, such as bipolar junction and field-effect transistors.

One of the most important problems when designing a transistor circuit is to find its dc operating point(s) (i.e., voltages and currents in a circuit when all sources are dc sources). The mathematical problem of finding a nonlinear circuit's dc operating points is described by a set of nonlinear algebraic equations constructed by applying Kirchhoff's voltage and current laws and by employing the characteristic of the circuit elements. A common numerical approach for finding these operating points is the Newton–Raphson method and its variants. These methods require a good starting point and sometimes fail. This is known as the dc convergence problem. In the past decade, several numerical techniques based on continuation, parameter-embedding, or homotopy methods have been proposed to successfully solve convergence problems that often appear in circuits possessing more than one dc operating point (Melville *et al.*, 1993; Trajković, 1999; Wolf and Sanders, 1996; Yamamura and Horiuchi, 1990; Yamamura *et al.*, 1999).

5.3.3 Qualitative Properties of Circuit Solutions

Many fundamental issues arise in the case of nonlinear circuits concerning a solution's existence, uniqueness, continuity, boundedness, and stability. Mathematical tools used to address these issues and examine properties of nonlinear circuits range from purely numerical to geometric (Smale, 1972). Briefly addressed here are solutions to a circuit's equations. Described are several fundamental results concerning their properties.

Existence and Uniqueness of Solutions

Circuits with nonlinear elements may have multiple discrete dc operating points (equilibriums). In contrast, circuits consisting of positive linear resistors possess either one dc operating point or, in special cases, a continuous family of dc operating points. Many resistive circuits consisting of independent voltage sources and voltage-controlled resistors, whose *v*–*i* relation characteristics are continuous strictly monotone-increasing functions, have at most one solution (Duffin, 1947; Minty, 1960; Willson, 1975). Many transistor circuits possess the same property based on their topology alone. Other circuits, such as flip-flops and memory cells, possess feedback structures (Nielsen and Willson, 1980). These circuits may possess multiple operating points with an appropriate choice of circuit parameters and biasing of transistors (Trajković and Willson, 1992). For example, a circuit containing two bipolar transistors possesses at most three isolated dc operating points (Lee and Willson, 1983). Estimating the number of dc operating points or even their upper bounds for an arbitrary nonlinear circuit is still an open problem (Lagarias and Trajković, 1999).

Continuity and Boundedness of Solutions

Properties such as continuity and boundedness of solutions are often desired in cases of well-behaved circuits. One would like to expect that "small" changes in the circuit's output will result from the "small" change of the circuit's input and that the bounded circuit's input leads to the bounded circuit's output. They are intimately related to the stability of circuit solutions.

Stability of Solutions

Once a solution to a circuit's currents and voltages is found, a fundamental question arises regarding its stability. A solution may be stable or unstable, and stability is both a local and a global concept (Hasler and Neirynck, 1986). Local stability usually refers to the solution that, with sufficiently close initial conditions, remains close to other solutions as time increases. A stronger concept of stability is asymptotic stability: if initial conditions are close, the solutions converge toward each other as time approaches infinity. Although no rate of convergence is implied in the case of asymptotic stability, a stronger concept of exponential stability implies that the rate of convergence toward a stable solution is bounded from above by an exponential function. Note that the exponential convergence to a solution does not necessarily imply its stability. Contrary to nonlinear circuits, stability (if it exists) of linear time-invariant circuits is always exponential. Linear time-invariant circuits whose natural frequencies have negative real parts have stable solutions. A global asymptotic (complete) stability implies that no matter what the initial conditions are, the solutions converge toward each other. Hence, a completely stable circuit possesses exactly one solution.

A fundamental observation can be made that there exist dc operating points of transistor circuits that are unstable: if the circuit is biased at such an operating point and if the circuit is augmented with *any* configuration of positive-valued shunt capacitors and/or series inductors, the equilibrium point of the resulting dynamic circuit will always be unstable (Green and Willson, 1992, 1994). A simple example is the common latch circuit that, for appropriate parameter values, possesses three dc operating points: two stable and one unstable.

5.4 Open Problems

In the area of analysis of resistive circuits, interesting and still unresolved issues are: Does a given transistor circuit possess exactly one, or more than one dc operating point? How many operating points can it possess? What simple techniques can be used to distinguish between those circuits having a unique operating point and those capable of possessing more than one? What can we say about the stability of an operating point? How can circuit simulators be used to find all the solutions of a given circuit? These and other issues have been and still are a focal point of research in the area of nonlinear circuits. The references cited provide more detailed discussions of the many topics considered in this elementary review of nonlinear circuits.

With the emergence of digital information age, there is an ever increasing need to integrate various technologies to efficiently perform advanced communication, computing, and information processing functions. Efficient generation and utilization of electric energy is of paramount importance in an energy and environmentally conscious society. This section deals with recent developments in these areas with relevant background information.

In Chapter 1, an account of voltage regulation modules (VRMs) used in powering microchips is provided with a particular emphasis on circuit switching topologies. Chapter 2 deals with noise in mixed-signal electronic systems with a focus on submicron ultra-large scale integrated (ULSI) system-on-a-chip (SOC) technologies. Noise in semiconductor devices and passive components becomes a key issue in addressing system-level signal integrity concerns. A detailed review and progress on metal-oxide-silicon field-effect transistors (MOSFETs) is discussed in Chapter 3 with emphasis on important performance and reliability degradation parameters. These devices form the basic electronic building blocks in a majority of microsystems.

Filters are used in a variety of signal processing circuits. Chapter 4 provides an account of latest advances in the design and application of active filters in microsystems. Although bipolar junction transistors (BJTs) are not as prominent as MOSFETs, nevertheless they are used in a variety of mixed-signal and poweer circuits. Chapter 5 discusses the state-of-the-art on diodes and BJTs in these circuits. Chapter 6 provides insight into basic semiconductor material physics and how it relates to device performance and reliability. The section concludes with a detailed account of the evolution and current state-of-the-art of power semiconductor devices for discrete as well as integrated applications. Power semiconductor devices are playing an increasingly important role in microsystems, especially for performing the power management function.

1.1 Introduction

Advances in microprocessor technology pose new challenges for supplying power to these devices. The evolution of microprocessors began when the high-performance Pentium processor was driven by a nonstandard power supply of less than 5 V instead of drawing its power from the 5-V plane on the motherboard (Goodfellow and Weiss, 1997).

Low-voltage power management issues are becoming increasingly critical in state-of-the-art computing systems. The current generation of high-speed CMOS processors (e.g., Alpha, Pentium, and Power PC) operate at above 300 MHz with 2.5- to 3.3-V output voltage. Future processors will be designed with even lower logic voltages of 1 to 1.5 V and increases in current demands from 13 A to 50 to 100 A (Zhang *et al.*, 1996). Meanwhile, operating frequencies will increase to above 1 GHz. These demands, in turn, require special power supplies, voltage regulator modules (VRMs), to provide lower voltages with higher current capabilities for microprocessors. Table 1.1 shows the specifications for present and future VRMs.

As the speed of the processors increases, the dynamic loading of the VRMs is also significantly increased. Future microprocessors are expected to exhibit higher current slew rates of up to 5 A/ns. These slew rates represent a severe problem for the large load changes that are encountered when systems transfer from the sleep mode to the active mode and vice versa. In these cases, the parasitic impedance of the power supply connection to the load and the equivalent series resistor (ESR) and equivalent series inductor (ESL) of the capacitors have a dramatic effect on VRM voltage (Zhang *et al.*, 1996). If this impedance is not low enough, the supply voltage may fall out of the required range during the transient period. Moreover, the total voltage tolerance will be much

tighter. Currently, the voltage tolerance is 5% (for a 3.3 V VRM output with a voltage deviation of ± 165 mV). In the future, the total voltage tolerance will be 2% (for a 1.1 V VRM output with a voltage deviation requirement of only ± 33 mV). All of these requirements pose serious design challenges and require VRMs to have very fast transient responses. Figure 1.1 shows today's VRMs and the road map of microprocessors' development.

Today's VRMs are powered up from the 5-V or 12-V outputs of silver boxes that are used for supplying various parts of the system, such as the memory chips, the video cards, and some sub buses. Future VRMs will be required to provide lower voltages and higher currents with tighter voltage regulations. The traditional centralized power system, the silver box, will no longer meet the stringent requirements for VRM voltage regulation because of the distributed impedance associated with a long power bus and the parasitic ringing due to high-frequency operation. On the other hand, with much heavier loads in the future, the bus loss becomes significant. To maintain system stability, a huge silverbox output capacitance is also needed. At the same time, to avoid the interaction between different outputs, a very large VRM input filter capacitance is required. Figure 1.2 shows the trend of computer power system architecture. In the future, a distributed power system (DPS) with a high-voltage bus, 12 V or 48 V, can be the solution for servers' and workstations' power systems. High-performance, high-input-voltage VRMs, however, must be developed.

To meet future requirements, a number of critical issues must be addressed. For example, advanced power devices and control technologies are needed for high-efficiency and high-frequency operations. Today's vertical power device technology cannot provide acceptable levels of conversion efficiency at a multimegahertz level due to its high conduction and switching and gate drive losses. This chapter addresses important issues of advanced VRM topologies for fast transient responses and low ripple voltages as well as advanced packaging technologies for improving power density and thermal management. In addition, this discussion covers the limitations of today's tech-

nologies, including VRM topologies, power devices, and power systems.

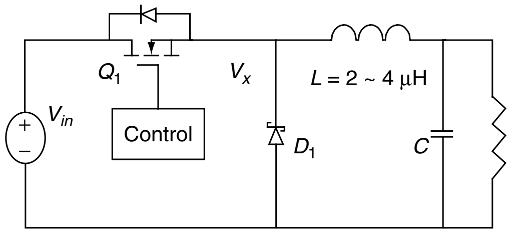

FIGURE 1.3 Conventional Buck Converter

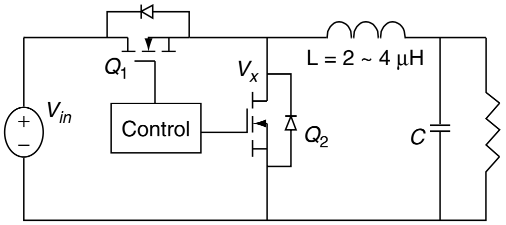

FIGURE 1.4 Synchronous Rectifier Buck Converter

1.2 Limitations of Today's Technologies

1.2.1 Limitations of Present VRM Topologies

Most of today's VRMs use **conventional buck** or **synchronous rectifier buck topologies**. Figure 1.3 shows the conventional buck circuit, which is the most cost-effective approach. Usually, Schottky diodes are used as rectifiers. The top metal-oxide-semiconductor field effect transitor (MOSFET) transfers energy from the input, and the bottom rectifier conducts the inductor current. The control regulates the output voltage by modulating the conduction interval at the top MOSFET. Figure 1.4 shows the synchronous rectifier buck circuit. This topology increases the efficiency by replacing the rectifier with a low Rds(on) MOSFET. The synchronous switch is controlled by the complementary signal of the top switch's gate signal. The synchronous rectifier buck always operates in continuous current mode. Its transient response is faster than that of a conventional buck converter. Conventional VRMs use large output filter inductances, 2 $\sim$ 4 μH, to reduce ripple.

Figure 1.5 shows the practical VRM load model (processor model). The packaging capacitor is the parasitic capacitor inside the microprocessor package. There are several decoupling capacitors near and around the microprocessors to reduce noise and maintain voltage regulation. Bulk capacitors are VRM output capacitors. In very high-speed and high-current systems, physical capacitors can no longer be simplified as ideal capacitors. The parasitic parameters play very important roles. The capacitor should be considered as an ideal capacitor in series with an ESR and an ESL, as shown in Figure 1.6 (Wong, 1997).

There are interconnection parasitic inductances and resistances between bulk capacitors and decoupling capacitors and between decoupling capacitors and packaging capacitors. Future microprocessor load transitions will have a 5-A/ns slew rate. In this case, all these parasitics have a significant

effect on the VRM transient voltage. Figure 1.7 shows the transient response of a synchronous rectifier VRM. The VRM's input voltage is 5 V, and its load changes from 0.8 A to 30 A. It is obvious that for future microprocessor loads, today's VRM topologies cannot meet the 2% transient requirement.

During the transient, there are three spikes in the voltage drop (Wong, 1997). The first high-frequency spike is dominated by loop 1, shown in Figure 1.8, which combines the parasitic of the packaging capacitors and decoupling capacitors and the interconnection between them. The second spike is controlled by loop 2, which combines the parasitic of the decoupling capacitors and VRM bulk capacitors and the interconnection between them. The third spike is decided by loop 3, which combines the parasitic of the VRM output filter inductor and the VRM output bulk capacitors.

The transient limitation of today's VRM topologies comes from their large output filter inductance. During the transient, this large inductor limits the energy transfer speed so that the capacitors have to store or discharge all the energy from the load. For future microprocessors, because of heavier load currents, higher load transient slew rates, and tighter voltage tolerance requirements, more decoupling capacitors will be required to reduce the second spike, and more VRM output bulk capacitors will be required to reduce the third spike. As a result, to meet future specifications, 23 times the decoupling capacitors will be needed, and 3 times VRM bulk capacitors will be needed (Wong, 1997). The VRM will be very large and expensive. The space of the VRM, however, is limited and the real estate of the motherboard is expensive. The need for a large quantity of capacitors makes VRMs, which use these topologies, impractical for future microprocessors.

1.2.2 Limitations from Power Devices

Another limitation of today's VRMs is efficiency. Figure 1.9 shows the conventional VRM efficiency at a 2-V output. Using IRL3803 as switches, with an on-resistance of 6 mΩ and a 30-V

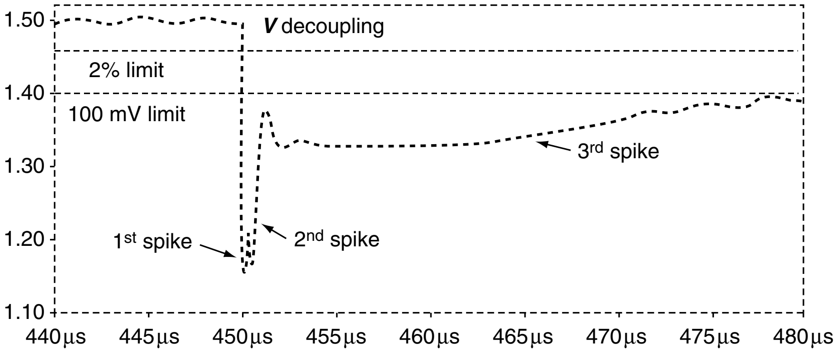

FIGURE 1.7 Transient Response of Conventional VRMs ($V_{in} = 5$ V, load: 0.8 A to 30 A, and $fs = 300$ kHz)

voltage rating, the conventional VRM cannot meet the 80% efficiency requirement at heavy load. For lower output voltages, it will be even more difficult to meet the efficiency requirement. Figure 1.10 shows the conventional VRMs' efficiency at a 1.2-V output. Their efficiency is lower than 80% in the whole load range.

This limitation stems from today's power devices' technology. Based on vertical power MOSFET technology, most of today's low-voltage power MOSFETs are available at a rating of 30 V. Roughly, the total power loss of a power device can be divided into three parts: conduction loss, gate drive loss, and switching loss. Figure 1.11 shows the relationship between conduction loss, gate drive loss, and switching loss. For this kind of low-voltage, high-current application, conduction loss contributes a large percentage of the total loss. When only one IRL3803 is used, the MOSFET's conduction loss is 25 times the gate drive loss plus the switching loss. To reduce conduction and total loss, more switches need to be paralleled. This does not necessarily mean, however, that more parallel switches equals lower total loss. When five IRL3803 are paralleled, the total loss is reduced to the minimum. After this point, adding more switches will not improve efficiency. Figure 1.12 shows the number of parallel switches needed to meet the 80% efficiency requirement when the input voltage is 5 V. In Figure 1.12 (A), when the output voltage is 2 V, paralleling two switches can enable the device to meet the efficiency requirement at heavy load. However, when the output voltage is 1.2 V, as shown in Figure 1.12 (B), no matter how many switches are in parallel, the VRM cannot meet the 80% efficiency requirement at heavy

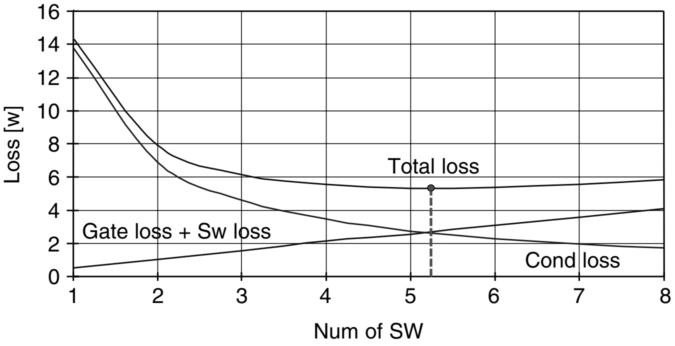

FIGURE 1.11 Switching Loss, Gate Drive Loss, and Conduction Loss of an IRL3803 Versus a Parallel Switch Number

load (>30). This limitation is due to the high figure of merit (FOM) of today's devices. The FOM is equal to Rds(on) times gate charge (Qg). For today's device technology, the lowest FOM value is around 300(m$\Omega \times$ nC). With such a high FOM value, power devices not only limit the VRM's efficiency but also limit the VRM's ability to operate at higher operating frequencies. Most of today's VRMs operate at a switching frequency lower than 300 kHz. This low switching frequency causes slow transient responses and creates a need for very large energy storage components.

1.3 Advanced VRM Topologies

1.3.1 Low-Input-Voltage VRM Topologies

A Fast VRM Topology: The Quasi-Square-Wave (QSW) VRM

To overcome the transient limitation occurring in conventional VRMs, a smaller output filter inductance is the most desirable option for increasing the energy transfer speed. Figure 1.13 shows the quasi-square-wave (QSW) circuit. The QSW topology keeps the VRM output inductor current touching zero in both sleep and active modes. When Q_1 turns on, the inductor current is charged to positive by the input voltage. After Q_1 turns off and before Q_2 turns on, the inductor current flows through Q_2's body diode. When Q_2 turns on, the inductor current is discharged to negative. After Q_2 turns off and before Q_1 turns on, the inductor current flows through Q_1's body diode. Compared with conventional buck and synchronous buck topologies, the output filter inductance is reduced significantly. At a 13-A load and a 300-kHz switching frequency, the QSW circuit needs only a 160-nH inductor, as compared with the $2 \sim 4\,\mu$H inductor needed in the conventional design. This small inductance makes the VRM transient response much faster. Figure 1.14 shows the transient response of the QSW topology. The third spike of the output voltage becomes insignificant, and the second spike is reduced significantly.

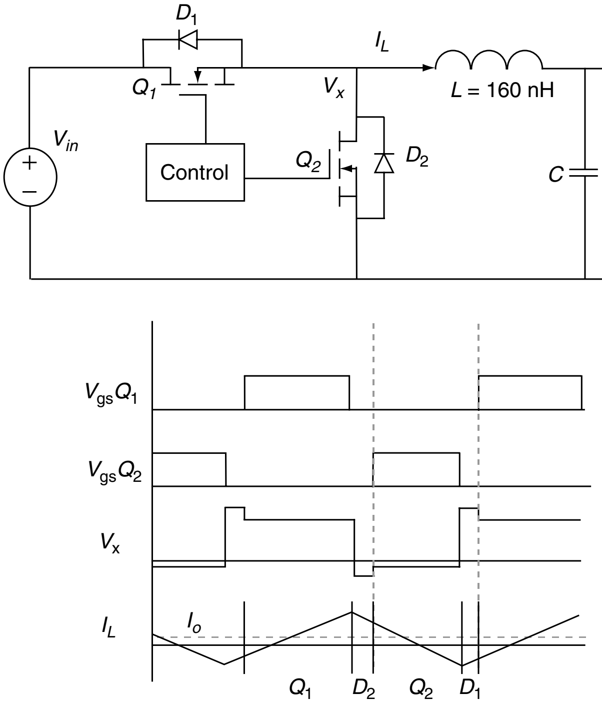

FIGURE 1.13 Quasi-Square-Wave (QSW) VRM Topology

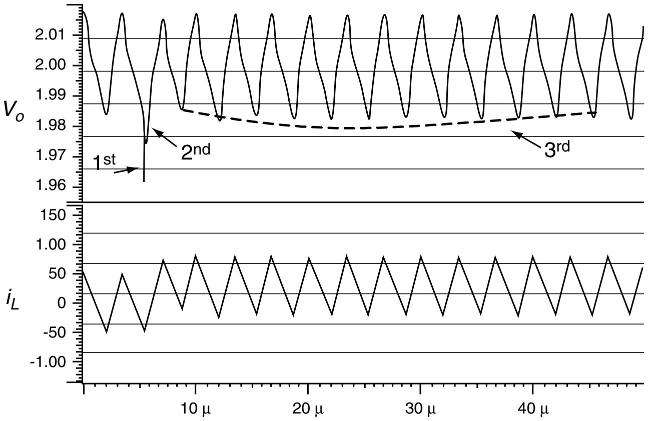

FIGURE 1.14 Transient Response of the QSW

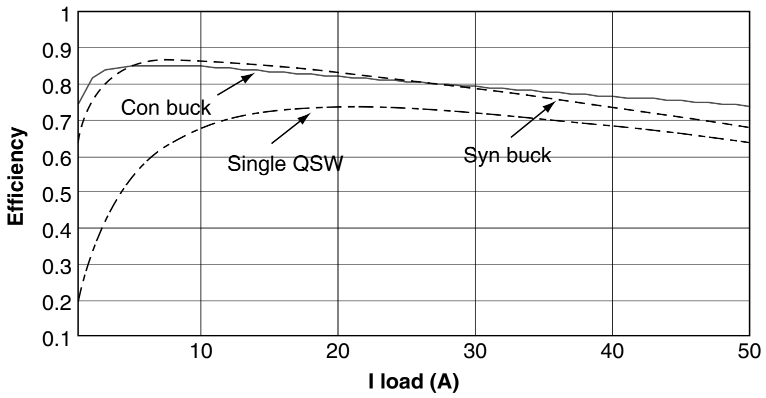

FIGURE 1.15 Efficiency of the QSW Compared with a Conventional VRM ($V_{in} = 5\,\text{V},\ V_o = 2\,\text{V},$ and $fs = 300$ kHz)

There are two disadvantages to this fast VRM topology. The first one is the large current ripple. A huge VRM output filter capacitance is needed to suppress the steady-state ripple. The smaller inductance results in a faster transient response but requires a larger bulk capacitance. The second disadvantage is its low efficiency. In Figure 1.15, due to the large ripple current, the QSW switch has a larger conduction loss. Its efficiency is lower than that of a conventional VRM.

A Fast VRM with a Small Ripple: The Interleaved QSW VRM

To meet both the steady state and transient requirements, a novel VRM topology, the interleaved QSW, is introduced in Figure 1.16. The interleaved QSW topology naturally cancels the output current ripple and still maintains the fast transient response characteristics of the QSW topology. A smaller capacitance is needed compared to both the single-module QSW VRM and the conventional VRM. The more modules in parallel, the better the ripple canceling effect. Figure 1.17 shows a four-module interleaved QSW VRM. Figure 1.18 shows its transient response. The results show that this technique can meet future transient requirements without a large steady-state voltage ripple. Compared with the single-module QSW topology, the efficiency is improved significantly. Figure 1.19 shows the efficiency comparison results.

Figure 1.20 shows a four-module interleaved QSW VRM prototype picture. In the VRM, an integrated magnetic design is used. Every two inductors use one magnetic core. As a result, in total, two magnetic cores are used for these four channel inductors. Figure 1.21 shows the integrated magnetic structure (Chen 1999). By taking advantage of the interleaving technology, the AC flux of the two inductors is canceled out in the center leg. As a result, the core loss and center leg crossing area are reduced. The planar core structure makes a very low-profile VRM. This kind of low-profile magnetic also has good thermal management. In the magnetic design, the PCB trace is used as the inductor winding. This approach is very cost-effective. In addition, the termination loss is eliminated.

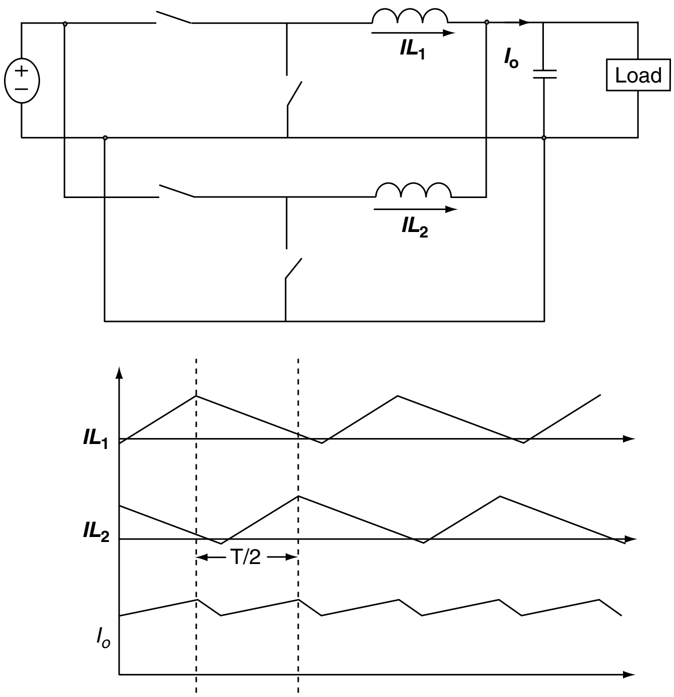

FIGURE 1.16 Current Ripple Cancelling Effect of Interleaved QSW

Table 1.2 compares the four-module interleaved QSW VRM design with the conventional VRM. Since the necessary capacitance is reduced, the VRM power density is dramatically increased by six times. Also, since each module handles a lower current, the circuit will be packaged more easily. The test results in Figure 1.22 show the transient response of the

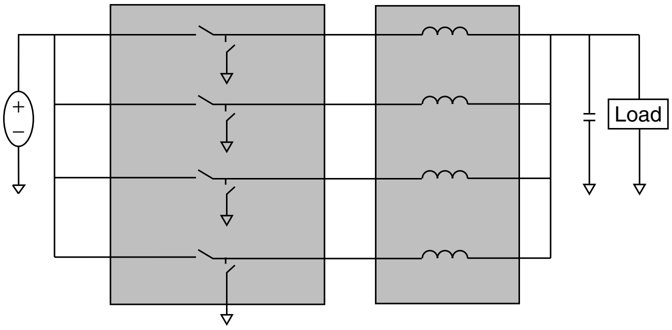

FIGURE 1.17 A Four-Module Interleaved QSW VRM

four-module interleaved QSW VRM compared to today's commercial VRM. The interleaved QSW topology can not only reduce output current ripple, but it can also reduce input current ripple.

1.3.2 High-Input-Voltage VRM Topologies

Most of today's VRMs draw power from the 5-V output of the silver box. This bus voltage is too low for future low-voltage, high-current processors' applications. A distributed power system (DPS) with a high bus voltage can be the solution for future computer systems, such as servers' and workstations' power systems. In a high-voltage bus-distributed system, the bus conduction loss is lower and the distribution bus is easy to

design. On the other hand, in this kind of system, the transient of the load-end converter will have less effect on the bus voltage and thus less effect on the other load-end converters. As a result, for future applications, the high-input-voltage VRMs' input filter size can be dramatically reduced. Figure 1.23 shows the results. When the bus voltage increases from 5 V to 48 V, the VRM input filter capacitance can be reduced from 10 mF to 10 μF.

For high-voltage bus systems, advanced high-input-voltage VRM topologies must be developed. For example, if the buck converter shown in Figure 1.3 is used in a high-voltage bus system, the VRM's duty cycle is very asymmetrical. When the input voltage is 12 V and the output voltage is 2 V, the VRM duty cycle is only 0.16. Figure 1.24 shows the asymmetrical transient response of a synchronous buck VRM. When the load changes from a light load to a heavy load, since the inductor charging voltage ($V_{in} - V_o$) is high, the VRM's step-down voltage drop is small. When the load changes from a heavy load to a light load, since the inductor discharging voltage V_o, is low, the VRM's step-up voltage drop is large. This asymmetrical transient response makes the output filter overdesigned. Besides, it is difficult to optimize efficiency in an asymmetrical duty cycle converter. Figure 1.25 shows the efficiency comparison for different input

voltages. With a higher input voltage, the VRM has a lower efficiency.

1.3.3 A Nonisolated, High-Input-Voltage VRM Topology: The Center-Tapped Inductor VRM

With advanced inductor designs, the VRM duty cycle can be adjusted. Figure 1.26 shows a changed inductor structure, a center-tapped inductor, that can improve the VRM duty cycle. Figure 1.27 shows an improved VRM topology with the center-tapped inductor structure and a loss-less snubber that can absorb the leakage inductance energy as well as reduce ripple and voltage spikes (Zhou, 1999). With this topology, VRMs do not need high-side gate drives, thus improving VRM efficiency at high-input-voltages. To reduce input and output current ripple, an interleave technique can be used, which is shown in Figure 1.28. Figure 1.29 shows the efficiency of this two-channel interleaved center-tapped inductor VRM efficiency. Its input voltage is 12 V, and its output voltage is 1.2 V. In the test, IRL3103D1 is used as top switch, and two MTP75N03DHs in parallel are used as a synchronous rectifier. This topology can achieve 80% efficiency at 1.2 V at a 60 A output.

1.3.4 An Isolated High-Input-Voltage VRM Topology: The Push-Pull Forward Topology

Another approach to adjusting the VRM duty cycle in high-voltage bus systems is to use transformers. By designing the transformer's turns ratio, VRMs can simply adjust their duty cycles to optimize efficiency and cancel the ripple.

Figure 1.30 shows the push-pull forward VRM topology (Zhou, 1999). In the primary side, switch and transformer windings are alternately connected in a circle. A capacitor is connected between any of two interleaved terminations. The left two terminations are connected to the input and ground, respectively. The two primary windings have the same turns. Figure 1.31 explains the operation of this converter.

Compared with conventional high-input-voltage VRM topologies, the push-pull forward converter has a higher power density, faster transient response, and higher efficiency. For example, compared with the forward flyback shown in Figure 1.32 and asymmetrical half-bridge shown in Figure 1.33, which are fourth-order systems, the push-pull forward converter is a second-order system. Therefore, its control is simpler, and its transient is faster. As a result, the output filter inductance and capacitance needed are significantly reduced. Due to its reduced input current ripple, the converter's input filter can also be reduced.

Compared with half-bridge converters and asymmetrical and symmetrical half-bridge converters, the push-pull forward topology has a larger transformer's turns ratio. For example, if VRM input voltage is 48 V and output voltage is 3.3 V, for both the symmetrical and asymmetrical half-bridges, the transformer's turns ratio is 3 to 1. For the push-pull forward converter, the transformer's turns ratio is 6 to 1. Therefore, the conduction loss of the primary switches in a push-pull forward converter is lower. As a result, the push-pull forward converter has a higher efficiency. At heavy load, the efficiency of the push-pull forward converter is 2 to 3% higher than that of either half-bridge converter.

Figures 1.34(A) and 1.34(B) show the efficiencies of the push-pull forward converter under 12 V and 48 V input voltages, respectively. For a 12-V input, this converter can achieve 81% efficiency at an output of 1.2 V at 60 A. For a 48-V input, this converter can achieve 83.6% efficiency at an output of 1.2 V at 60 A.

1.4 Future VRMs

1.4.1 High-Frequency and High-Power-Density *VRMs*

To develop low-cost, high-efficiency, low-profile, high-power density, fast-transient-response, board-mount VRM modules for future generation microprocessor loads, high operating frequencies are desirable. Figure 1.35 shows the transient response of the interleaved QSW VRM when it operates at 1 MHz. Obviously, the voltage spike is reduced significantly. Figure 1.36 shows the inductance and capacitance needed in the interleaved QSW VRM when it operates at a high switching frequency. At 10 MHz, the inductance needed is only 9.25 nH and the capacitance needed is only 5.26 µF. With such a small inductance and capacitance, very high-power-density VRMs can be created, and energy storage costs can be dramatically reduced. Because of today's device technology, however, most VRMs' operating frequencies are lower than 300 kHz. Even at this frequency, the VRM cannot meet efficiency requirements. When the frequency is increased, the resulting VRM efficiency levels are shown in Figure 1.37. At 10 MHz, the VRM will only

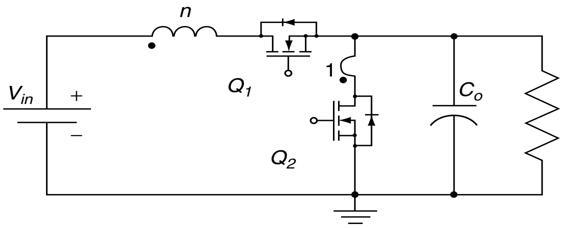

FIGURE 1.26 Center-Tapped Inductor Structure

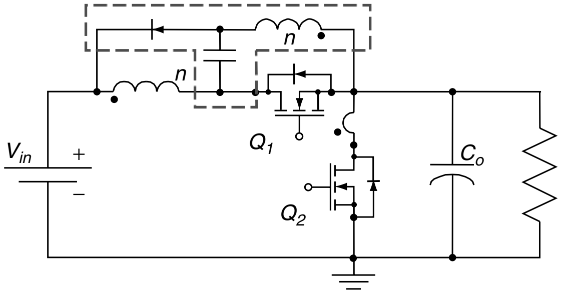

FIGURE 1.27 Improved VRM Topology with a Center-Tapped Inductor and a Lossless Snubber

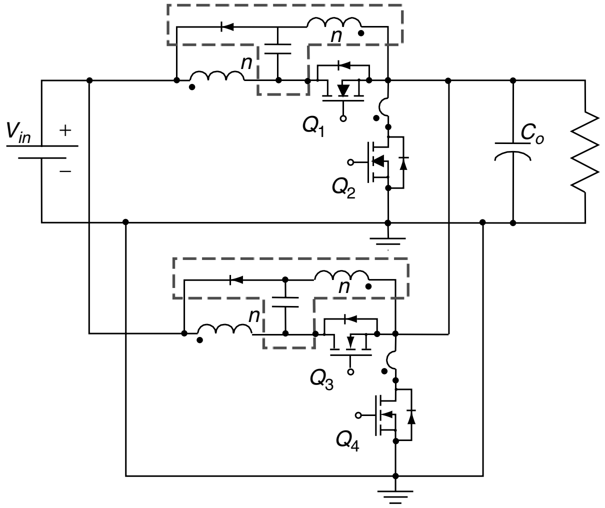

FIGURE 1.28 Interleaved Center-Tapped Inductor VRM

have 40% efficiency. This efficiency makes thermal management and packaging very difficult.

For future microprocessor applications, the power device must have a smaller FOM value [$< 100(\text{m}\Omega \times nC)$] and a lower miller charge. With improved device technologies, such as the SOI LDDMOS technology (Huang, 1998), future VRM efficiency will be higher than 90% at several megahertz operating frequencies. Figure 1.38 shows the difference between a vertical DMOS and the proposed LDD MOSFET on

SOI structure, whose power density is higher than $100\,\text{W/in}^3$. Table 1.3 shows the VRM efficiency comparison based on today's device technology and the improved LDDMOS technology.

Although advanced topologies have very fast transients, and future device techniques can operate at very high frequencies,

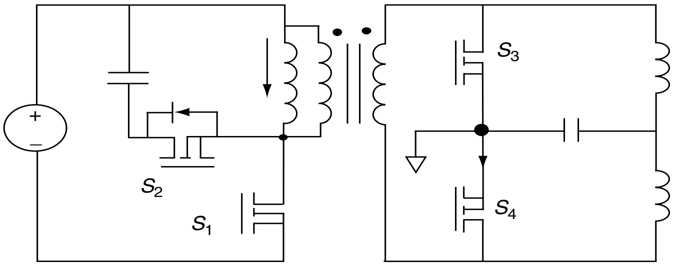

FIGURE 1.32 Flyback Forward Converter

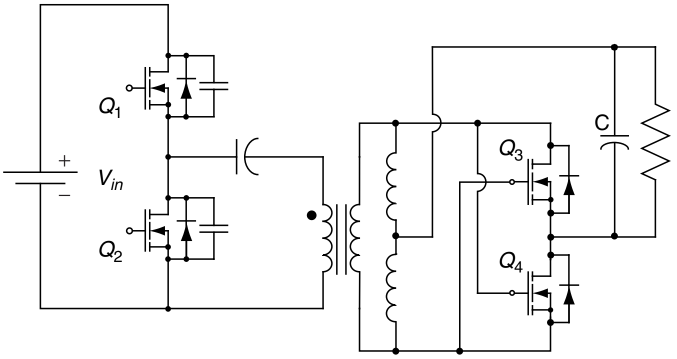

FIGURE 1.33 Asymmetrical Half-Bridge Converter

to minimize the effects of the interconnections an innovative design with a possible integration of the VRM and the processor is still the key to meeting the ever-increasing demand for processor performance and speed.

The integration of the VRM with the processor can take either a hybrid or a monolithic approach. In the hybrid approach, the VRM can be made as a silicon chip with all the control functions. Figure 1.39 shows an integration-packaging example. As shown in Figure 1.39(A) and (B), several VRM chips can be placed in parallel and be mounted close to the microprocessor on the same cartridge. Ceramic capacitors with small ESRs and ESLs can be used as the output capacitors and can be placed on the PCB board next to the processor. By connecting the output of the VRM and the power input of the processor via a path through a magnetic material sheet, the small output inductor can also be created. With this kind of packaging approach, interconnection parasitics can be minimized. For future applications, some other advanced packaging technologies, such as flip-chip technology, can also be used.

1.5 Conclusions

For future microprocessor applications, there are many power management issues that need to be addressed, such as those concerning VRM topologies, power device technologies, and packaging technologies. To meet future requirements, VRMs should have high-power densities, high efficiencies, and fast transient performances. To achieve this target, advanced VRM topologies, advanced power devices, and advanced packaging technologies must be developed.

Noise in Analog and Digital Systems

Department of Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, Illinois, USA

2.1 Introduction

Noise from an analog (or **small-signal**) perspective is a random time-varying signal that is generated in all passive and active electronic devices. It can be represented as either a current or a voltage, $i_n(t)$ or $v_n(t)$. Over a fixed time period, t, the average value of noise is zero. Analog noise, therefore, is commonly presented in terms of its **mean-square** value (I^2_{rms} or V^2_{rms}). It is sometimes also described by its **root-mean-square** value (I_{rms} or V_{rms}).

Noise in digital (or **large-signal**) circuits is the perturbation of one nonlinear signal, the **noise victim**, by a second nonlinear signal, the **noise aggressor**. The perturbation is introduced by a parasitic coupling path that is resistive, capacitive, or inductive in nature. Since digital systems are typically characterized by voltage levels, digital noise is presented in terms of voltage and voltage transients, $v_n(t)$ and dv_n/dt.

The impact of noise differs for analog and digital systems and leads to unique equivalent circuit models and analytical techniques. Analog noise is treated by linearized expressions that correspond to small-signal equivalent circuit parameters. Digital noise is analyzed by large-signal expressions that define logic transitions. In this chapter, the characteristics of noise are presented for both systems. Several examples are included for each type of system.

For further reading, several respected books are listed in the Bibliography section of this chapter. These provide a more thorough background on analog and digital systems, network theory, and the introduction of noise to classical systems analysis.

2.2 Analog (Small-Signal) Noise

Noise in analog systems is typically characterized by its impact as a small-signal perturbation. In this form, noise is considered to be an independent alternating current (ac) source (either voltage or current). Table 2.1 lists the nomenclature for discussing analog noise. These measures are derived and defined throughout the chapter.

The relationships as a function of time for noise voltage, square noise voltage, and mean-square noise voltage are illustrated in Figure 2.1; similar waveforms can also be shown for representating noise current. If multiple noise sources are present, they are considered to be independent and uncorrelated. Therefore, the cumulative noise contribution can be expressed in mean-square units by:

$$\overline{i_n^2} = \overline{i_{n1}^2} + \overline{i_{n2}^2}, \tag{2.1}$$

as the sum of the individual mean-square components. In *rms* terms, the total noise is represented by:

$$i_{n,\,rms} = \sqrt{i^2_{n1,\,rms} + i^2_{n2,\,rms}}. \tag{2.2}$$

TABLE 2.1 Nomenclature in Analog (Small-Signal) Noise Analysis

Name	Current-referred symbol	Units	Voltage-referred symbol	Units
Noise signal	$i_n(t)$	A	$v_n(t)$	V
Mean-square noise signal	$\overline{i_n^2(t)}$	A^2_{rms}	$\overline{v_n^2(t)}$	V^2_{rms}
Root-mean-square noise signal	$\sqrt{\overline{i_n^2(t)}}$ or $i_{n,\ rms}$	A_{rms}	$\sqrt{\overline{v_n^2(t)}}$ or $v_{n,\,rms}$	V_{rms}

Root noise power spectral density	$\sqrt{S_I(f)}$	$A/\sqrt{Hz}$	$\sqrt{S_V(f)}$	$V/\sqrt{Hz}$

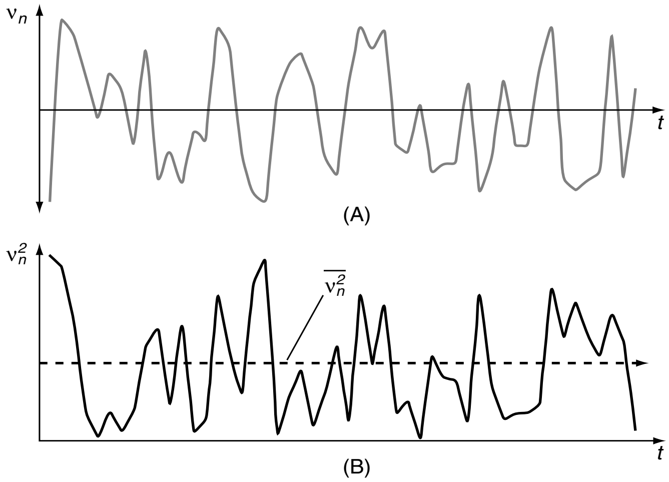

FIGURE 2.1

Some noise also exhibits a frequency dependence. If the noise mean-square value of spectral components in a narrow bandwidth (Δf) is determined, then the ratio of that value to Δf is defined as the **noise power spectral density** (the noise **mean-square per bandwidth**). Mathematically, the definition is expressed in terms of noise current as:

$$S_I(f) = \lim_{\Delta f \to 0} \frac{\overline{i_n^2(t)}}{\Delta f}. \tag{2.3}$$

The relationship can be reversed to define the mean-square noise current in terms of the noise power spectral density by:

$$\overline{i_n^2} = \int_{f_1}^{f_2} S_I(f)\,df. \tag{2.4}$$

Equivalent expressions can be derived for $S_V(f)$, the noise power in terms of noise voltage.

2.2.1 Noise Categories

Analog small-signal noise can be subdivided into two categories: frequency independent (or **white**) noise and frequency dependent (or **pink**) noise. The spectrum of the former is constant to frequencies as high as 10^{14} Hz. In the latter, the noise power is a function of $1/f^n$, where typically $n = 1$ (although some forms of noise obey a power relationship with $n \geq 2$). The total noise power in an element, as shown in Figure 2.2, is the combination of both, and a clear knee frequency is observed. The terms S_{Iw} and S_{Ip} are used to refer to the specific contributions of white and pink noise, respectively, to the total noise power.

Table 2.2 lists the common characteristics of small-signal noise. The expressions are developed more fully in the following subsections.

2.2.2 White Noise

White noise sources are composed of **thermal** (also called **Johnson** or **Nyquist**) noise and **shot** noise. Thermal noise is generated by all resistive elements and is associated with the random motion of carriers in an electronic element. It is a function only of temperature. Shot noise is associated with the discretization of charged particles and is always present in semiconductor *pn* junctions. It is a function only of dc current flow.

The thermal noise of a resistance, *R*, can be modeled as an ideal resistor and an independent current or voltage source, as shown in Figure 2.3. The Thevenin equivalent noise voltage is given by:

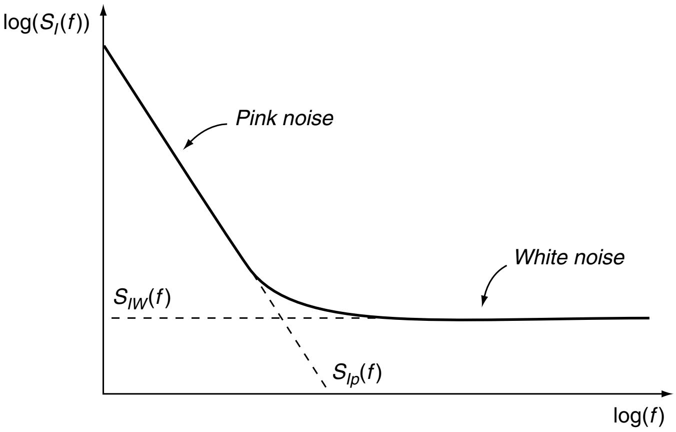

FIGURE 2.2

$K_R \approx 5 \times 10^{-24}\ \mathrm{cm^2/\Omega^2}$

$K_D \approx 10^{-21}\ \mathrm{cm^2 \cdot A}$

$$K_M \approx \begin{cases} 10^{-33}\mathrm{C^2/cm^2}(p\mathrm{JFET}) \\ 10^{-32}\mathrm{C^2/cm^2}(\mathrm{PMOSFET}) \\ 4 \times 10^{-31}\mathrm{C^2/cm^2}(\mathrm{NMOSFET}) \end{cases}$$

$$\overline{v_n^2} = 4\hat{k}TR\Delta f, \tag{2.5}$$

where $\hat{k}$ is Boltzmann's constant ($1.38 \times 10^{-23}\ \mathrm{V \cdot C/K}$), T is absolute temperature (in degrees Kelvin), and Δf is the noise bandwidth. The Norton equivalent noise current can also be obtained. It is expressed as:

$$\overline{i_n^2} = 4\hat{k}T\frac{1}{R}\Delta f. \tag{2.6}$$

A MOSFET's channel resistance also produces a thermal noise current according to equation 2.6. Since it is informative to compare the MOSFET noise current with the small-signal input stimulus, the output noise current can be referred back to the source using the amplifier gain expression:

$$i_d = g_m v_{gs}, \tag{2.7}$$

such that the equivalent input noise voltage is as follows:

$$\overline{v_{n,\,\mathrm{eq}}^2} = \frac{4\hat{k}T}{Rg_m^2}\Delta f. \tag{2.8}$$

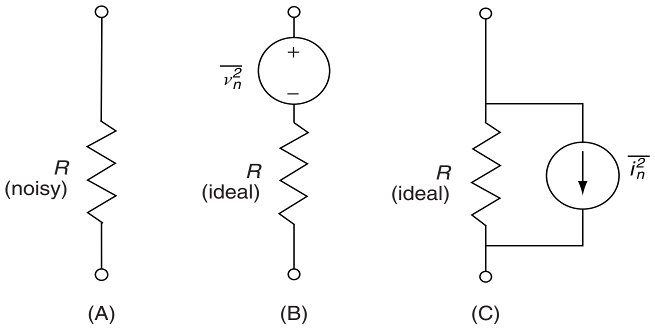

FIGURE 2.3

In the saturation regime, the channel resistance can be approximated by $1/g_m$, and the channel pinch-off reduces the effective noise to about 66% of its nominal value. Therefore, equation 2.8 can be simplified to:

$$\overline{v_{n,\,\mathrm{eq}}^2} = \frac{8\hat{k}T}{3}\frac{1}{g_m}\Delta f. \tag{2.9}$$

Both MOSFET channel thermal noise source configurations are shown in Figure 2.4. It should be noted that the input noise voltage representation is valid only at low frequencies. As the frequency rises, the admittance of gate parasitic capacitances (C_{GD} and C_{GS}) becomes higher; $\overline{v_{n,\,\mathrm{eq}}^2}$ is dropped partly on the gate impedance and partly on the output resistance of the

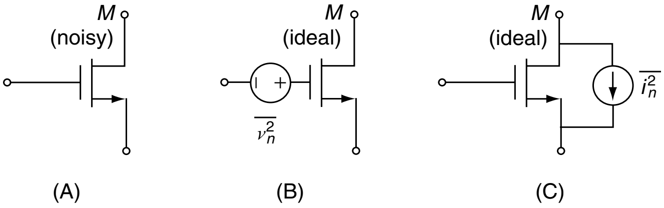

FIGURE 2.4

preceding device. Therefore, the ideal noiseless MOSFET is stimulated by an erroneously low noise voltage, resulting in inaccurate predictions of output noise.

Likewise, the shot noise of a junction diode, *D*, can be modeled as an ideal diode and an independent current source, as shown in Figure 2.5. The Norton equivalent noise current is given by

$$\overline{i_n^2} = 2qI\Delta f, \tag{2.10}$$

where *I* is the dc current conducted by the diode and Δf is the noise bandwidth. Noise is generated by the junction in both forward- and reverse-biased conditions since either a forward current or a leakage current is present.

Many analog circuits such as filters, sample-and-hold amplifiers, and switched-capacitor networks employ a resistor or a conductance that is bandwidth-limited by a capacitance or inductance. Just as the reactance of the inductor or capacitor limits the bandwidth of the input signal, it also affects the noise bandwidth. In the case of an RC circuit, the *rms* noise voltage is expressed as:

$$v_{n,\,rms} = \sqrt{\frac{\hat{k}T}{C}}. \tag{2.11}$$

A complementary result can be obtained for RL circuits, with the *rms* noise current expressed as:

$$i_{n,\,rms} = \sqrt{\frac{\hat{k}T}{L}}. \tag{2.12}$$

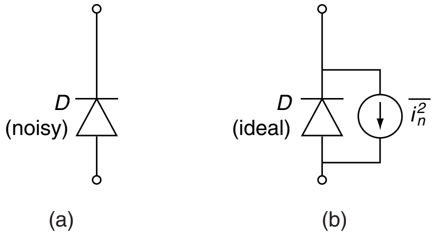

FIGURE 2.5

The expressions of equations 2.11 and 2.12 are interesting in that the resulting noise voltage or current is independent of the resistance or conductance. The total noise can be reduced only by choosing larger values for the reactive elements.

2.2.3 Pink Noise

Pink noise sources consist of **flicker** (also called $1/f$) **noise** and **popcorn noise**. Flicker noise pertains to the conductive properties of an electronic element. Other theories attribute flicker noise to interface traps present at oxide-semiconductor interfaces or to fluctuations in mobility. The noise is a function of the material homogeneity, its volume, the current, and the frequency. Popcorn noise, on the other hand, is proportional to $1/f^2$ and is an indication of poor semiconductor manufacturing. It is associated with distinct recombination processes and appears as a series of low-frequency noise bursts. Because it is uncommon, popcorn noise is not discussed further.

Flicker noise is proportional to current and inversely proportional to volume. Since electronic devices are three-dimensional structures, planar resistors and semiconductor junctions have unique expressions and scaling factors. For example, the flicker noise voltage of a resistor, *R*, is given as:

$$\overline{v_n^2} = K_R \frac{R_{\mathrm{sq}}^2}{A} V^2 \frac{\Delta f}{f}, \tag{2.13}$$

where R_{sq} is the sheet resistance, *A* is the planar area of the resistor, *V* is the dc voltage, and K_R is a technology scaling constant ($\approx 5 \times 10^{-24}\,\mathrm{cm}^2/\Omega^2$). The flicker noise current of a junction diode is similarly found as:

$$\overline{i_n^2} = \frac{K_D I}{A} \frac{\Delta f}{f}, \tag{2.14}$$

where *A* is the cross-sectional area of the diode, *I* is the dc current, and K_D is a diode scaling constant ($\approx 10^{-21}\,\mathrm{cm}^2 \cdot \mathrm{Å}$).

Finally, the input referred flicker noise voltage in a MOSFET is found by an expression that is derived from equation 2.14. It is given by:

$$\overline{v_{n,\,\mathrm{eq}}^2} = \frac{K_M}{WLC_{\mathrm{ox}}^2} \frac{\Delta f}{f}, \tag{2.15}$$

where W and *L* are, respectively, the gate width and length, C_{ox} is the oxide capacitance per unit area, and technology constant K_M is found experimentally. Recent empirical values for three types of FET are:

p-type JFET	$\approx 10^{-33}\,\mathrm{C}^2/\mathrm{cm}^2$
PMOSFET	$\approx 10^{-32}\,\mathrm{C}^2/\mathrm{cm}^2$
NMOSFET	$\approx 4 \times 10^{-31}\,\mathrm{C}^2/\mathrm{cm}^2$

2.3 Digital (Large-Signal) Noise

Noise in digital systems is typically characterized by the integrity of the voltages that represent the logic 0 and logic 1 states. Noise can manifest itself either during switching (when it may result in switching times that exceed theoretical results) or in static conditions. Even in CMOS logic, which nominally provides fully rail-to-rail logic levels, dynamic noise events can momentarily perturb a voltage level. Deep submicron technologies, which typically employ supply voltages of under 1.8 V, may be especially susceptible to logic glitches or errors that are induced by random coupled noise.

Table 2.3 lists the nomenclature used for discussing digital noise. These terms are derived and defined throughout the chapter.

2.3.1 Noise Categories

Several categories of noise are present in digital circuits. These include **series resistance**, dynamic charge sharing of hard and soft nodes, and ***I/O* integrity**, which are the types discussed in this chapter. They can appear in any combination, but for simplicity, the analysis below considers each noise source independently. All are strongly dependent on the specifications of the semiconductor manufacturing process, the physical arrangement of gates and interconnections on an integrated circuit, the switching frequency, and the relative activity level of adjacent gates or interconnections.

Table 2.4 lists the fundamental characteristics of large-signal noise. The expressions derived below demonstrate the impact of noise on either the input logic level (V_{IL} or V_{IH}) or the output logic level (V_{OL} or V_{OH}). Through these four parameters, noise indirectly affects the low and high noise margins.

2.3.2 Series Resistance

The effect of **series resistance** is to degrade output voltage levels (push them away from the rails). Series resistance can be present in the supply rail and/or the ground rail. Each series resistance has a different effect on the output characteristics. Ground rail resistance degrades V_{OL} and supply rail resistance degrades V_{OH}.

For example, consider the CMOS inverter shown in Figure 2.6(A) that includes a ground resistance R_{series}. The output voltage, V_O, can be modeled [see Figure 2.6(B)] as a resistor–divider network such that:

$$V_O = \frac{R_{\text{NMOS}} + R_{\text{series}}}{R_{\text{NMOS}} + R_{\text{PMOS}} + R_{\text{series}}} Vdd, \tag{2.16}$$

where R_{NMOS} and R_{PMOS} are the output resistances of the inverter gates and R_{series} is the ground resistance. If the inverter input is a logic 1, the NMOS is strongly conducting and therefore $R_{\text{NMOS}} \approx 0$. Then equation 2.16 can be simplified to:

$$V_O = \frac{R_{\text{series}}}{R_{\text{PMOS}} + R_{\text{series}}} Vdd. \tag{2.17a}$$

The output voltage is increased by the presence of the series resistance. A complementary result can be obtained for a supply rail resistance and an input of logic 0, which yields:

TABLE 2.3 Nomenclature in Digital (Large-Signal) Noise Analysis

TABLE 2.4 Characteristics of Digital (Large-Signal) Noise

Name	Expression (CMOS)	Expression (NMOS)
V_{OL}	0	$\frac{1}{k}\frac{V_{TD}^2}{2(Vdd - V_{TN})}$
V_{OH}	Vdd	Vdd
V_{IL}	$\frac{3Vdd + 3V_{TP} + 5V_{TN}}{8}$	$V_{TN} - \frac{V_{TD}}{\sqrt{k(1+k)}}$
V_{IH}	$\frac{5Vdd + 5V_{TP} + 3V_{TN}}{8}$	$V_{TN} - \frac{2V_{TD}}{\sqrt{3k}}$
NM_L	$V_{IL} - V_{OL}$	
NM_H	$V_{OH} - V_{IH}$	

$$V_O = \frac{R_{\mathrm{NMOS}}}{R_{\mathrm{NMOS}} + R_{\mathrm{series}}} Vdd. \quad (2.17b)$$

Supply and ground rails are designed to have minimal resistance to alleviate such effects as series resistance. This is accomplished by using low resistivity materials, increasing the cross-sectional area of the conductors, using shorter interconnection lengths, and applying other techniques. Two conditions, however, may still produce large voltage deviations. One condition is high-current *I/O* buffers, and the second condition is simultaneous switching of many parallel gates. The latter situation is illustrated in Figure 2.6(C).

If *n* gates (inverters in this example) with a common series resistance simultaneously switch the expressions of equations 2.17a and 2.17b, they can be modified as:

$$V_O = \frac{nR_{\mathrm{series}}}{R_{\mathrm{PMOS}} + nR_{\mathrm{series}}} Vdd. \quad (2.18a)$$

and

$$V_O = \frac{R_{\mathrm{NMOS}}}{R_{\mathrm{NMOS}} + nR_{\mathrm{series}}} Vdd. \quad (2.18b)$$

The effect of simultaneous switching becomes more pronounced as device density on integrated circuits rises and die sizes also increase.

2.3.3 Dynamic Charge Sharing

The phenomenon of **dynamic charge sharing** occurs when two functionally unrelated nodes become coupled due to a capacitance or mutual inductance. Coupling appears between any two interconnected lines that are adjacent or that overlap. In general, noise coupling is proportional to the cross-sectional area that is shared by the two lines. Coupling is also proportional to frequency and inversely proportional to the separation. Therefore, as integrated circuits are scaled to smaller dimensions and operate at higher frequencies, the detrimental effects of charge sharing become more severe.

Until recently, coupling was exclusively capacitive in nature. As integrated circuits reach frequencies of 1 GHz and above, however, inductive coupling also becomes significant. Results in this chapter, though, are limited to conventional capacitive coupling.

Consider, as shown in Figure 2.7(A), the two nodes v_n (the **noise aggressor** or source) and v_v (the **noise victim**) that are coupled by a capacitor C_c. Node v_v is also tied to ground through a generic admittance *Y*. In digital circuits, v_v can be either a **floating node** (such as found in dynamic logic, pass transistor logic, or memory cells) or a **driven node** (such as found in static logic). The admittance *Y* is therefore equivalent to either a second coupling capacitance C_p (from the floating node to the ground plane) or a resistance r_a (representing the output impedance of the gate driving the node). Both cases are illustrated in Figure 2.7.

A floating node's change in voltage at v_v that is produced by a signal at v_n is expressed as:

$$v_v = \frac{v_n C_c}{C_c + c_p}. \quad (2.19)$$

Because c_p is usually just the input capacitance of a logic gate, it is very small. Any value of C_c can cause significant charge-sharing to occur. Active nodes are much less susceptible to disruption by noise coupling since the equivalent output resistance, r_a, of the driving gate may be large ($> 10\,\mathrm{k}\Omega$). The noise coupled to the victim node is written as:

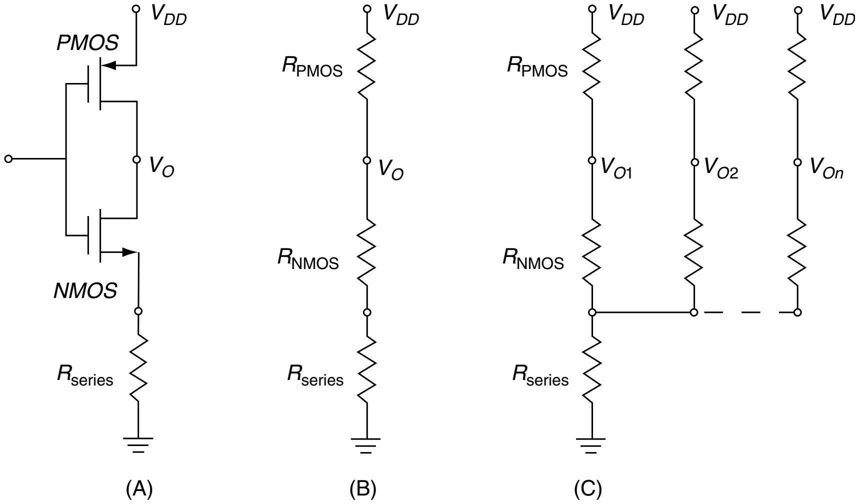

FIGURE 2.6

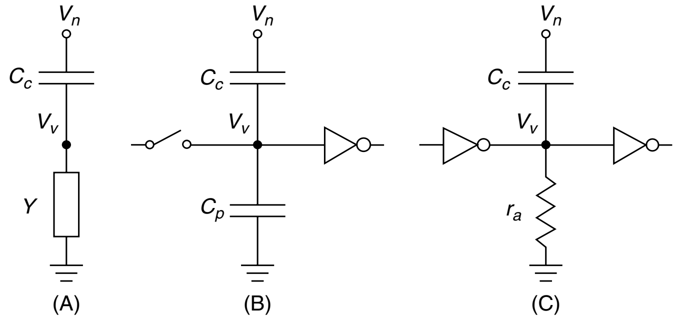

FIGURE 2.7

$$v_v = \frac{v_n r_a C_c s}{1 + r_a C_c s}. \tag{2.20}$$

Because typically $|r_a C_c s| \ll 1$, equation 2.20 can be reduced to:

$$v_v = v_n r_a C_c s. \tag{2.21}$$

Clearly for an actively driven node, a much larger coupling capacitance is necessary to produce a significant perturbation of the victim node.

2.3.4 Noise Margins

The *I/O* noise margins, NM_L and NM_H, refer to the ability of a logic gate to accommodate input noise without producing a faulty logic output. The input noise threshold levels, V_{IL} andV_{IH}, are by convention defined as the input voltages that result in a slope of -1 in the dV_O/dV_I response. This is shown in Figure 2.8. As is clear from Table 2.4, the noise margins of CMOS logic gates are larger than for comparable NMOS technologies. This is evident because CMOS delivers rail-to-rail outputs, whereas the V_{OL} is a circuit constraint in NMOS.

The noise margins of a CMOS gate can be found by first examining the dc transfer curve shown in Figure 2.8. From graphical analysis, the V_{IL} occurs when the PMOS is in its linear regime and the NMOS is in its saturation regime. Since a CMOS gate is complementary in operation, the V_{IH} by symmetry occurs when the PMOS is in its saturation regime and the NMOS is in its linear regime.

Considering first the CMOS V_{IL}, begin by equating the NMOS and PMOS currents:

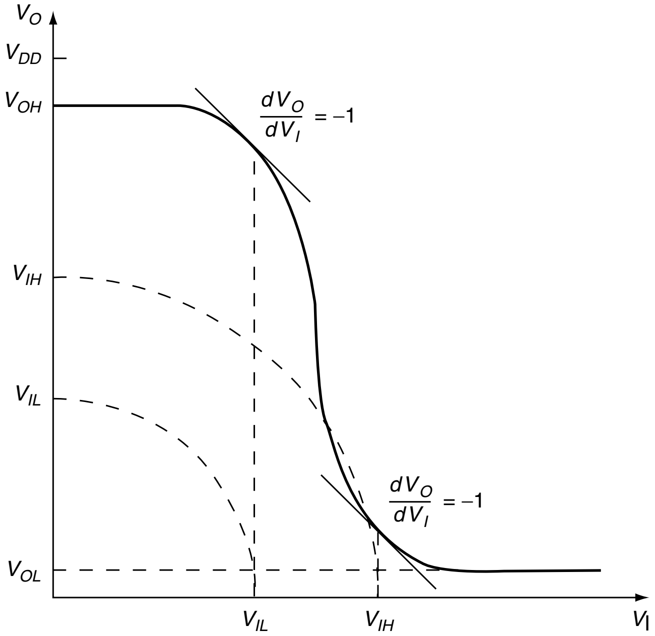

FIGURE 2.8

$$k_n \frac{W_n}{L_n} \frac{(V_I - V_{Tn})^2}{2} = k_p \frac{W_p}{L_p} \left(V_I - Vdd - V_{Tp} - \frac{V_O - Vdd}{2} \right) (V_O - Vdd). \tag{2.22}$$

Assuming that the inverter is designed to have a balanced transfer curve such that:

$$k_n \frac{W_n}{L_n} = k_p \frac{W_p}{L_p}, \tag{2.23}$$

then equation 2.22 reduces to a simpler form such that:

$$V_{IL} = \frac{3Vdd + 3V_{TP} + 5V_{TN}}{8}. \tag{2.24}$$

Considering next the CMOS V_{IH}, equating the NMOS and PMOS currents results in:

$$k_n \frac{W_n}{L_n} (V_I - V_{Tn} - \frac{V_O}{2}) V_O = k_p \frac{W_p}{L_p} \frac{(V_I - Vdd - V_{Tp})^2}{2}. \tag{2.25}$$

Again using the assumption of equation 2.23, this expression can also be reduced and rearranged, yielding the form:

$$V_{IH} = \frac{5Vdd + 5V_{TP} + 3V_{TN}}{8}. \tag{2.26}$$

The noise margins of an NMOS inverter can be found using similar methods. The derivations are not shown here but the steps are identified. Beginning with V_{IH} and examining through graphical techniques the output characteristics, the NMOS inverter is found to be equivalent to the CMOS case; that is, the driver (enhancement mode) is in the linear regime and the load (depletion mode) is in the saturation regime. Assuming that the inverter pull-up: pull-down ratio is k, then:

$$V_{IH} = V_{TN} - \frac{2V_{TD}}{\sqrt{3k}}. \tag{2.27}$$

Considering the NMOS V_{IL}, the driver and load bias regimes are exchanged (as in CMOS), and the result is as follows:

$$V_{IL} = V_{TN} - \frac{V_{TD}}{\sqrt{k(1+k)}}. \tag{2.28}$$

Note that the $\mathrm{NM_H}$ of NMOS and CMOS inverters are similar since both achieve $V_{OH} \approx Vdd$. Because an NMOS inverter V_{OL} is not zero (100 mV – 500 mV are typical values), however, the NM_L of NMOS is considerably lower than for a CMOS inverter.

3.1 Introduction

The concept of modulating the electrical current in a semiconductor by an external electrical field was first proposed by Julius Lilienfeld in the 1930s. Years later, William Shockley, a scientist at Western Electric, led a research program to create a semiconductor device based on this "field effect" concept. To replace bulky vacuum tubes then used in telephone switching. Two scientists in Shockley's team, W. Brattain and J. Bardeen, invented the point contact transistor in 1947. Subsequently, Shockley invented the bipolar-junction transistor (BJT). Shockley later developed the junction field effect transistor (JFET); however, the JFET was not able to challenge the dominance of BJT in many applications. The development of field effect devices continued with moderate progress until the early 1960s, when the metal-oxide-silicon field effect transistor (MOSFET) emerged as a prominent device. This device quickly became popular in semiconductor memories and digital integrated circuits. Today, the MOSFET dominates the integrated circuit technology, and it is responsible for the computer revolution of the 1990s.

The first half of this chapter is dedicated to the basic theory of the MOSFET, beginning with its fundamental building block, the MOS capacitor. The second half of the chapter presents an overview of less common field effect devices used only in specific applications. Their coverage is limited to a qualitative explanation of the operating principles and basic equations. The reader is referred to other books available in literature to obtain detailed information.

3.2 Metal-Oxide-Silicon Capacitor

The metal-oxide-silicon (MOS) capacitor is at the core of the complementary metal-oxide-silicon (CMOS) technology. MOSFETs rely on the extremely high quality of the interface between SiO_2, the standard gate dielectric, and silicon (Si). Before presenting the MOSFET in detail, it is essential to achieve a satisfactory understanding of the MOS capacitor fundamentals.

The simplified schematic of the MOS capacitor is shown in Figure 3.1. The structure is similar to a parallel plate capacitor in which the bottom electrode is replaced by a semiconductor. When Si is used as the substrate material, the top electrode, known as the gate, is typically made of polycrystalline silicon (polysilicon), and the dielectric is thermally grown silicon dioxide. In MOS terminology, the substrate is commonly referred to as the *body*.

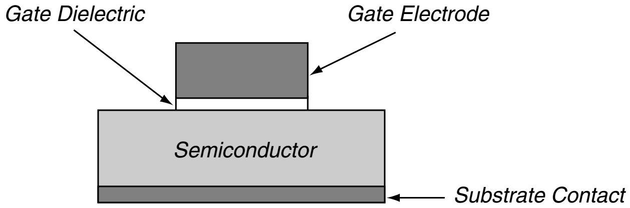

FIGURE 3.1

3.2.1 The Ideal MOS Capacitor

The energy band diagram of an ideal p-type substrate MOS capacitor at zero bias is shown in Figure 3.2. In an ideal MOS capacitor, the metal work function, ϕ_m, is equal to the semiconductor work function, ϕ_s. Therefore, when the Fermi level of the semiconductor, E_{FS}, is aligned with the Fermi level of the gate, E_{Fm}, there is no band bending in any region of the MOS capacitor. Furthermore, the gate dielectric is assumed to be free of any charges, and the semiconductor is uniformly doped.

Figure 3.3 shows the energy band diagram and the charge distribution in an ideal MOS structure for different gate-to-body voltages (V_{GB}).

With a negative gate bias (Figure 3.3(A)), the gate charge, Q_G, is negative. The source of this negative charge is electrons supplied by the voltage source. In an MOS capacitor, charge neutrality is always preserved. This requires:

$$Q_G + Q_C = 0, \tag{3.1}$$

where Q_C is the charge induced in the semiconductor. Therefore, a net positive charge, Q_C, must be generated in the silicon substrate to counterbalance the negative charge on the gate. This is achieved by accumulation of the positively charged holes under the gate. This condition, where the majority carrier concentration is greater near the $Si-SiO_2$ interface compared to the bulk, is called **accumulation**.

Under an applied negative gate bias, the Fermi level of the gate is raised with respect to the Fermi level of the substrate by an amount equal to qV_{GB}. The energy bands in the semiconductor bend upward, bringing the valence band closer to the Fermi level that is indicative of a higher hole concentration under the dielectric. It is important to note that the Fermi level in the substrate remains invariant even under an applied bias since no current can flow through the device due to the presence of an insulator.

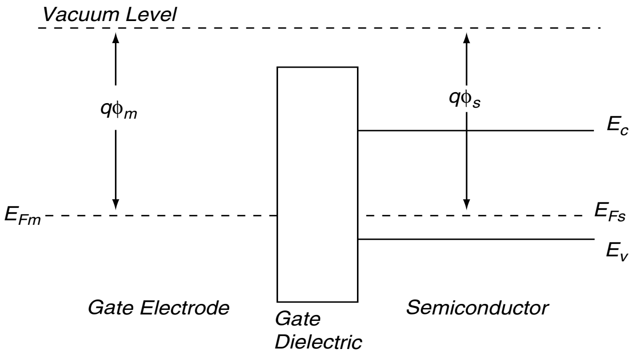

FIGURE 3.2

The applied gate voltage is shared between the gate dielectric and the semiconductor such that:

$$V_G = V_{ox} + V_c, \tag{3.2}$$

where V_{ox} and V_c are the voltages that drop across the oxide and the semiconductor, respectively. The band bending in the oxide is equal to qV_{ox}. The electric field in the oxide can be expressed as:

$$E_{ox} = \frac{V_{ox}}{t_{ox}}, \tag{3.3}$$

where t_{ox} is the oxide thickness. The amount of band bending in the semiconductor is equal to $q\psi_s$, where ψ_s is the surface potential and is negative when the band bending is upward.

Figure 3.3(B) shows the energy band diagram and the charge distribution for a positive gate bias. To counterbalance the positive gate charge, the holes under the gate are pushed away, leaving behind ionized, negatively charged acceptor atoms, which creates a **depletion region**. The charge in the depletion region is exactly equal to the charge on the gate to preserve charge neutrality. With a positive gate bias, the Fermi level of the gate is lowered with respect to the Fermi level of the substrate. The bands bend downward, resulting in a positive surface potential. Under the gate, the valence band moves away from the Fermi level indicative of hole depletion. When the band bending at the surface is such that the intrinsic level coincides with the Fermi level, the surface resembles an intrinsic material. The surface potential required to have this condition is given by:

$$\psi_s = \phi_F = \frac{1}{q}(E_i - E_F), \tag{3.4}$$

where

$$\phi_F = \frac{kT}{q}\ln\frac{N_A}{n_i} \tag{3.5}$$

Under a larger positive gate bias, the positive charge on the gate increases further, and the oxide field begins to collect thermally generated electrons under the gate. With electrons, the intrinsic surface begins to change into an *n*-type inversion layer. The negative charge in the semiconductor is comprised of ionized acceptor atoms in the depletion region and free electrons in the inversion layer. As noted above, at this point, the electron concentration at the surface is still less than the

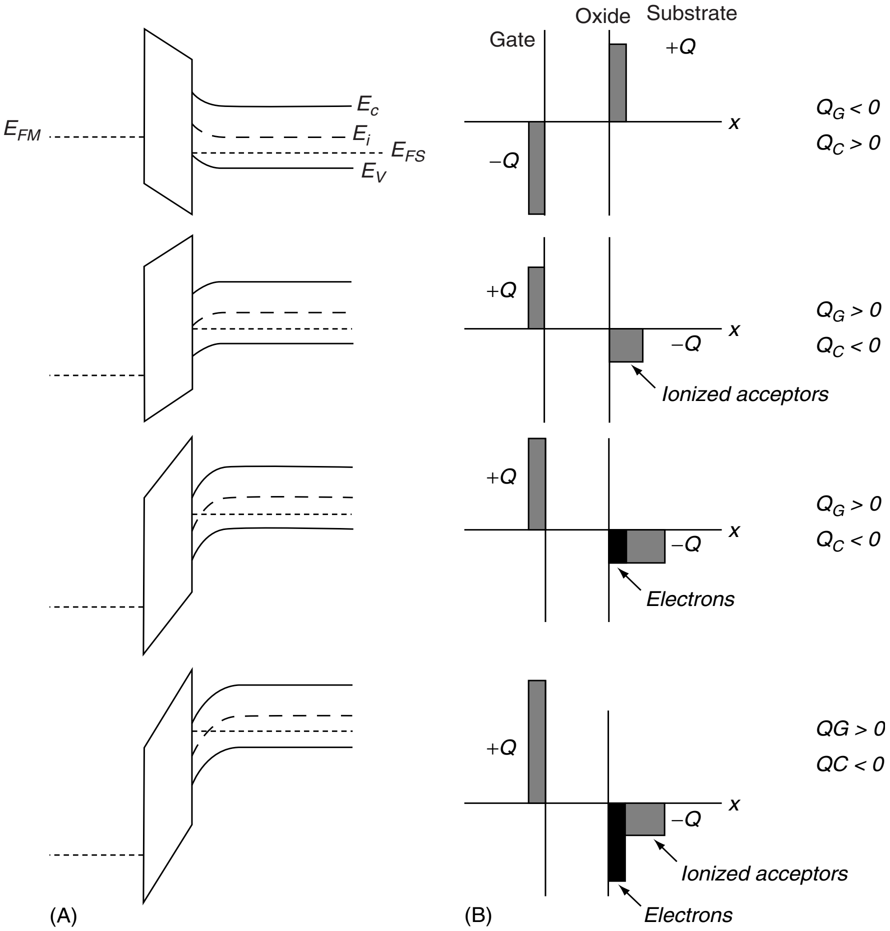

FIGURE 3.3

hole concentration in the neutral bulk. Thus, this condition is referred to as **weak inversion** and $\psi_s = \phi_F$ is defined as the onset of weak inversion and is shown in Figure 3.3(B).

As the gate bias is increased further, the band bending increases. The depletion region becomes wider, and the electron concentration in the inversion layer increases. When the electron concentration is equal to the hole concentration in the bulk, a **strong inversion** layer is said to form. The surface potential required to achieve strong inversion is equal to:[1]

$$\psi_s = 2\phi_F = \frac{2}{q}(E_i - E_F). \tag{3.6}$$

The inversion and depletion charge variation with ψ_s is shown in Figure 3.4. The electron concentration in the inversion layer is an exponential function of the surface potential and is given by:

$$n_{inv} \approx N_A e^{q(\psi_s - 2\phi_F)/kT} \tag{3.7}$$

On the other hand, the charge density in the depletion region is written as:

$$Q_D = -qN_A W_D, \tag{3.8}$$

where W_D is the depletion region width is given by:

$$W_D = \sqrt{\frac{2\varepsilon_s}{qN_A}}\sqrt{\psi_s}. \tag{3.9}$$

Therefore, the charge density in the depletion region is a weak function of the surface potential. Consequently, when the gate bias is further increased beyond the value required to reach strong inversion, the extra positive charge on the gate can be easily compensated by new electrons in the inversion layer. This eliminates the need to uncover additional acceptor atoms in the depletion region. After this point, the depletion region width and, hence, the band bending can increase only

[1] In some texts, $\psi_s = 2\phi_F$ is taken as the onset of moderate inversion. For strong inversion, the surface potential is required to be ~ 6 kT/q above this level.

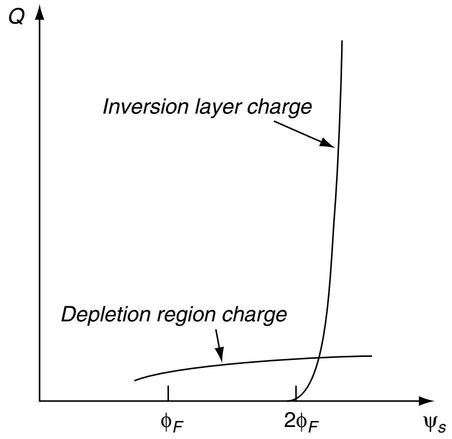

FIGURE 3.4

negligibly. The surface potential is pinned to its maximum value, which is a few kT/q over $2\phi_F$. For simplicity, $2\phi_F$ is generally taken as the maximum value for the surface potential, ψ_s.[2] The maximum depletion layer width, $W_{D,max}$, reached at the onset of strong inversion is given by:

$$W_{D,max} = \sqrt{\frac{2\varepsilon_s}{qN_A}}\sqrt{2\phi_F}. \tag{3.10}$$

3.2.2 Deviations from the Ideal Capacitor

In practical devices, the work function of the metal, ϕ_m, is not equal to that of the semiconductor, ϕ_s. Consider a MOS capacitor with $\phi_m < \phi_s$ at zero gate bias (gate connected to the substrate). Electrons in the metal reside at energy levels above the conduction band of the semiconductor. As a result, electrons flow from the metal into the semiconductor until a potential that counterbalances the difference in the work functions is built up between the two plates. This induces a negative charge under the gate dielectric accompanied by a downward band bending and, hence, a positive surface potential.

If an external voltage equal to this difference is applied to the gate, the net charge in the semiconductor disappears and the bands return to their flat position. This voltage is defined as the flatband voltage, V_{FB}, and can be expressed as:

$$V_{FB} = q\phi_{ms} = q(\phi_m - \phi_s). \tag{3.11}$$

Another modification to the above picture comes from charges that reside in the dielectric. These charges may originate from processing, from defects in the bulk, or from charges that exist at the interface between Si and SiO_2. The charges in the oxide or at the interface induce opposite charges in the semiconductor and the gate. This can cause the bands to bend up or down. Therefore, the flat-band voltage will have to be adjusted to take this into account. Assuming that all oxide fixed charges reside at the $Si{-}SiO_2$ interface, the flat-band voltage can be expressed as:

$$V_{FB} = \phi_{ms} - \frac{Q_o}{C_{ox}}, \tag{3.12}$$

where Q_o is the oxide charge and C_{ox} is the oxide capacitance.

In addition, defects located at the $Si{-}SiO_2$ interface may not be fixed in their charge state and may vary with the surface potential of the substrate. These defects are referred to as **fast interface traps** and have an impact on switching characteristics of MOSFETs as will be discussed later.

Based on the values of ψ_s, different regions of operation can be defined and are shown in Table 3.1.

3.2.3 Small-Signal Capacitance

If the gate voltage is changed by a small positive amount, a small positive charge will flow into the gate. To preserve charge neutrality, an equal amount of charge must flow out of the semiconductor. The relation of the small change in charge due to a small change in voltage is defined as the small-signal capacitance and can be written as:

$$C_{gb} \equiv \frac{dQ_G}{dV_{GB}}. \tag{3.13}$$

The equivalent circuit for the total gate capacitance is shown in Figure 3.5. The total gate capacitance consists of the oxide and semiconductor capacitances, where the semiconductor capacitance is the sum of the depletion, the inversion capacitance, and the interface states capacitance.

3.2.4 Threshold Voltage

The threshold voltage of an MOS capacitor is the gate voltage, V_{GB}, required to create strong inversion (i.e., $\psi_s = 2\phi_F$) under the gate. Figure 3.6 shows the inversion charge as a function of V_{GB}. The straight-line extrapolation of this charge to the *x*-axis

Inversion	$\psi_s > 0$	$V_{GB} >> V_{FB}$	$Q_c < 0$

[2] A more accurate definition for the onset of strong inversion is the surface potential at which the inversion layer charge is equal to the depletion region charge, which is ~ 6 kT/q above the onset of moderate inversion.

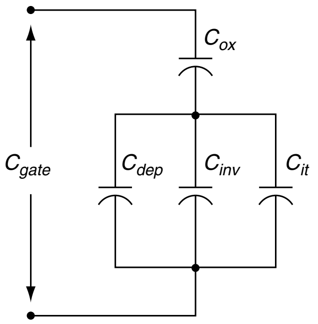

FIGURE 3.5

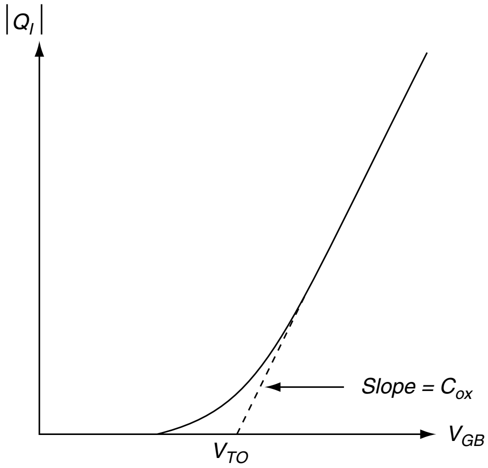

FIGURE 3.6

is called the extrapolated threshold voltage, V_{TO}. When the semiconductor (body) is at ground potential ($V_B = 0$), V_{TO} is given by:

$$V_{TO} = V_{FB} + 2\phi_F + \gamma\sqrt{2\phi_F}, \tag{3.14}$$

where γ is referred to as the body-effect coefficient and can be expressed as:

$$\gamma = \frac{\sqrt{2q\varepsilon_S N_A}}{C_{OX}}. \tag{3.15}$$

With a body bias, the threshold voltage is given by:

$$V_T = V_{FB} + 2\phi_F + \gamma\sqrt{2\phi_F + V_B}. \tag{3.16}$$

As shown in the above equation, the threshold voltage increases when a back bias is applied. A positive bias on the substrate results in a wider depletion region and assists in balancing the gate charge. This causes the electron concentration in the inversion layer to decrease. Thus, a higher gate voltage is needed to achieve the onset of inversion resulting in an increase of the threshold voltage. In addition, the doping concentration and oxide thickness can also have an impact on the threshold voltage dependence on back bias. Lower doping concentrations and thinner oxides result in a weaker dependence of back bias on threshold voltage.

3.3 Metal-Oxide-Silicon Field Effect Transistor

The MOSFET is the building block of the current ultra large-scale integrated circuits (ICs). The growth and complexity of MOS ICs have been continually increasing over the years to enable faster and denser circuits. Shown in Figure 3.7 is the simplified schematic of a MOSFET. The device consists of a MOS gate stack formed between two *pn* junctions called the **source** and **drain** junctions. The region under the gate is often referred to as the channel region. The length and the width of this region are called the **channel length** and **channel width**, respectively. An inversion layer under the gate creates a conductive path (i.e., channel) from source to drain and turns the transistor on. When the channel forms right under the gate dielectric, the MOSFET is referred to as a **surface channel MOSFET**. Buried channel MOSFETs in which the channel forms slightly beneath the surface are also used, but they are becoming less popular with the continuous downscaling of MOSFETs. A fourth contact to the substrate is also formed and referred to as the **body contact**.

The standard gate dielectric used in Si-integrated circuit industry is SiO_2. The gate electrode is heavily doped *n*-type or *p*-type polysilicon. The source and drain regions are formed by ion-implantation.

We shall first consider MOSFETs with uniform doping in the channel region. Later in the chapter, however, we shall learn how nonuniform doping profiles are used to enhance the performance of MOSFETs.

The MOSFET shown in Figure 3.7 is an *n*-channel MOSFET, in which electrons flow from source to drain in the channel

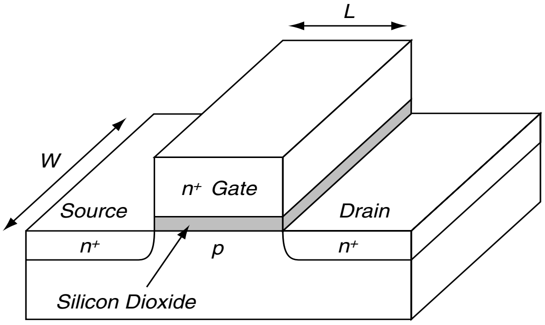

FIGURE 3.7

induced under the gate oxide. Both *n*-channel and *p*-channel MOSFETs are extensively used. In fact, CMOS IC technology relies on the ability to use both devices on the same chip. Table 3.2 shows the dopant types used in each region of the two structures.

3.3.1 Device Operation

Figure 3.8 shows an *n*-channel MOSFET with voltages applied to its four terminals. Typically, $V_S = V_B$ and $V_D > V_S$. Shown in Figure 3.9 is the typical $I_{DS} - V_{DS}$ characteristics of such a device. For simplicity, we assume that the body and the source terminals are tied to the ground (i.e. $V_{SB} = 0$. This yields.

$$\begin{aligned} V_{GS} &= V_{GB} - V_{SB} = V_{GB} = V_G. \\ V_{DS} &= V_{DB} - V_{SB} = V_{DB} = V_D. \end{aligned} \tag{3.17}$$

As shown, at low V_{DS}, the drain current increases almost linearly with V_{DS}, resulting in a series of straight lines with slopes increasing with V_{GS}. At high V_{DS}, the drain current saturates and becomes independent of V_{DS}.

In this section, we present a description of the device operation complete with important equations valid in different regions of operation. We shall refer to Figure 3.10, which shows the inversion layer and the depletion regions that form under the inversion layer and around the source and drain junctions. Now we can begin to discuss MOSFET regions of operation in detail.

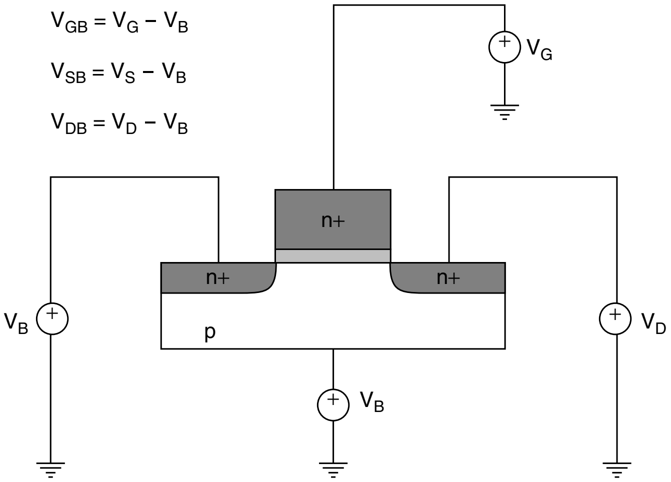

FIGURE 3.8

Linear Region

With a small positive voltage on the drain and no bias on the gate (i.e., $V_{DS} > 0$ and $V_{GS} = 0$), the drain is a reverse-biased *pn* junction. Conduction band electrons in the source region encounter a potential barrier determined by the built-in potential of the source junction. As a result, electrons cannot enter the channel region and, hence, no current flows from the source to the drain. This is referred to as the *off* state. With a small positive bias on the gate, band bending in the channel region ($\psi_s > 0$) brings the conduction band in the channel region closer to the conduction band in the source region, thus reducing the height of the potential barrier to electrons. Electrons can now enter the channel and a current flow from source to drain is established.

In the low-drain-bias regime, the drain current increases almost linearly with drain bias. Indeed, here the channel resembles an ideal resistor obeying Ohm's law. The channel resistance is determined by the electron concentration in the channel, which is a function of the gate bias. Therefore, the channel acts like a voltage-controlled resistor whose resistance is determined by the applied gate bias. As shown in Figure 3.9, as the gate bias is increased, the slope of the *I–V* characteristic gradually increases due to the increasing conductivity of the channel. We obtain different slopes for different gate biases. This region where the channel behaves like a resistor is referred to as the **linear region** of operation. The drain current in the linear regime is given by:

$$I_{D,\,lin} = \frac{W}{L}\mu C'_{ox}\left[(V_{GS} - V_T)V_{DS} - \frac{\alpha}{2}V_{DS}^2\right], \tag{3.18}$$

where V_T is the threshold voltage, C'_{ox} is the gate capacitance per unit area, α is a constant, and μ is the effective channel mobility (which differs from bulk mobility). We shall deal with the concept of effective channel mobility later in this chapter.

Threshold voltage in the above equation is defined as:

$$V_T = V_{FB} + 2\phi_F + \gamma\sqrt{2\phi_F + V_{SB}}. \tag{3.19}$$

For small V_{DS}, the second term in the parenthesis can be ignored, and the expression for drain current reduces to:

$$I_{D,\,lin} = \frac{W}{L}\mu C'_{ox}(V_{GS} - V_T)V_{DS}, \tag{3.20}$$

which is a straight line with a slope equal to the channel conductance:

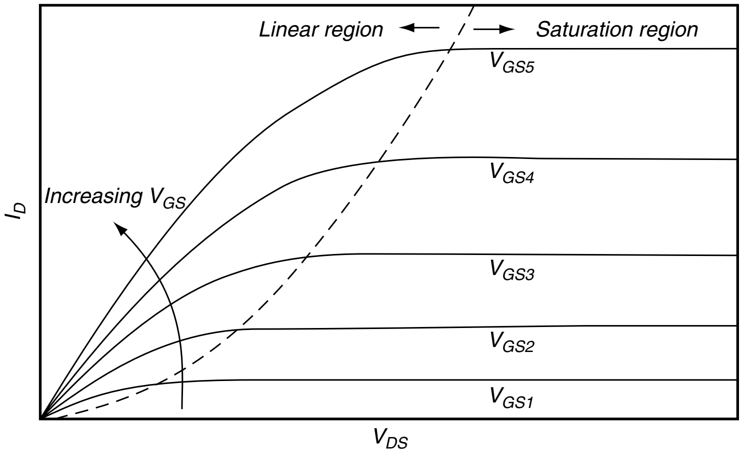

FIGURE 3.9

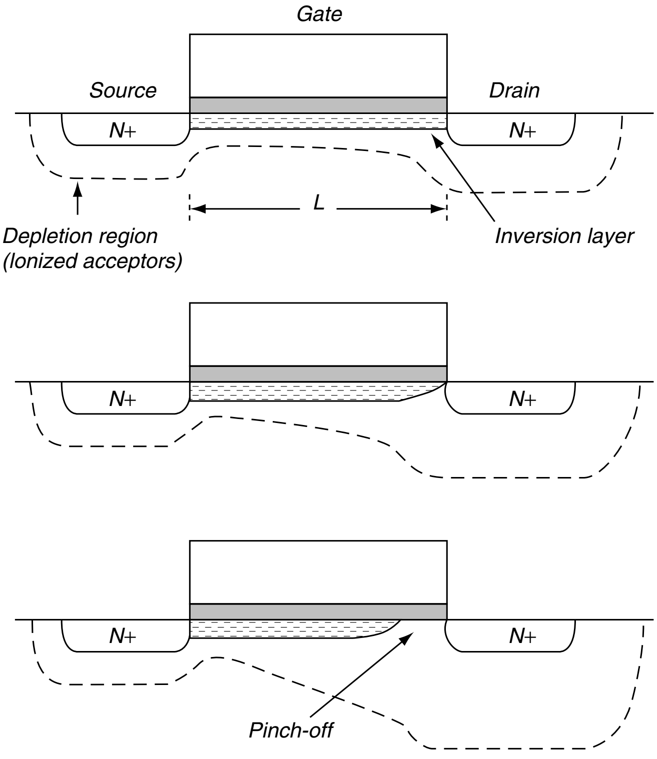

FIGURE 3.10

$$\sigma_c = \frac{W}{L}\mu C'_{ox}(V_{GS} - V_T). \quad (3.21)$$

Saturation Region

For larger drain biases, the drain current saturates and becomes independent of the drain bias. Naturally, this region is referred to as the **saturation region**. The drain current in saturation is derived from the linear region current shown in equation 3.18, which is a parabola with a maximum occurring at $V_{D,sat}$ given by:[3]

$$V_{D,sat} = \frac{V_{GS} - V_T}{\alpha}. \quad (3.22)$$

To obtain the drain current in saturation, this $V_{D,sat}$ value can be substituted in the linear region expression, which gives:

$$I_{D,\ sat} = \frac{W}{L}\mu C'_{ox}\frac{(V_{GS} - V_T)^2}{2\alpha}. \quad (3.23)$$

As V_{DS} increases, the number of electrons in the inversion layer decreases near the drain. This occurs due to two reasons. First, because both the gate and the drain are positively biased, the potential difference across the oxide is smaller near the drain end. Because the positive charge on the gate is determined by the potential drop across the gate oxide, the gate charge is smaller near the drain end. This implies that the amount of negative charge in the semiconductor needed to preserve charge neutrality will also be smaller near the drain. Consequently, the electron concentration in the inversion layer drops. Second, increasing the voltage on the drain increases the depletion width around the reverse-biased drain junction. Since more negative acceptor ions are uncovered, a fewer number of inversion layer electrons are needed to balance the gate charge. This implies that the electron density in the inversion layer near the drain would decrease even if the charge density on the gate was constant. The reduced number of carriers causes a reduction in the channel conductance, which is reflected in the smaller slope of $I_{DS} - V_{DS}$ characteristics as V_{DS} approaches $V_{D,sat}$, and the MOSFET enters the saturation region. Eventually, the inversion layer completely

[3] The V_{DS} at which the linear drain current parabola reaches its maximum can be found by setting $\partial I_{DS}/\partial V_{DS}$ equal to zero.

disappears near the drain. This condition is called **pinch-off**, and the channel conductance becomes zero. As shown in Figure 3.9, $V_{D,sat}$ increases with gate bias. This results because a larger gate bias requires a larger drain bias to reduce the voltage drop across the oxide near the drain end. As given in equation 3.22, $V_{D,sat}$ increases linearly with V_{GS}.

As V_{DS} is increased beyond $V_{D,sat}$, the width of the pinch-off region increases. However, the voltage that drops across the inversion layer remains constant and equal to $V_{D,sat}$. The portion of the drain bias in excess of $V_{D,sat}$ appears across the pinch-off region. In a long channel MOSFET, the width of the pinch-off region is assumed small relative to the length of the channel. Thus, neither the length nor the voltage across the inversion layer change beyond the pinch-off, resulting in a drain current independent of drain bias. Consequently, the drain current saturates. In smaller devices, this assumption falls apart and leads to **channel length modulation**, which is discussed later in the chapter.

From the above discussion, it is also evident that the electron distribution is highest near the source and lowest near the drain. To keep a constant current throughout the channel, the electrons travel slower near the source and speed up near the drain. In fact, in the pinch-off region, the electron density is negligibly small. Therefore, in this region, to maintain the same current level, the electrons have to travel at much higher speeds to transport the same magnitude of charge.

An important figure of merit for MOSFETs is transconductance, g_m, in the saturation regime, which is defined as:

$$g_m = \frac{\partial I_{D,sat}}{\partial V_{GS}} = \frac{W}{L}\frac{\mu C'_{ox}}{\alpha}(V_{GS} - V_T). \tag{3.24}$$

Transconductance is a measure of the responsiveness of the drain current to variations in gate bias.

Subthreshold Region: MOSFET in Weak Inversion

When the surface potential at the source end is sufficient to form an inversion layer but the band bending is less than what is needed to reach strong inversion (i.e., $\phi_F < \Psi_s < 2\phi_F$), the MOSFET is said to operate in weak inversion. This region of operation is commonly called the **subthreshold region** and plays an important role in determining switching characteristics of logic circuits. When an *n*-channel MOSFET is in weak inversion, the drain current is determined by diffusion of electrons from the source to the drain. This is because the drift current is negligibly small due to the low lateral electric field and small electron concentration in weak inversion.

Even though the electron concentration in weak inversion is small, it increases exponentially with gate bias. Consequently, the drain current in weak inversion also rises exponentially, and it can be expressed as:

$$I_{DS} = \frac{W}{L} I' e^{q(V_{GS}-V_T)/nkT}\left(1 - e^{-q^{V_{DS}/kT}}\right), \tag{3.25}$$

where I' and n are constants defined as:

$$I' = \mu \frac{\sqrt{2q\varepsilon_S N_A}}{2\sqrt{2\phi_F + V_{SB}}}\phi^2 \tag{3.26}$$

$$n = 1 + \frac{\gamma}{2\sqrt{2\phi_F + V_{SB}}}. \tag{3.27}$$

When the drain bias is larger than a few *kT/q*, the dependence on the drain bias can be neglected, and the above equation reduces to:

$$I_{DS} = \frac{W}{L} I' e^{q^{(V_{GS}-V_T)/nkT}}, \tag{3.28}$$

which yields an exponential dependence on gate bias. When $\log I_{DS}$ is plotted against gate bias, we obtain:

$$\log I_{DS} = \log\left(\frac{W}{L} I'\right) + \frac{q}{kT}\frac{V_{GS} - V_T}{n}, \tag{3.29}$$

which is a straight line with a slope:

$$\frac{1}{S} = \frac{1}{n}\frac{q}{kT}. \tag{3.30}$$

The parameter S in the above equation is the MOSFET **subthreshold swing**, which is one of the most critical performance figures of MOSFETs in logic applications. It is highly desirable to have a subthreshold swing as small as possible since this is the parameter that determines the amount of voltage swing necessary to switch a MOSFET from its *off* state to its *on* state. This is especially important for modern MOSFETs with supply voltages approaching 1.0 V.

Figure 3.11 shows typical subthreshold characteristics of a MOSFET. As predicted by the above model, $\log I_{DS}$ increases linearly with gate bias up to V_T. In strong inversion, the subthreshold model is no longer valid, and either equation 20 or 23 must be used depending on the drain bias. When $V_{GS} = V_T$, $\log I_{DS}$ deviates from linearity. In practice, this is a commonly used method to measure the threshold voltage. In terms of device parameters, subthreshold swing can be expressed as:

$$S \cong \frac{kT}{q}\left(1 + \frac{C'_{dep} + C'_{it}}{C'_{ox}}\right)\ln(10), \tag{3.31}$$

where C'_{dep} is depletion region capacitance per unit area of the MOS gate determined by the doping density in the channel region, and C'_{it} is the interface trap capacitance. Lower

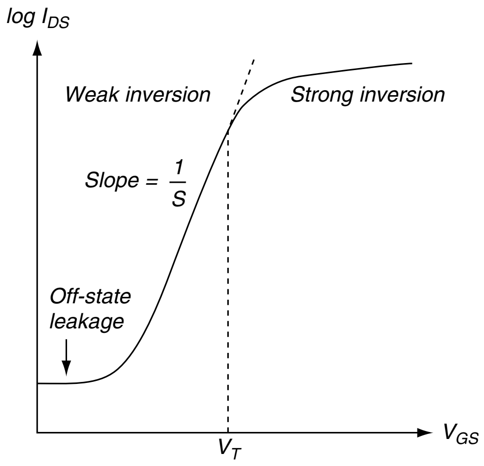

FIGURE 3.11

channel doping densities yield wider depletion region widths and hence smaller values for C'_{dep}. Another critical parameter is the gate oxide thickness, which determines C'_{ox}. To minimize S, the thinnest possible oxide must be used. The most widely used unit for S is mV/decade. Typical values range from 60 to 100 mV/decade.

The lower limit of the subthreshold current is determined by the leakage current that flows from source to drain when the transistor is off. This current, which is referred to as the **off-state leakage**, is determined by the source-to-channel potential barrier as well as the leakage currents of the source and drain junctions. For this reason, it is critical to be able to form low leakage junctions.

3.3.2 Effective Channel Mobility

The mobility term used in the previous equations differs from the bulk mobility due to additional scattering mechanisms associated with the surface, including interface charge scattering, coulombic scattering, and surface roughness scattering. These mechanisms tend to lower the carrier mobility in the channel. These mechanisms also tend to exhibit a dependence on the vertical electric field, E_y. At low fields, interface and coulombic scattering are the dominant mechanisms. At high fields, the surface roughness scattering dominates. Since the vertical field varies along the channel, mobility also varies. The dependence on the vertical field is generally expressed as:

$$\mu = \frac{\mu_o}{1 + \alpha E_y}, \tag{3.32}$$

where μ_o is roughly half of the bulk mobility and α is roughly 0.025 μm/V at room temperature. This mobility equation is not useful in device equations because E_y varies along the channel. To be able to use the standard equations, the field dependence is lumped into a constant termed the **effective channel mobility**, $\boldsymbol{\mu_{eff}}$. A simple yet intuitive model for μ_{eff} *is* as follows:

$$\mu_{eff} \approx \frac{\mu_o}{1 + \theta(V_{GS} - V_T)}, \tag{3.33}$$

where θ is a constant inversely proportional to the gate oxide thickness, t_{ox}. A typical plot of effective mobility as a function of gate bias is shown in Figure 3.12 (A). The effect of mobility degradation on $I_{DS} - V_{GS}$ characteristics is shown in Figure 3.12(B).

3.3.3 Nonuniform Channels

Typical channels in today's MOSFETs are nonuniform, which consist of a higher doped region placed underneath the Si–SiO$_2$ interface. This is done primarily to optimize the threshold voltage value while keeping the substrate concentration low. The new threshold voltage can be expressed as:

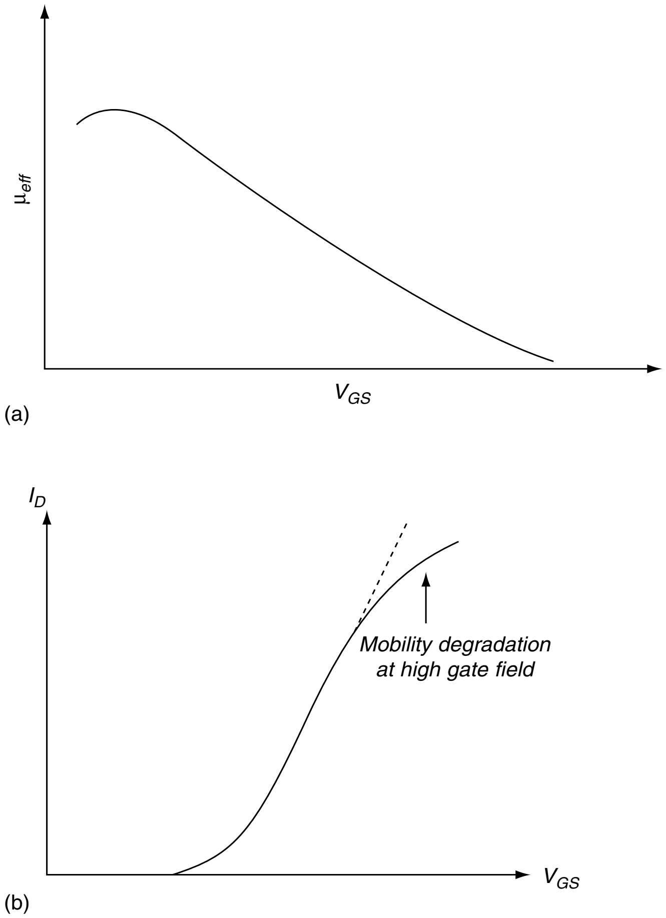

FIGURE 3.12

$$V_T = V'_{FB} + 2\phi_F + \gamma\sqrt{2\phi_F + V_B}, \tag{3.34}$$

where, V'_{FB} is given by:

$$V'_{FB} = V_{FB} + \frac{qM}{C_{ox}}. \tag{3.35}$$

The variable M is the implant dose. This equation assumes that the threshold adjust implant is very shallow and behaves as a sheet of fixed charge located under the gate oxide. In some cases, additional doped layers are placed in the channel to suppress punchthrough, a term that will be discussed later.

3.3.4 Short Channel Effects

MOSFETs are continually downscaled for higher packing density, higher device speed, and lower power consumption. The scaling methods are covered later in this chapter in a dedicated subsection. When physical dimensions of MOSFETs are reduced, the equations for drain current have to be modified to account for the so-called **short channel effects**. The three primary short channel effects included in this chapter are the following:

1. *Velocity saturation*: Limits the maximum carrier velocity in the channel to the saturation velocity in Si
2. *Channel length modulation*: Causes the drain current to increase with drain bias in the saturation region
3. *Drain-induced barrier lowering (DIBL)*: Causes the threshold voltage to change from its long channel value with dependence on device geometry as well as drain bias

Velocity Saturation

As discussed earlier, in long channel MOSFETs, the drain current saturates for V_{DS} larger than $V_{D,sat}$. The potential drop across the inversion layer remains at $V_{D,sat}$, and the horizontal electric field, E_x, along the channel is fixed at:

$$E_x = \frac{V_{Dsat}}{L}. \tag{3.36}$$

The electron drift velocity as a function of applied field is shown in Figure 3.13. At low fields, the drift velocity is given by:

$$v_d = \mu E_x, \tag{3.37}$$

where μ is generally referred to as the low-field mobility. At high fields, the velocity saturates due to phonon scattering. In a short channel device, the electric field across the channel can become sufficiently high such that carriers can suffer from velocity saturation. The effect of velocity saturation on MOSFET drain current can be severe. In short channel MOSFETs, it is impossible to overcome this effect. Thus, it is safe to say that all devices used in modern logic circuits suffer from velocity saturation to some extent.

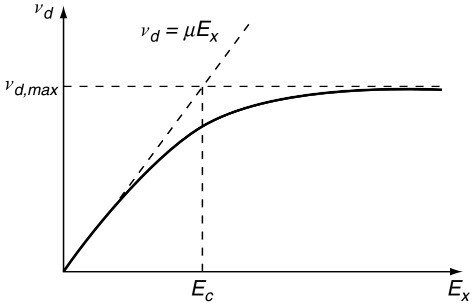

FIGURE 3.13

To account for this phenomenon, I_{DS} has to be obtained using velocity dependence on the electric field. A simple yet intuitive model for I_{DS} contains the original long channel drain current expression in the linear regime (equation 18) divided by a factor that accounts for velocity saturation. This formula is written as:

$$I_{DS}(\text{with velocity saturation}) = \frac{I_{DS}(\text{without velocity saturation})}{1 + V_{DS}/LE_c} \tag{3.38}$$

where E_c is the critical field above which velocity saturation occurs (Figure 3.13) and is given by:

$$E_c = \frac{v_{sat}}{\mu}. \tag{3.39}$$

The $V_{D,sat}$ value obtained using the modified current is smaller than the long channel $V_{D,sat}$ value. The drain current in saturation can be obtained from the linear region expression by assuming the drain current saturates for $V_{DS} > V_{D,sat}$:

$$I_{D,sat} \approx W\mu C_{ox}(V_{GS} - V_T)E_C. \tag{3.40}$$

It is important to note that with velocity saturation, the dependence of drain current on V_{GS} is linear instead of square, as it is the case for the long channel MOSFET.

Channel Length Modulation

After pinch-off occurs at the drain end, the length of the inversion layer and, hence, the channel resistance continually decrease as the drain bias is raised above $V_{D,sat}$. In long channel devices, the length of the pinch-off region is negligibly small. Since the voltage drop across the channel is pinned at $V_{D,sat}$, drain current increases only negligibly. However, in short channel devices, this pinch-off region can become a significant fraction of the total channel length. This reduction of channel length manifests itself as a finite slope in the

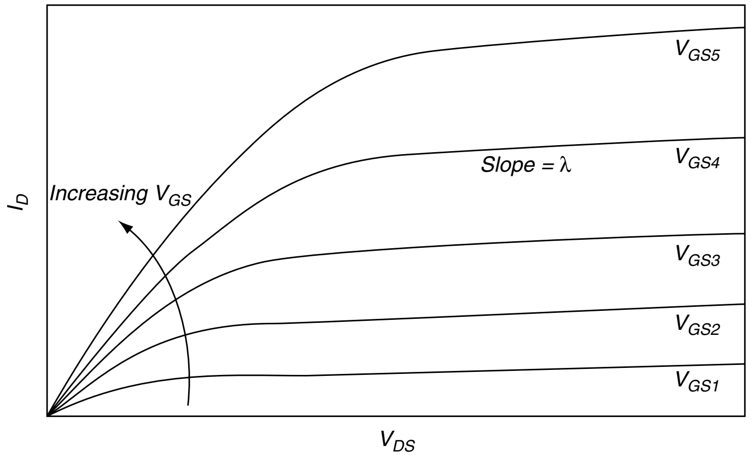

FIGURE 3.14

$I_{DS} - V_{DS}$ characteristics beyond $V_{D,sat}$ as shown in Figure 3.14. A commonly used expression for MOSFET drain current in saturation with channel length modulation is the following:

$$I_{D,sat} = \frac{W}{L}\mu C'_{ox}\frac{(V_{GS} - V_T)^2}{2\alpha}(1 + \lambda V_{DS}), \qquad (3.41)$$

where λ is known as the channel length modulation factor expressed as:

$$\lambda = \frac{1}{E_o L}, \qquad (3.42)$$

and E_o is the magnitude of the electric field at the pinch-off point. If both velocity saturation and channel length modulation are taken into account, the saturation drain current can be written as:

$$I_{D,sat} \approx W\mu C_{ox}(V_{GS} - V_T)E_C(1 + \lambda V_{DS}) \qquad (3.43)$$

Drain-Induced Barrier Lowering

Another major short channel effect deals with the reduction of the threshold voltage as the channel length is reduced. In long channel devices, the influence of source and drain on the channel depletion layer is negligible. However, as channel lengths are reduced, overlapping source and drain depletion regions start having a large effect on the channel depletion region. This causes the depletion region under the inversion layer to increase. The wider depletion region is accompanied by a larger surface potential, which makes the channel more attractive to electrons. Therefore, a smaller amount of charge on the gate is needed to reach the onset of strong inversion, and the threshold voltage decreases. This effect is worsened when there is a larger bias on the drain since the depletion region becomes even wider. This phenomenon is called drain-induced barrier lowering (DIBL). Figure 3.15 shows the variation of surface potential from source to drain for a short channel and a long channel MOSFET. As shown, for the long channel device, the potential is nearly constant throughout the channel and is determined only by the gate bias.[4] The height of the potential barrier for electrons at the source end is given by:

$$\phi_{BL} \approx 2\phi_F. \qquad (3.44)$$

For the smaller device, the surface potential is larger due to additional band bending. In addition, the surface potential is

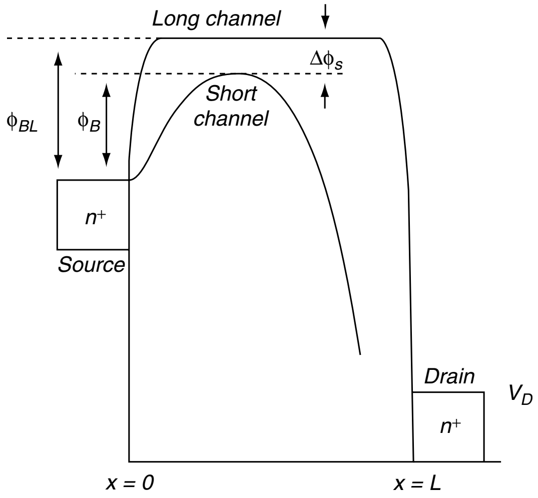

FIGURE 3.15

[4] The channel potential actually increases gradually toward the drain due to small yet finite resistance of the inversion layer. When pinch-off occurs at the drain end, majority of the drain-to-source bias appears across the pinch-off region due to its much larger resistivity.

no longer constant throughout the channel. With a larger surface potential, the barrier for electrons between the source and the channel is reduced and is given by:

$$\phi_B = \phi_{BL} - \Delta\phi_B. \tag{3.45}$$

The change in threshold voltage due to DIBL has been modeled Liu *et al.* (1993) as:

$$\Delta V_T \approx -[3(\phi_{bi} - 2\phi_F) + V_{DS}]e^{-L/\lambda_{\mathrm{DIBL}}}, \tag{3.46}$$

where ϕ_{bi} is the built-in potential of the drain junction and:

$$\lambda_{\mathrm{DIBL}} = \sqrt{\frac{\varepsilon Si^{t}_{ox} W_D}{\varepsilon_{ox}\beta}}. \tag{3.47}$$

In the above equation, W_D is the depletion region width under the inversion layer, and β is a fitting parameter. The model indicates that ΔV_T is a strong function of the λ_{DIBL} term in the exponential and must be minimized. This requires higher doping density in the channel to reduce W_D and downscaling of the gate oxide thickness, t_{ox}. The model does not include the well-known dependence of ΔV_T on source/drain junction depths although some modifications have been suggested.

The impact of DIBL on V_T can be measured by plotting the subthreshold characteristics for increasing values of V_{DS} as shown in Figure 3.16. The subthreshold slope degrades and the impact of drain bias on ΔV_T increases as the channel length is reduced. This methodology is valid only until the subthreshold slope remains intact. A very large subthreshold swing implies that the device cannot be turned off. This phenomenon is called **punchthrough** and occurs roughly when the source and drain depletion regions meet. Since the depletion region becomes wider at larger drain biases, the onset of punchthrough is reached sooner. Punchthrough can occur either at or below the surface depending on the doping profile in the channel region. Surface punchthrough occurs for uniformly doped substrates and results in the loss of gate control of the channel region, causing the device to fail. Bulk punchthrough occurs for ion-implanted channels that have a higher doping concentration at the surface. In this condition, there still exists a channel that is gate controlled, but the background leakage becomes very high and is strongly dependent on V_{DS}. The common solution is to add a shallow punchthrough implant typically placed immediately below the threshold adjust implant. This raises the doping density under the channel while keeping the bulk doping density as low as possible. The goal is to minimize junction depletion region capacitance, which has an impact on device switching speed.

Similarly, for a fixed drain bias, a larger body bias increases the reverse bias on the drain junction and, thus, has the same effect as increasing the drain bias. Lowering of the threshold voltage due to DIBL is demonstrated in Figure 3.17. Note that the effect of body bias on threshold voltage for large channel MOSFETs is determined by equation 3.15. Here we are interested in lowering of the threshold voltage due to body bias only for short channel lengths.

In addition to the short channel effects described above, the scaling of the channel width can also have a large effect on the threshold voltage, and its nature depends on the isolation technology (Tsividis, 1999). In the case of LOCOS isolation, the threshold voltage increases as the channel width decreases. On the other hand, for shallow trench isolation, the threshold voltage decreases as the channel width decreases. In today's technologies, shallow trench isolation is the predominant isolation technique.

3.3.5 MOSFET Scaling

Scaling of MOSFETs is necessary to achieve (a) low power, (b) high speed, and (c) high packing density. Several scaling methodologies have been proposed and used, which are

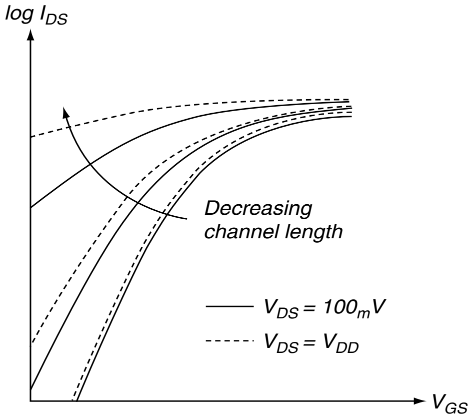

FIGURE 3.16

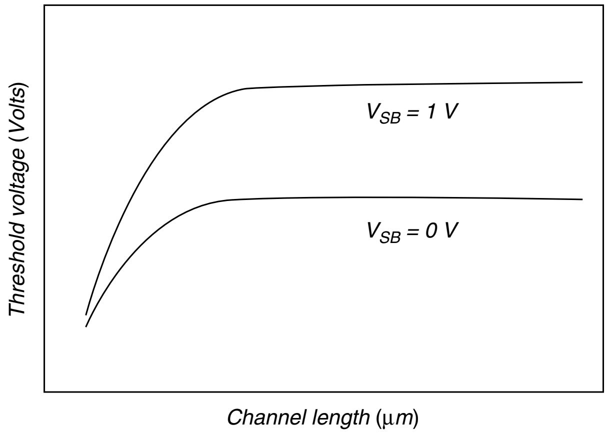

FIGURE 3.17

derivatives of constant field scaling. In constant-field scaling, the supply voltage and the device dimensions (both lateral and vertical) are scaled by the same factor, κ such that the electric field remains unchanged. This results in scaling of the drain current or current drive. At the same time, gate capacitance is also scaled due to reduced device size. This provides a reduction in the gate charging time, which directly translates into higher speed. Furthermore, power dissipation per transistor is also reduced.

Constant field scaling provides a good framework for CMOS scaling without degrading reliability. However, there are several parameters, such as the kT/q and an energy gap, that do not scale with reduced voltages or dimensions and present challenges in device design. Since the junction built-in potential, ϕ_{bi}, and the surface potential, ψ_s, are both determined by the bandgap, they do not scale either. Consequently, depletion region widths do not scale as much as other parameters, which results in worsened short channel effects.

Another parameter that does not scale easily is the threshold voltage. This sets the lower limit for the power-supply voltage since a safe margin between the two parameters is required for reliable device operation. Other parameters that do not scale well include the off-state current and subthreshold slope.

Although **constant field scaling** provides a reasonable guideline, scaling of the voltages by the same factor as the physical dimensions is not always practical. This is due to the inability to scale the subthreshold slope properly as well as standardize voltage levels of prior generations. This is the basis for **constant voltage scaling** and other modified scaling methodologies. One problem with constant voltage scaling is that the oxide field increases since the t_{ox} is also scaled by κ. To reduce this problem, the oxide thickness is reduced by κ' where $\kappa' < \kappa$. Modifications of the constant voltage and constant field scaling have also been tried to avoid high-field problems. For example, in **quasi-constant voltage scaling**, physical dimensions are scaled by κ, whereas the voltages are scaled by a different factor, κ'. Furthermore, since depletion layers do not scale proportionately, the doping concentration, N_A, must be increased by more than what is suggested by constant-field scaling. This is called **generalized scaling** and the doping scaling factor is greater than κ. The scaling rules discussed above are shown in Table 3.3.

It should be noted that there are other effects that can limit the performance of scaled devices. These include (a) reduction of the effective oxide capacitance due to finite thickness of the inversion layer, (b) depletion in the polysilicon gate, (c) quantum effects in the inversion layer that increase V_T, and (d) quantum mechanical tunneling of carriers through the thin oxide, which is a critical issue for $t_{ox} < 50$ A.

3.3.6 Modern MOSFETs

Today's MOSFET has evolved through many modifications to provide solutions for parasitic problems that emerge during scaling. A modern n-channel MOSFET structure is shown in Figure 3.18. The gate dielectric is SiO_2 and is grown by thermal oxidation. As a result of continued scaling, the gate oxide has thinned down to the extent that direct tunneling has become a serious concern. Currently, alternate high-κ dielectrics are being considered as replacements for SiO_2. The goal is to achieve higher capacitance without compromising gate leakage. The standard gate electrode is heavily doped polysilicon defined by anisotropic reactive ion etching. Extension junctions are formed by ion-implantation using the polysilicon gate as an implant mask. Because a separate masking step is not needed to define the junction regions, the approach is named **self-aligned polysilicon gate technology**. At the same time, the junction sheet resistance must be sufficiently low not to increase the device series resistance. Extension junctions must be as shallow as possible to reduce DIBL. When formed by ion-implantation, shallow junctions require low doses and low energies. Unfortunately, low dose results in higher series resistance. Sidewall spacers are formed by deposition of a dielectric (SiO_2 or Si_3N_4) followed by anisotropic reactive ion etching. The spacers must be as thin as possible to minimize the series resistance contribution of the extension junctions. Deep source and drain junctions are formed by ion-implantation following spacer formation. Because they are separated from the channel by the spacers, their contribution to DIBL is negligible. These junctions must be sufficiently deep to allow formation of good quality silicide contacts. Both Ti and Co silicides are used as source/drain contact materials. Silicides are formed by an approach referred to as **self-aligned-silicide** (SALICIDE), which selectively forms the silicide on the junctions as well as polysilicon. Silicide formation consumes the Si substrate in the deep source/drain regions and can lead to excessive junction leakage. To avoid this, the deep source/drain regions are required to be about 50 nm deeper than the

amount consumed. An important advantage of the SALICIDE process is that the entire junction area up to the sidewall spacer is used for contact formation, which translates into low contact resistance. The channel doping profile typically consists of the threshold adjust and punchthrough stop implants. The gate electrode is very heavily doped to avoid polysilicon depletion.

The MOSFET continues to maintain its dominance in today's digital ICs. To ensure continued benefits from MOSFET scaling, several structural and material changes are required. These include new gate dielectric materials to reach equivalent SiO_2 thicknesses less than 1 nm, new doping technologies that provide ultra-low resistance and ultra-shallow junctions, as well as metal gate electrodes that do not suffer from depletion effects.

3.4 Junction Field Effect Transistor

The junction field effect transistor (JFET) was first proposed by William Shockley in 1952. The first demonstration was made the following year by Dacey and Ross. Due to the large popularity of the bipolar junction transistor (BJT) at the time, major advancements in JFET fabrication did not occur until the 1970s. With the introduction of MOSFET, the use of JFET remained limited to specific applications.

Figure 3.19 shows a simplified schematic of the JFET. The device consists of an *n*-type channel region sandwiched between two p^+n junctions that serve as the gate. The p^+ regions can be tied together to form a dual-gate JFET. The heavily doped $n+$ source and drain regions serve as low resistivity ohmic contacts to the *n*-type channel. As such, a conductive path exists between the source and the drain contacts. The device is turned off by depleting the channel off the free carriers.

The $I_{DS} - V_{DS}$ characteristics of a JFET are very similar to those of a MOSFET. Figure 3.20 illustrates the operation of a JFET in different regions. The depletion region widths of the two p^+n junctions are determined by the gate bias and the potential variation along the channel. The widths of the depletion regions at the source end are determined mainly by the built-in potential of the junction. The depletion regions are wider at the drain end due to the large positive bias applied to the drain terminal. Figure 3.20(A) corresponds to the linear region of the JFET. Even though the channel depth is reduced at the drain end, the *n*-type channel extends from the source to the drain. The channel resembles a resistor, and the current is a linear function of the drain bias. The depth and, hence, the resistance of the channel is modulated by the gate bias. The drain current in the linear region can be expressed as:

$$I_{D,\,lin} = \frac{G_o}{2V_P}(V_G - V_T)V_D, \qquad (3.48)$$

where V_P is the pinch-off voltage corresponding to the potential drop across the gate junction when the two depletion

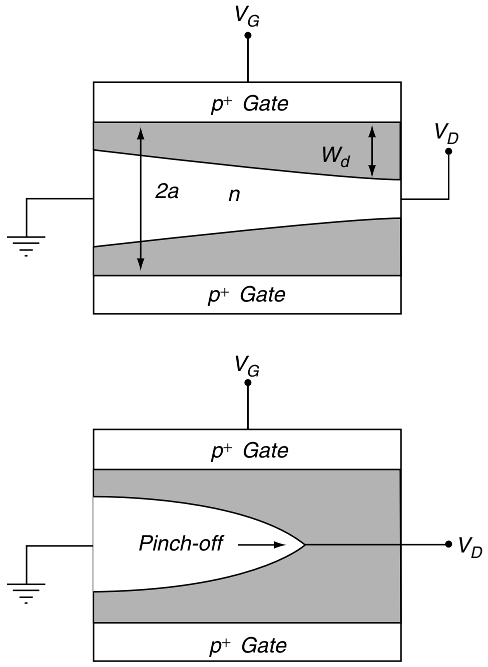

FIGURE 3.20

regions meet at the drain end. The variable G_o is the full channel conductance with a channel depth equal to $2a$. These can be expressed as:

$$G_o = 2aq\mu_n N_D \frac{W}{L} \tag{3.49}$$

and

$$V_P = \frac{qN_D a^2}{2\varepsilon_s}. \tag{3.50}$$

When the two depletion regions meet at the drain end, the JFET enters the saturation region. As shown in Figure 3.20(B), the pinch-off point moves toward the source as the drain bias is raised. The potential at the pinch-off point, however, remains pinned at:

$$V_{D,sat} = V_P - \psi_{bi} + V_G = V_G - V_T. \tag{3.51}$$

The built-in potential ψ_{bi} is a function of the doping concentrations in both sides of the junction. For large devices, the reduction in channel length due to pinch-off can be negligibly small. Hence the channel conductance remains approximately the same with a fixed voltage equal to $V_{D,sat}$ across the conductive channel. The drain current no longer increases with drain bias, and JFET is said to operate in the saturation region. The drain current after pinch-off can be expressed as:

$$I_{D,sat} = \frac{G_o}{4V_P}\left(1 + \frac{V_G}{V_P}\right)^2. \tag{3.52}$$

In JFETs with short channel lengths, the electric field along the channel can be large enough to cause carrier velocity saturation even before pinch-off. This requires a drain bias of:

$$V_D = E_c L, \tag{3.53}$$

where E_c is the critical field for velocity saturation.

3.5 Metal-Semiconductor Field Effect Transistor

A MESFET is very similar to a metal-semiconductor field effect transistor (MOSFET). The main difference is that in a MESFET, the MOS gate is replaced by a metal-semiconductor (Schottky) junction. A self-aligned GaAs MESFET structure is shown in Figure 3.21. The heavily doped source and drain junctions are formed in an n-type epitaxial layer formed on semi-insulating GaAs, which provides low parasitic capacitance. The n-type channel region has a thickness, a, which is typically less than 200 nm. The source and drain junctions are formed by ion-implantation followed by annealing. Common source and drain contact materials are AuGe alloys. Popular Schottky gate metals include Al, Ti-Pt-Au-layered structure, Pt, W, and WSi$_2$. However, in a self-aligned MESFET, since the source and drain implantation and implant annealing must be performed after gate formation, refractory metals that can withstand the annealing temperatures are preferred.

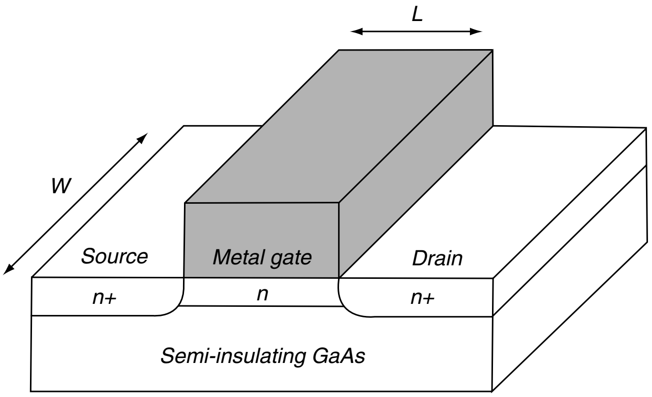

FIGURE 3.21

MESFET is better suited to materials that do not have a good dielectric to form a high-quality MOS gate. Today, MESFETs are commonly fabricated on compound semiconductors, predominantly GaAs. Because of high mobility of carriers in GaAs and low capacitance due to the semi-insulating GaAs, MESFETs have the speed advantage over MOSFETs. They are used in microwave applications, which require high-speed devices. Application areas include communication, high-speed computer, and military systems.

Although the MESFET structure resembles the MOSFET, its operation is much closer to that of the JFET. Figure 22 shows the MESFET cross-section in different regions of operation. The MESFET has a conductive path between the source and the drain since the channel is of the same conductivity type as the junctions. Therefore, to turn-off a MESFET, a sufficiently high gate bias must be applied to deplete the channel. The depletion region under the gate modulates the width and the resistance of the conductive channel from source to drain. As such, in a MESFET, the Schottky gate plays the exact same role that the pn junction gate plays in a JFET.

The width of the depletion region is wider at the drain end since the source is grounded and a finite bias is applied to the drain. At small drain biases, the channel is conductive from source to drain. However, the width of the channel is smaller at the drain end due to the wider depletion region. The depletion region width under the gate is given by:

$$W_d(x) = \sqrt{\frac{2\varepsilon_s[\psi_{bi} + \psi(x) - V_G]}{qN_D}}, \tag{3.54}$$

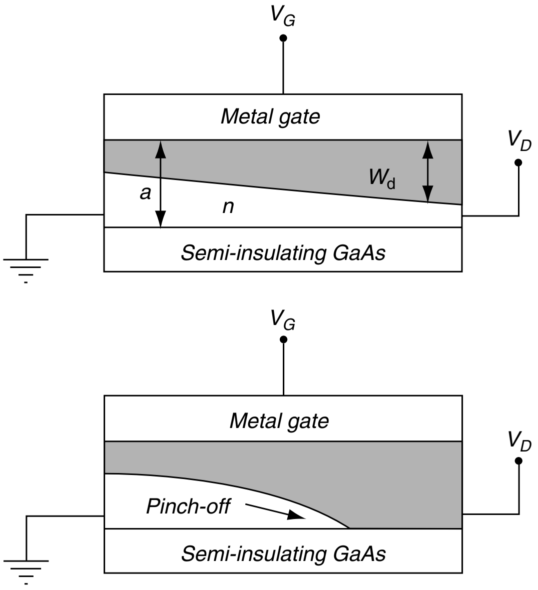

FIGURE 3.22

where ψ_{bi} is the band bending in the semiconductor due to the metal-semiconductor work function difference, and $\psi(x)$ is the channel potential with respect to the source. In this regime, the MESFET channel resembles a voltage, controlled resistor. The drain current varies linearly with the drain bias. The gate bias changes the width of the depletion region to modulate the width and the resistance of the channel. This is the linear region of operation for a MESFET.

For a long channel MESFET ($L \gg a$), the drain current in the linear region is approximately equal to:

$$I_{D,\,lin} \approx \frac{G_i}{2V_P}(V_G - V_T)V_D, \tag{3.55}$$

where

$$G_i = \frac{W}{L} q\mu_n N_D a \tag{3.56}$$

is the channel conductance without depletion under the Schottky gate. The variable V_P in equation 3.55 is called the pinch-off voltage, which is the net potential across the gate junction when the depletion region width under the gate is exactly equal to the channel depth, a. The pinch-off voltage is given by:[5]

$$V_P = \frac{qN_D a^2}{2\varepsilon_s}. \tag{3.57}$$

Finally, V_T is the threshold voltage, and it is given by:

$$V_T = \psi_{bi} - V_P$$

In saturation, the drain current is given by:

$$I_{D,\,sat} \approx \frac{G_i}{4V_P}(V_G - V_T)^2, \tag{3.59}$$

yielding a transconductance of:

$$g_{m,\,sat} = G_i\left(1 - \sqrt{\frac{\psi_{bi} - V_G}{V_P}}\right). \tag{3.60}$$

When pinch-off occurs, the voltage at the pinch-off point is pinned at V_P even when the channel length is continually reduced at higher drain biases. In long channel MESFETs, the length of the pinch-off region is negligibly small and can be ignored. This results in saturation of the drain current for voltages beyond V_P. In smaller devices, however, the length and the resistance of the channel decreases as the pinch-off region becomes wider. Similar to channel length modulation in MOSFETs, this results in a gradual increase in drain current with applied drain bias.

In short channel devices, the horizontal field in the channel is high enough to reach the velocity saturation regime, which degrades the drain current as well as the transconductance. Velocity saturation can be reached even before pinch-off. With velocity saturation, the drain current in the saturation region can be expressed as:

$$I_{D,\,sat} = qv_s WN_D a\left(1 - \sqrt{\frac{\psi_{bi} - V_G}{V_P}}\right), \tag{3.61}$$

which gives a transconductance of:

$$g_{m,\,sat} \approx \frac{qv_s WaN_D}{2\sqrt{V_P(\psi_{bi} - V_G)}}. \tag{3.62}$$

3.6 Modulation-Doped Field Effect Transistor

The modulation-doped field effect transistor (MODFET) is also known as the high-electron mobility transistor (HEMT). The device relies on the ability to form a high-quality heterojunction between a wide bandgap material lattice matched to a narrow bandgap material. The preferred material system is AlGaAs–GaAs; however, MODFETs have also been demonstrated using other material systems including $\mathrm{Si{-}Si_xGe_{1-x}}$. The device was developed in the

[5] This comes from the depletion region of equation 3.54 by replacing the potential term with V_P and the depletion region width with the channel depth.

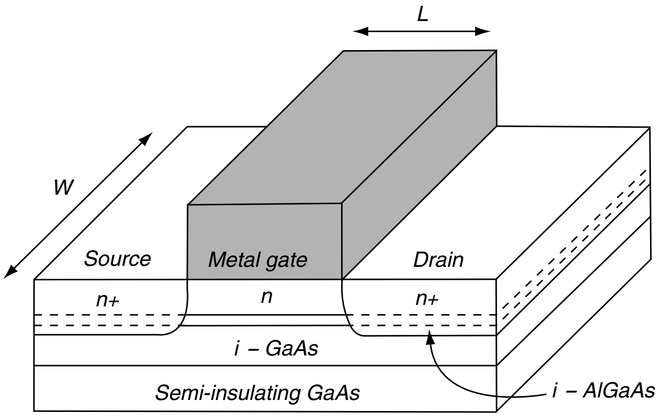

FIGURE 3.23

1970s. Enhanced mobility was first demonstrated by Dingle in 1978.

Figure 3.23 shows the simplified schematic of a self-aligned MODFET. The current conduction takes place in the undoped GaAs layer. The *n*-type AlGaAs layer located under the metal (Schottky barrier) gate is separated from the undoped GaAs by a thin undoped AlGaAs that acts as a buffer layer. A two-dimensional (2-D) electron gas is formed in GaAs immediately under the AlGaAs. High mobility results from the absence of ionized impurity scattering in the undoped layer. The thickness of the undoped AlGaAs buffer layer is critical. The buffer layer must be sufficiently thin to allow electrons to diffuse from the *n*-type AlGaAs into GaAs. At the same time, it must be sufficiently thick to place the 2-D electron gas sufficiently far away from the ionized impurities in the doped AlGaAs layer. The thickness of this layer is typically around 80 A.

The semiconductor layers are typically grown by molecular beam epitaxy (MBE); however, metal-organic chemical vapor deposition (MOCVD) has also shown to be feasible.

The energy band diagram at the onset of threshold is shown in Figure 3.24. The threshold is typically taken as the gate bias at which the conduction band of the GaAs layer coincides with the Fermi level. The 2-D electron gas forms at the heterointerface immediately under the undoped AlGaAs buffer layer and resembles the inversion layer that forms under the gate dielectric of a MOSFET.

The threshold voltage can be expressed as:

$$V_T = \phi_{bn} - V_P - \frac{\Delta E_C}{q}, \tag{3.63}$$

where V_P is the pinch-off voltage for the AlGaAs layer given by:

$$V_P = \frac{q_N D x_d^2}{2\varepsilon_s}. \tag{3.64}$$

The drain current in the linear regime is given by:

$$I_{D,\,lin} \cong \frac{\mu_n C_o W(V_G - V_T)V_D}{L}, \tag{3.65}$$

where

$$C_o = \frac{\varepsilon_S}{x_d + x_{ud} + \Delta d}. \tag{3.66}$$

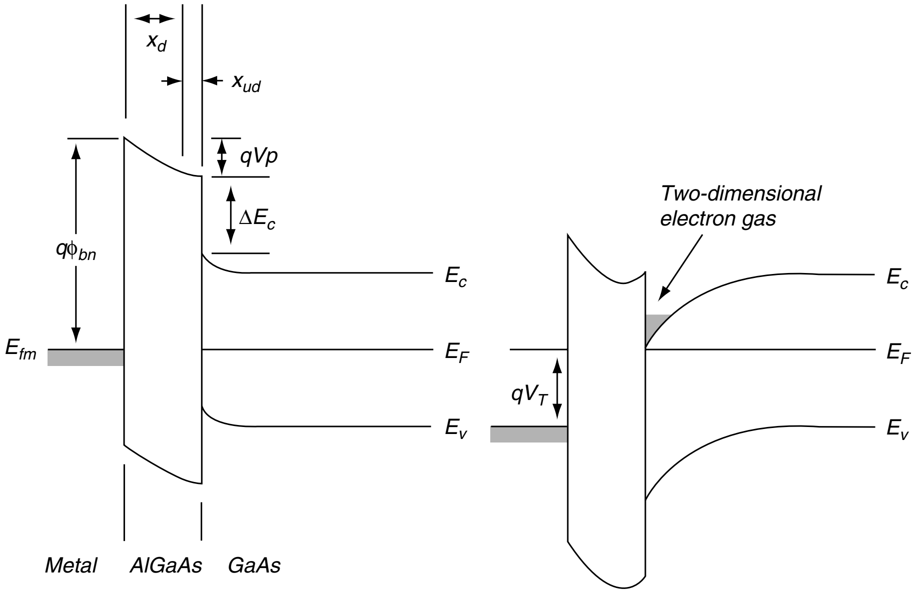

FIGURE 3.24

In the above equations, x_d and x_{ud} are the doped and undoped AlGaAs thicknesses, and Δd is the thickness of the 2-D electron gas that is typically less than 100 A. The threshold voltage can be made positive or negative by adjusting x_d. Hence, both enhancement and depletion mode devices are possible. The transconductance in the linear region is given by:

$$g_{m,\,lin} \equiv \frac{dI_{D,\,lin}}{dV_G} = \frac{\mu_n C_o W V_D}{L}. \tag{3.67}$$

When the drain bias is sufficiently large, electron concentration in the 2-D gas is reduced to zero at the drain end and the drain current saturates with V_D. This occurs at a drain bias of:

$$V_{D,\,sat} = V_G - V_T. \tag{3.68}$$

The drain current in saturation is given by:

$$I_{D,\,sat} = \frac{\mu_n C_o W}{2L}(V_G - V_T)^2, \tag{3.69}$$

yielding a transconductance of:

$$g_{m,\,sat} \equiv \frac{dI_{D,\,sat}}{dV_G} = \frac{\mu_n C_o W(V_G - V_T)}{L}. \tag{3.70}$$

In practical devices, the lateral electric field can be high enough that the carriers suffer from velocity saturation even before the drain current saturates. This is especially an issue for MODFETs due to high mobilities achieved in the 2-D electron gas since high mobility also implies low E_c. With velocity saturation, the drain current saturates at a drain bias of:

$$V_{D,\,sat} \approx E_c L. \tag{3.71}$$

The drain current is then given by:

$$I_{D,\,sat} = WC_o(V_G - V_T)v_s, \tag{3.72}$$

where v_s is the saturated drift velocity. This yields a transconductance of:

$$g_{m,\,sat} \equiv \frac{dI_{D,\,sat}}{dV_G} = WC_o v_s, \tag{3.73}$$

It is interesting to note that the saturation current is independent of channel length, and the transconductance is independent of both L and V_G. The device, however, benefits from a velocity overshoot that provides higher drive current.

Active Filters

Department of Electrical and
Computer Engineering,

Portland, Oregon, USA

4.1 Introduction

Electrical filters are circuits designed to shape the magnitude and/or phase spectrum of an input signal to generate a desired response at the output. Thus, a frequency range can be defined as the **passband** where the input signal should be transmitted through the filter undistorted and unattenuated (or possibly amplified); **stopbands** require transmission to be blocked or the signal to be at least highly attenuated. In the frequency domain, the transmission characteristic is described by the **transfer function**:

$$\begin{aligned} T(s) &= \frac{V_{\text{out}}}{V_{\text{in}}} = \frac{N_m(s)}{D_n(s)} \\ &= \frac{b_m s^m + b_{m-1}s^{m-1} + \cdots + b_1 s + b_0}{s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0}. \end{aligned} \tag{4.1}$$

The *n*th-order function $T(s)$ is a ratio of two polynomials in frequency $s = j\omega$. In a passband, the transfer function should be approximately a constant, typically unity (i.e., $|T(j\omega)| \approx 1$), so that the attenuation is $\alpha = -20 \log |T(j\omega)| \approx 0\,\text{dB}$. In the stopband, we need $|T(j\omega)| << 1$ so that the attenuation α is large, say $\alpha = 60\,\text{dB}$ for $|T(j\omega)| = 0.001$. $N_m(s)$ and $D_n(s)$, with $n \geq m$, are chosen so that the attenuation specification is as prescribed (Schaumann and van Valkenburg, 2001). All numerator coefficients b_j are real and, for stable circuits, all denominator coefficients a_i are positive. As a realistic example, consider a low-pass filter. Its passband attenuation must vary by no more than 0.1 dB in $0 \leq f \leq 21\,\text{kHz}$; the stopband attenuation must be at least 22 dB in $f \geq 26\,\text{kHz}$, and it is required to have 12.5-dB low-frequency gain. These requirements call for the fifth-order elliptic function (Zverev, 1967):

$$T(s) = \frac{9.04(s^4 + 2,718.9s^2 + 1,591,230.9)}{s^5 + 40.92s^4 + 897.18s^3 + 28,513.8s^2 + 400,103.6s + 3,411,458.7}, \tag{4.2}$$

where the frequency is normalized with respect to 1 krad/s. A sketch of the function is shown in Figure 4.1.

The denominator polynomial of $T(s)$ in equation 4.1 can be factored to display its *n* roots, the **poles**, which are restricted to the left half of the *s* plane. Assuming that *n* is even and keeping conjugate complex terms together, the factored expression is as written here:

$$\begin{aligned} D_n(s) &= s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0 \\ &= \prod_{i=1}^{n/2} \left(s^2 + s\frac{\omega_{0i}}{Q_i} + \omega_{0i}^2 \right). \end{aligned} \tag{4.3}$$

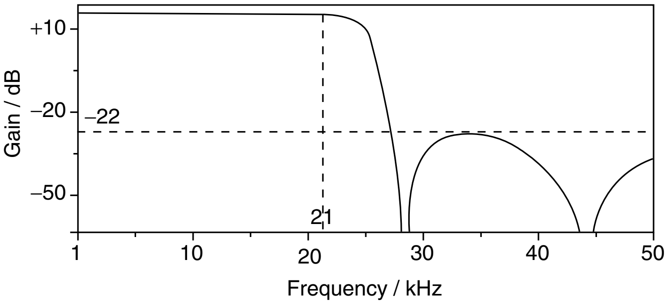

FIGURE 4.1 Sketch of the Elliptic Low-Pass Filter Characteristic of Equation 4.2

The variable ω_{0t} represents the pole frequencies, and Q_i refers to the pole quality factors of the conjugate complex pole pairs:

$$p_i, p_i^* = -\omega_{0i}\left(\frac{1}{2Q_i} \pm j\sqrt{1 - \frac{1}{4Q_i^2}}\right). \tag{4.4}$$

Note that $Q_i > 0$ for stable circuits with poles in the left half of the s plane and that the poles are complex if $Q_i > 1/2$. If n is odd, the product in equation 4.3 contains one first-order term. Similarly, $N_m(s)$ may be factored to give:

$$\begin{aligned} N_m(S) &= b_m s^m + b_{m-1}s^{m-1} + \cdots + b_1 s + b_0 \\ &= \prod_{j=1}^{m/2} (k_{2j}s^2 + k_{1j}s + k_{0j}), \end{aligned} \tag{4.5}$$

where a first-order term (i.e., $k_{2j} = 0$) will appear if m is odd. The roots of $N_m(s)$ are the **transmission zeros** of $T(s)$ and may lie anywhere in the s plane. Thus, the signs of k_{ij} are unrestricted. For example, $k_{1j} = 0$ for transmission zeros on the $j\omega$ axis. Assuming now $m = n$, the following is true:

$$\begin{aligned} T(s) = \frac{N_m(s)}{D_n(s)} &= \frac{\prod_{j=1}^{m/2} (k_{2j}s^2 + k_{1j}s + k_{0j})}{\prod_{i=1}^{n/2} (s^2 + s\omega_{0i}/Q_i + \omega_{0i}^2)} \\ &= \prod_{i=1}^{n/2} \frac{k_{2i}s^2 + k_{1i}s + k_{0i}}{s^2 + s\omega_{0i}/Q_i + \omega_{0i}^2} = \prod_{i=1}^{n/2} T_i(s). \end{aligned} \tag{4.6}$$

In case $m < n$, the numerator of equation 4.6 has $(n - m)/2$ factors equal to unity. The objective is now to design filter circuits that realize this function.

For the fifth-order example function in equation 4.2, factoring results in three sections:

$$\begin{aligned} T(s) &= T_1(s)T_2(s)T_3(s) \\ &= \frac{38.73}{s + 16.8}\,\frac{0.498(s^2 + 29.2^2)}{s^2 + 19.4s + 20.01^2}\,\frac{0.526(s^2 + 43.2^2)}{s^2 + 4.72s + 22.52^2}, \end{aligned} \tag{4.7}$$

where the gain constants are determined to equalize[1] the signal level throughout the filter and to realize a 12.5-dB passband gain. Obtained were two second-order low-pass functions, each with a finite transmission zero (at 29.2 kHz and at 43.2 kHz), and one first-order low-pass.

4.2 Realization Methods

Typically, filter applications have sharp transitions between passbands and stopbands and have complex poles close to the $j\omega$ axis; that is, their quality factors, Q_i, are large. The realization of such high-Q poles requires circuit impedances that change their values with frequency very rapidly. This problem has been solved traditionally with **resonance**: the implementation requires inductors, L, and capacitors, C, because RC circuits have poles only on the negative real axis in the s-plane where $Q \leq 1/2$. Because inductors are large and bulky, LC circuits cannot easily be miniaturized (except at the highest frequencies) so that other approaches are needed for filters in modern communications and controls systems. A popular and widely used solution that avoids bulky inductors makes use of the fact that complex high-Q pole pairs can be implemented by combining RC circuits with **gain**. Gain in active circuits is most commonly provided by the operational amplifier, the op-amp, or sometimes by the operational transconductance amplifier (OTA). It is very easy to see that complex poles can indeed be obtained from **active RC** circuits. Consider an inverting lossy integrator, as shown in Figure 4.2(A), and a noninverting lossless (ideal) integrator, as shown in Figure 4.2(B). Using conductances, $G = 1/R$, and assuming the op-amps are ideal, the lossy and lossless integrators, respectively, realize the functions:

$$\frac{V_B}{V_1} = -\frac{G}{sC + G_q} = -\frac{1}{s\tau + q}$$

and

$$\frac{V_L}{V_B} = \frac{G}{sC} = \frac{1}{s\tau}. \tag{4.8}$$

The integrator time constant is $\tau = RC$ and the loss term is $q = R/R_q$. If these two integrators are connected in a two-integrator loop shown in Figure 4.3, the function realized is:

$$V_L = \left(-\frac{1}{s\tau + q} \times \frac{1}{s\tau}\right)(KV_{in} + V_L)$$

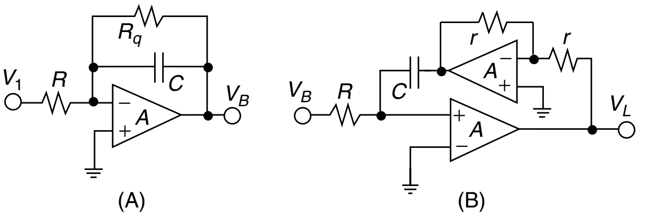

FIGURE 4.2 Integrators (A) Lossy Inverting Integrator (B) Lossless Noninverting Integrator

[1] Since the signal level that an op-amp can handle without distortion is finite and the circuits generate noise, dynamic range is limited. To maximize dynamic range, the first- and second-order blocks in equation 4.7 are cascaded in Figure 4.4 in the order of increasing Q values, and the gain constants are chosen such that the signal level throughout the cascade stays constant.

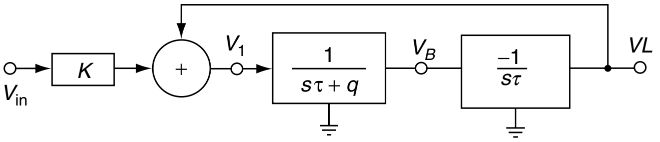

FIGURE 4.3 Two-Integrator Loop Realizing a Second-Order Active Filter (Note that one of the blocks in inverting so that the loop gain is negative for stability).

or

$$\frac{V_L}{V_{\text{in}}} = -\frac{K}{s^2\tau^2 + s\tau q + 1}. \tag{4.9a}$$

If we compare the denominator of equation 4.9a with a pole-pair factor in equation 4.3, we notice that the pole frequency is implemented as $\omega_{0i} = 1/\tau = 1/(RC)$, and the pole quality factor is $Q_i = 1/q = R_q/R$. Clearly, we may choose R_q larger than R, so that $Q_i > 1$ and the poles are complex. In addition, a band-pass function is realized at the output V_B because according to Figure 4.3, we have $V_B = s\tau V_L$ to give with equation 4.9a:

$$\frac{V_B}{V_{\text{in}}} = -\frac{s\tau K}{s^2\tau^2 + s\tau q + 1}. \tag{4.9b}$$

After this demonstration that inductors are not required for high-Q filters, we need to consider next how to implement practical high-order active filters as described in equation 4.6. We shall discuss the two methods that are widely used in practice: **cascade design** and **ladder simulation**.

When analyzing the circuits in Figure 4.2 to obtain equation 4.8, we did assume **ideal op-amps** with infinite gain A and infinite bandwidth. The designer is cautioned to investigate very carefully the validity of such an idealized model. Filters designed with ideal op-amps will normally not function correctly except at the lowest frequencies and for moderate values of Q. A more appropriate op-amp model that is adequate for most filter applications uses the finite and frequency-dependent gain $A(s)$:

$$A(s) = \frac{\omega_i}{s + \sigma} \approx \frac{\omega}{s}. \tag{4.10}$$

That is, the op-amp is modeled as an integrator. The op-amp's -3-dB frequency, σ, (typically less than 100 Hz), can be neglected for most filter applications as is indicated on the right-hand side of equation 4.10. The ω_t is the op-amp's gain-bandwidth product (greater than 1 MHz). To achieve predictable performance, the operating frequencies of active filters designed with op-amps should normally not exceed about $0.1\omega_t$. The Ackerberg-Mossberg and *GIC* second-order sections discussed below have been shown to be optimally insensitive to the finite value of ω and to behave very well even when designed with real operational amplifiers.

4.2.1 Cascade Design

In cascade design, a transfer function is factored into low-order blocks or sections as indicated in equation 4.6. The low-order blocks are then connected in a chain, or are **cascaded** as in Figure 4.4, such that the individual transfer functions multiply:

$$\begin{aligned}\frac{V_{\text{out}}}{V_{\text{in}}} &= \frac{V_1}{V_{\text{in}}} \times \frac{V_2}{V_1} \times \frac{V_3}{V_2} \times \cdots \times \frac{V_{\text{out}}}{V_{n/2-1}} \\ &= T_1 T_2 T_3 \cdots T_{n/2-1} = \prod_{i=1}^{n/2} T_i,\end{aligned} \tag{4.11}$$

as required by equation 4.6. This simple process is valid provided that the individual sections do not interact. Specifically, section T_{i+1} must not load section T_i. In active filters, this is generally not a problem because the output of a filter section is taken from an op-amp output. The output impedance of an op-amp is low, ideally zero, and therefore can drive the next stage in the cascade configuration without loading effects. A major advantage of cascade design is that transfer functions with zeros anywhere in the s-plane can be obtained. Thus, arbitrary transfer functions can be implemented. Ladder simulations have somewhat lower passband sensitivities to component tolerances, but their transmission zeros are restricted to the $j\omega$ axis.

To build a cascade filter, we need to identify suitable second-order (and first-order, if they are present) filter sections that realize the factors in equation 4.6. The first- and second-order functions, respectively, are the following:

$$T_1(s) = \frac{as + b}{s + \sigma} \tag{4.12a}$$

and

$$T_2(s) = \frac{k_2 s^2 + k_1 s + k_0}{s^2 + s\omega_0/Q + \omega_0^2}. \tag{4.12b}$$

In the first-order function, T_1, a and b may be positive, negative, or zero, but σ must be positive. Similarly, in the second-order function, the coefficients k_1 can be positive, negative, or zero, depending on where T_2 is to have transmission zeros. For example, T_2 can realize a low-pass ($k_2 = k_1 = 0$), a high-pass ($k_1 = k_0 = 0$), a band-pass ($k_2 = k_0 = 0$), a band-rejection or

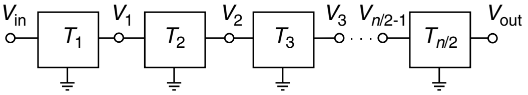

FIGURE 4.4 Realizing a High-Order Filter as a Cascade Connection of Low-Order Sections

"notch" filter ($k_1 = 0$) with transmission zeros at $\pm j\sqrt{k_0/k_2}$, and an all-pass or delay equalizer ($k_2 = 1, k_0 = \omega_0^2, k_1 = -\omega_0/Q$). An example for the choice of coefficients of a first-order low-pass and two second-order notch circuits was presented in equation 4.7.

First-Order Filter Sections

The function T_1 in equation 4.12a is written as:

$$T_1(s) = \frac{V_2}{V_1} = -\frac{sC_1 + G_1}{sC_2 + G_2} = -\frac{(C_1/C_2)s + 1/(C_2R_1)}{s + 1/(C_2R_2)}, \quad (4.13)$$

from which we can identify:

$$a = \frac{C_1}{C_2}, \quad b = \frac{1}{C_2R_1}, \quad \sigma = \frac{1}{C_2R_2} \quad (4.14)$$

Note, however, that the circuit is inverting and causes a (normally unimportant) phase shift of 180°. The example of the first-order low-pass in equation 4.7 is realized by the circuit in Figure 4.5 with $C_1 = 0$, $R_2 = 2.31R_1$, and $C_2R_2 = 1/(16.8\,\text{krad/s})$. The components can be determined if C_2 is chosen (e.g., as $1\,\text{nF}$). We obtain $R_1 = 4.10\,\text{k}\Omega$ and $R_2 = 9.47\,\text{k}\Omega$.

Often, a zero in the right half of the plane is needed (i.e., $b/a < 0$). For this case, the circuit in Figure 4.5(B) can be used. It realizes, with $\sigma = 1/(RC)$:

$$T_1(s) = \frac{V_2}{V_1} = \frac{s - (R_F/R)\sigma}{s + \sigma}. \quad (4.15)$$

For $R_F = R$, the circuit in Figure 4.5(B) realizes a first-order all-pass function that changes the phase but not the magnitude of an input signal.

Second-Order Filter Sections. The literature on active filters contains a large number of second-order sections, the so-called **biquads**, which can be used to realize T_2 in equation 4.12b. Among those, we shall only present three circuits that have proven themselves in practice because of their versatility and their low sensitivities to component tolerances and to finite ω_t-values of the op-amps. The first is the four-amplifier **Ackerberg-Mossberg biquad** that may be called a universal filter because it can implement any kind of second-order transfer function. Then we shall consider the more restrictive two-amplifier **GIC section** that is derived from an **RLC** prototype and has been found to have excellent performance. Finally, we shall present the single-amplifier **Delyiannis-Friend biquad**, which is more sensitive than the previous two circuits but may be used in applications where considerations of cost and power consumption are critical.

The Ackerberg-Mossberg Biquad. The Ackerberg-Mossberg biquad is a direct implementation of the two-integrator loop in Figure 4.3 with the two integrators of Figure 4.2. Adding further a summer that combines all amplifier output voltages weighted by different coefficients, we obtain the circuit in Figure 4.6. Using routine analysis,[2] we can derive the transfer function of the circuit as:

$$\frac{V_{\text{out}}}{V_{\text{in}}} = -\frac{as^2 + s\omega_0/Q[a - b(kQ)] + \omega_0^2[a - (c - d)k]}{s^2 + s\omega_0/Q + \omega_0^2}. \quad (4.16)$$

The parameters a, b, c, d, and k, and the quality factor Q are given by the resistors shown in Figure 4.6, and the pole frequency equals $\omega_0 = 1/(RC)$. If we compare the function with

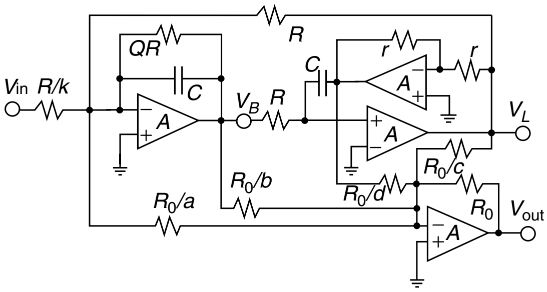

FIGURE 4.6 The Ackerberg-Mossberg Biquad with Output Summer

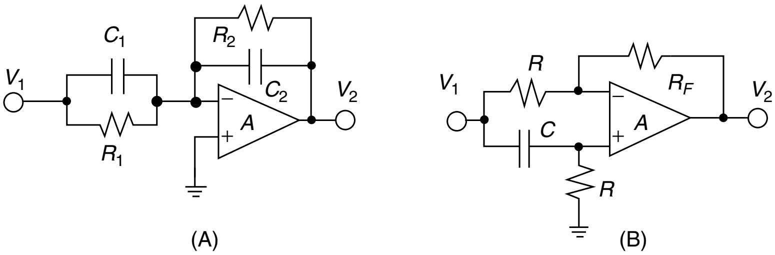

FIGURE 4.5 Active Circuits Realizing the Bilinear Function. (A) Realization for Equation 4.13. (B) Realization for Equation 4.15.

[2] The op-amps are again assumed ideal. This assumption is justified because the combination of the two particular integrators in the Ackerberg-Mossberg circuit causes cancellation of most errors induced by finite ω_t.

T_2 in equation 4.12b, it becomes apparent that an arbitrary set of numerator coefficients can be realized by the Ackerberg-Mossberg circuit. For example, a notch filter with a transmission zero on the $j\omega$ axis requires that $a = bkQ$ by equation 4.16. Notice that the general configuration with the summer is not required for low-pass and band-pass functions: a low-pass function is obtained directly at the output V_L and a band-pass at V_B as we saw in equations 4.9a and 4.9b.

As a design exercise, let us realize T_2 and T_3 in our example function in equation 4.7. We equate formula 4.16 with:

$$T_2(s) = \frac{0.498(s^2 + 29.2^2)}{s^2 + 19.4s + 20.01^2}$$

and

$$T_3(s) = \frac{0.526(s^2 + 43.2^2)}{s^2 + 4.72s + 22.52^2}.$$

With $\omega_{02} = 20.01$ (normalized) and $Q_2 = 20.01/19.4 = 1.03$ for T_2, we find by comparing coefficients that $a = 0.498$, $b = a/(kQ) = 0.498/(1.03 \cdot k)$, and $a - (c - d)k = 1.06$. Choosing for convenience, $k = 1$ and $c = 0$ yields $b = 0.483$ and $d = 0.562$. The choice of $C = 1\,\text{nF}$ leads to $R = 7.95\,\text{k}\Omega$. The value r for the inverter is uncritical, as is R_0; let us pick $r = R_0 = 5\,\text{k}\Omega$; the remaining resistor values are then determined. Similarly, we have for T_3 $\omega_{03} = 22.52$ (normalized) and $Q_3 = 4.77$. We choose again $k = 1$ and $c = 0$ to get $a = 0.526$, $b = a/Q = 0.118$, and $d = 1.41$. The choice of $C = 1\,\text{nF}$ results in $R = 7.07\,\text{k}\Omega$, and $r = R_\text{o} = 5\,\text{k}\Omega$ settles the remaining resistor values. If these two second-order sections and the first-order block determined earlier are cascaded according to Figure 4.4, the resulting filter realizes the prescribed function of equation 4.2.

The GIC Biquad A very successful second-order filter is based on the RLC band-pass circuit in Figure 4.7(A) that realizes the following:

$$\frac{V_\text{out}}{V_\text{in}} = \frac{G}{G + sC + 1/(sL)} = \frac{sG/C}{s^2 + sG/C + 1/(LC)}. \qquad (4.17)$$

Since inductors have to be avoided, circuits that use only capacitors, resistors, and gain were developed whose input impedance looks inductive. The concept is shown in Figure 4.7(B) where the box labeled GIC is used to convert the resistor R_L to the inductive impedance Z_L. The **general impedance converter (GIC)** generates an input impedance as $Z_L = sTR_L$, where T is a time constant. For the inductor L in the *RLC* circuit, we then can substitute a GIC loaded by a resistor $R_L = L/T$.

One way to develop a GIC is to construct a circuit that satisfies the following two-port equations (refer to Figure 4.7(B)):

$$V_1 = V_2, \quad I_1 = I_2/(sT). \qquad (4.18)$$

In that case, we have:

$$Z_L = \frac{V_1}{I_1} = sT\frac{V_2}{I_2} = sTR_L, \qquad (4.19)$$

exactly as desired. A circuit that accomplishes this feat is shown in the dashed box in Figure 4.7(C). Routine analysis yields $V_2 = V_1$ and $I_2 = s(C_2R_1R_3/R_4)I_1 = sTI_1$ to give the inductive impedance:

$$Z_L(s) = \frac{V_1}{I_1} = s\left(C_2\frac{R_1R_3}{R_4}\right)R_L = sTR_L. \qquad (4.20)$$

Normally one chooses in the GIC band-pass filter identical capacitors to save costs: $C = C_2$. Further, it can be shown that the best choice of resistor values (to make the simulated inductor optimally insensitive to the finite gain-bandwidth product, ω_t, of the op-amps) is the following:

$$R_1 = R_3 = R_4 = R_L = 1/(\omega_0 C_2), \qquad (4.21)$$

where ω_0 is a frequency that is critical for the application, such as the center frequency in our band-pass case of Figure 4.7 or the passband corner in a low-pass filter. The simulated inductor is then equal to $L = C_2R_1^2$. Finally, the design is completed by choosing $R = QR_1$ to determine the quality factor.

A further small problem exists because the output voltage in the RLC circuit of Figure 4.7(A) is taken at the capacitor node. In the active circuit, this node (V_1 in Figure 4.7(C)), is not an op-amp output and may not be loaded without disturbing the filter parameters. A solution is readily obtained. The voltage V_out in Figure 4.7(C) is evidently proportional to V_1 because $V_2 = V_1$: $V_\text{out}/V_1 = 1 + R_4/R_L = 2$. Therefore,

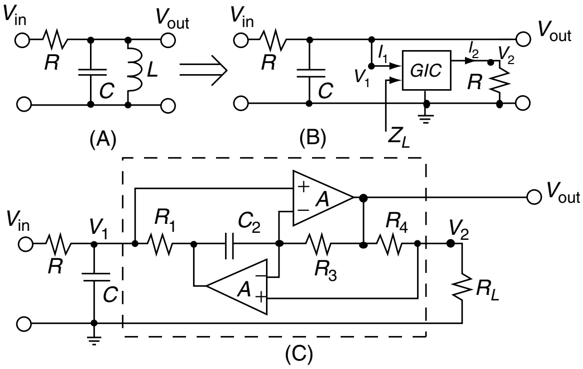

FIGURE 4.7 (A) RLC Prototype Band-Pass Filter (B) Inductor Simulation with a General Impedance Converter (C) The Final GIC Band-Pass Filter with *GIC* Enclosed

we may take the filter output at V_{out} for a preset gain of $V_{\text{out}}/V_1 = 2$. The band-pass transfer function realized by the circuit is then

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{2s/(CR)}{s^2 + s/(CR) + 1/(C^2R_1^2)} = \frac{2s\omega_0/Q}{s^2 + s\omega_0/Q + 1/\omega_0^2}. \qquad (4.22)$$

Transfer functions other than a band-pass can also be obtained by generating additional inputs to the GIC band-pass kernel in Figure 4.7(c).

The Single-Amplifier Biquad On occasion, considerations of cost and power consumption necessitate using a single op-amp per second-order section. In that case, the single-amplifier biquad (SAB) of Figure 4.8 may be used. Depending on the choice of components, the circuit can realize a variety of, but not all, different transfer functions. The function realized by this circuit is written as:

$$T(s) = b\frac{s^2 + s\frac{\omega_0}{Q_0}\left[1 + 2Q_0^2\left(1 - \frac{a/b}{1-K}\right)\right] + \omega_0^2}{s^2 + s\frac{\omega_0}{Q_0}\left(1 - 2Q_0^2\frac{K}{1-K}\right) + \omega_0^2}. \qquad (4.23)$$

The pole frequency equals $\omega_0 = 1/\left(C\sqrt{R_1R_2}\right)$. To optimize the performance, $R_2 = 9R_1$ and $Q_0 = 1.5$ are chosen. The realized pole quality factor then becomes:

$$Q = \frac{1.5}{1 - 4.5K/(1-K)}. \qquad (4.24)$$

Evidently, Q is very sensitive to the tap position, K, of the resistor R and must be adjusted carefully. This filter is particularly useful for building low-Q gain or delay equalizers to improve the performance of a transmission channel.

4.2.2 Realization of Ladder Simulations

Because of their low passband sensitivity to component tolerances, LC ladders have been found to be among the best performing filters that can be built. Therefore, a tremendous effort has gone into designing active filters that retain the excellent performance of LC ladders without having to build and use inductors. A ladder filter consists of alternating series and shunt immittance branches that, as the name implies, are lossless and contain only inductors and capacitors. A typical structure of an LC ladder is shown in Figure 4.9. The circuit consists of five ladder arms (C_1, $L_2\|C_2$, C_3, $L_4\|C_4$, and C_5) and source and load resistors R_1 and R_2. It can realize the fifth-order low-pass function of equation 4.2 with the transfer behavior sketched in Fig. 2.6.1. The two transmission zeros at 29.2 kHz and 43.2 kHz are realized by the parallel resonance frequencies of $L_2\|C_2$ and $L_4\|C_4$. The question to be addressed is how to implement such a circuit without the use of inductors.

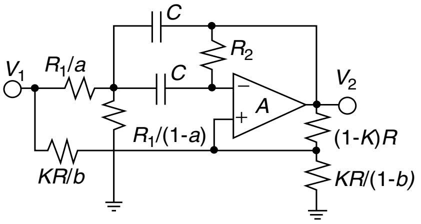

FIGURE 4.8 The Delyiannis-Friend Single-Amplifier Biquad (SAB)

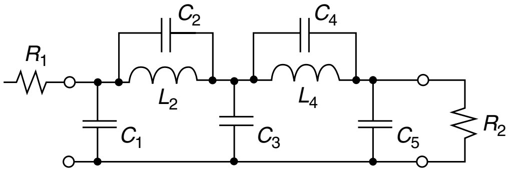

FIGURE 4.9 Typical (Low-Pass) LC Ladder Filter: This circuit is of the form required to realize the transfer function of equation 4.2 with the attenuation curve of Figure 4.1.

The problem is attacked in two different ways. The **element replacement method** eliminates the inductors by electronic circuits whose input impedance is inductive over the relevant frequency range. We encountered this method in Figure 4.7, where the need for an inductor was avoided when L was replaced by a GIC terminated in a resistor. The **method of operational simulation** makes use of the fact that inductors and capacitors fundamentally perform the function of integration, 1/s. Specifically, the voltage V across an inductor generates the current $I = V/(sL)$, and the current I through a capacitor is integrated to produce the voltage $V = I/(sC)$. Thus, we should need only to employ electronic integrators, as in Figure 4.2, to arrive at an inductorless simulation of an LC ladder.

The Element-Replacement Method

In a complete analogy to the GIC biquad discussed earlier, we now create the inductive impedance Z_L at the input of a GIC that is loaded by a resistor R [see Figure 4.10(A)]. The GIC circuit used here is shown in Figure 4.10(B). Notice that compared to Figure 4.7(C), we interchanged the capacitor and the resistor in positions 2 and 4. From equation 4.20, the time constant equals $T = C_4R_1R_3/R_2$. This change is immaterial as far as Z_L is concerned, but the selection is optimal for this case. Note that we have attached the label 1:sT to the GIC boxes to help us keep track of their orientation in the following development: the sT side faces the resistive load. It was shown in equation 4.18 that the GIC implements the two-port equations for the element choice in Figure 4.10(B):

$$V_1 = V_2,\ I_2 = C_4\frac{R_1R_3}{R_2} = sTI_1. \qquad (4.25)$$

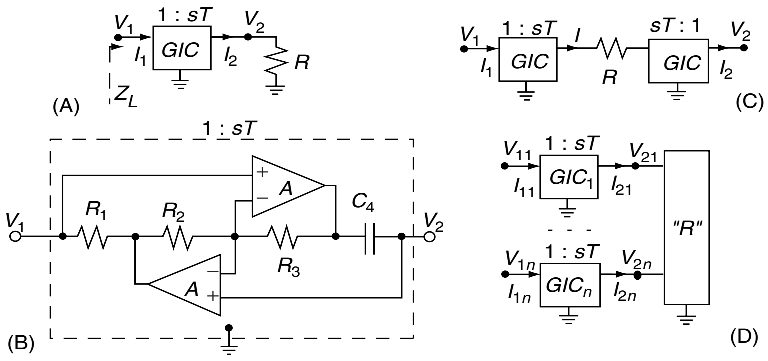

FIGURE 4.10 Circuits for the Element-Replacement Method

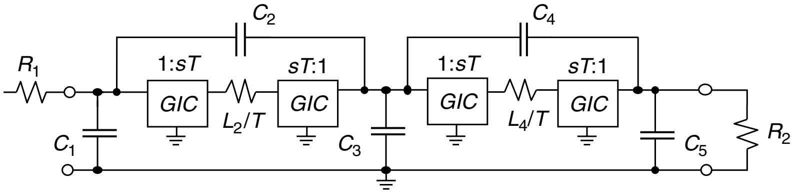

FIGURE 4.11 Inductors in the LC Ladder of Figure 4.9: The inductors simulated by resistors of value $L_i/T, i = 2, 4$, which are embedded between two GICs.

Consequently, the input impedance of the circuit in Figure 4.10(A) is that of a grounded inductor $L = TR$:

$$Z_L = \frac{V_1}{I_1} = sT\frac{V_2}{I_2} = sTR = sL, \tag{4.26}$$

and this scheme can be used to replace any **grounded** inductor in a filter. A **floating** inductor can be implemented by using two GICs as shown in Figure 4.10(C). It is a simple extension of the circuit in Figure 2.10(A), obtained by noting that the resistor is grounded as in Figure 4.10(A) for $V_2 = 0$, according to equation 4.25, input and output voltages of the GIC are the same. The same is true for $V_1 = 0$. Because the voltage $\Delta V = V_1 - V_2$ appears across the series resistor R, we have $I = (V_1 - V_2)/R$. Observing the orientation of the two GIC boxes, we find further $I_2 = I/(sT)$ and:

$$I_1 = I_2 = \frac{V_1 - V_2}{sTR} = \frac{V_1 - V_2}{sL}. \tag{4.27}$$

Evidently, this equation describes a floating inductor of value $L = TR$. This method affords us a simple way to implement floating inductors L by embedding resistors of value L/T between two GICs. Specifically, for the filter in Figure 4.9, we obtain the circuit in Figure 4.11.

We still remark that this method is relatively expensive in requiring two GICs (four op-amps) for each floating inductor and one GIC (two op-amps) for each grounded inductor. A simplification is obtained by the circuit illustrated in Figure 4.10(D). We have shown a resistive network R that has a 1:sT GIC inserted in each input lead. The network R is described by the equation:

$$\mathbf{V}_{2k} = \mathbf{R}\mathbf{I}_{2k}, \tag{4.28}$$

where $\mathbf{V}_{2k}$ and $\mathbf{I}_{2k}$ are the vectors of the input voltages and currents, respectively, identified in Figure 4.10(D) and $\mathbf{R}$ is the resistance matrix describing the network and linking the two vectors. By equation 4.25, we have from the GICs the relationships $\mathbf{V}_{1k} = \mathbf{V}_{2k}$ and $\mathbf{I}_{2k} = sT\mathbf{I}_{1k}$ so that with equation 4.28, we obtain the result:

$$\mathbf{V}_{1k} = \mathbf{V}_{2k} = \mathbf{R}\mathbf{I}_{2k} = \mathbf{R}sT\mathbf{I}_{1k} = sT\mathbf{R}\mathbf{I}_{1k} \tag{4.29}$$

or

$$\mathbf{V}_{1k} = sT\mathbf{R}\mathbf{I}_{1k} = s\mathbf{L}\mathbf{I}_{1k}. \tag{4.30}$$

This equation implies that a resistive network embedded in GICs appears like an inductive network **of the same topology** with the inductance matrix $\mathbf{L} = T\mathbf{R}$, that is, each inductor L is replaced by a resistor of value L/T. This procedure is the **Gorski-Popiel** method. Its significance is that it permits complete inductive subnetworks to be replaced by resistive subnetworks embedded in GICs, rather than requiring each inductor to be treated separately. Depending on the topology

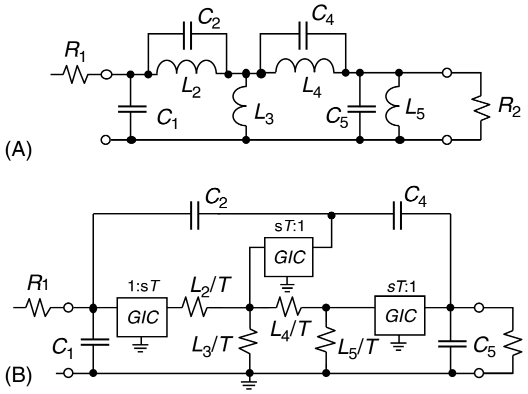

FIGURE 4.12 (A) *LC* Band-Pass Ladder (B) Realization by Gorski-Popiel's Element-Replacement Method

of the *LC* ladder, Gorski-Popiel's method may save a considerable number of GICs, resulting in reduced cost, power consumption, and noise. The simulation of the band-pass ladder in Figure 4.12(A) provides an example for the efficiencies afforded by Gorski-Popiel's procedure. Converting each inductor individually would require six GICs, whereas identifying first the inductive subnetwork consisting of all four inductors leads to only three GICs for the active simulation of the ladder shown in Figure 4.12(B).

Operational Simulation or Signal-Flow Graph Implementation of LC Ladders

As mentioned earlier, in the SFG simulation of an LC ladder filter, each inductor and capacitor are interpreted as signal-flow integrators that can be implemented by an RC/op-amp circuit. The method is completely general in that it permits arbitrary ladder arms to be realized, but in this chapter, we shall illustrate the procedure only on low-pass ladders.

Consider the general section of a ladder shown in Figure 4.13(A). It can be represented by the equations:

$$V_1 = \frac{I_0 - I_2}{Y_1},\ V_3 = \frac{I_2 - I_4}{Y_3},\ V_5 = \frac{I_4 - I_6}{Y_5}. \tag{4.31a}$$

$$I_2 = \frac{V_1 - V_3}{Z_2},\ I_4 = \frac{V_3 - V_5}{Z_4}. \tag{4.31b}$$

For example, in all-pole low-pass filters, all branches Y_i and Z_j are single capacitors and inductors, respectively, so that the five expressions in equations 4.31(A) and 4.31(B) represent integration. Generally, however, Y_i and Z_j may be arbitrary LC immittances. Equations 4.31(A) and 4.31(B) indicate that differences of voltages and currents that need to be formed, which requires more complicated circuitry than simple summing. To achieve operation with only summers, we recast equations 4.31(A) and 4.31(B) as follows by introducing a number of multiplications with (-1):

$$\begin{aligned} V_1 &= \frac{I_0 + (-I_2)}{Y_1}, \\ (-V_3) &= \frac{(-I_2) + I_4}{Y_3},\ V_5 = \frac{I_4 + (-I_6)}{Y_5}. \end{aligned} \tag{4.32a}$$

$$(-I_2) = \frac{V_1 + (-V_3)}{-Z_2},\ I_4 = \frac{(-V_3) + V_5}{-Z_4}. \tag{4.32b}$$

Figure 4.13(B) shows the resulting block diagram.

To be able to sum only voltages, we next convert the currents in equations 4.32(A) and 4.32(B) into voltages. This step is accomplished by multiplying all currents by a scaling resistor R and, simultaneously, by multiplying the admittances by R to obtain so-called "transmittances" $t_Y = 1/(RY)$ or $t_Z = R/Z$ as is shown in equation 4.33:

$$\begin{aligned} V_1 &= \frac{RI_0 + (-RI_2)}{RY_1} \Rightarrow v_1 = t_{Y1}[v_{10} + (-v_{12})]. \\ (-RI_2) &= \frac{V_1 + (-V_3)}{-Z_2/R} \Rightarrow -v_{12} = -t_{Z2}[v_1 + (-v_3)]. \\ (-V_3) &= \frac{(-RI_2) + RI_4}{RY_3} \Rightarrow -v_3 = t_{Y3}[(-v_{12}) + v_{14}]. \\ RI_4 &= \frac{(-V_3) + V_5}{-Z_4/R} \Rightarrow v_{14} = -t_{Z4}[(-v_3) + v_5]. \\ V_5 &= \frac{RI_4 + (-RI_6)}{RY_5} \Rightarrow v_5 = t_{Y5}[v_{14} + (-v_{16})]. \end{aligned} \tag{4.33}$$

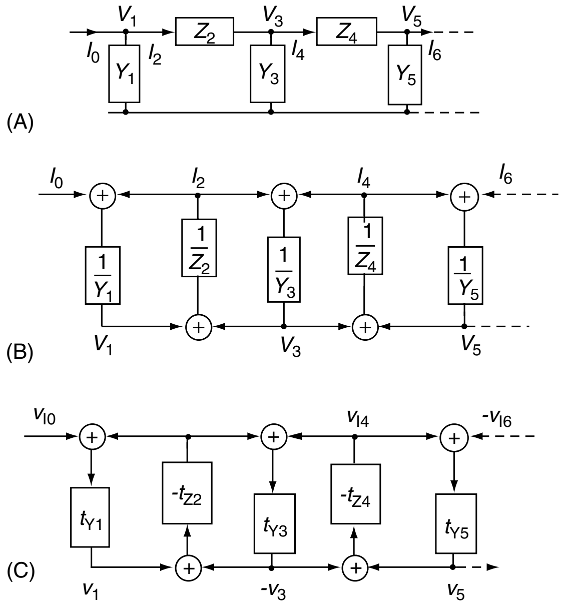

FIGURE 4.13 (A) Section of a General Ladder (B) Signal-Flow Graph Representation for Equation 4.32 (C) Signal-Flow Graph Representation for Equation 4.33

For consistency, we have labeled all voltages, the signals of the SFG implementation, by lowercase symbols and have used the subscripts I, Z, and Y to be reminded of the origin of the dimensionless signals, v, and transmittances, t. Observe that all equations have the same format, $v_k = t_k \times (v_{k-1} + v_{k+1})$, that the signs of all signals are consistent, and (for low-pass ladders) that all t_Z transmittances are inverting and the t_Y transmittances are noninverting integrators: $t_Y = 1/(RY) = 1/(sRC)$, $t_Z = -R/Z = -R/(sL)$. Note also that this process may lead to a normally unimportant sign inversion in the realization. Equations 4.33 are represented by the signal-flow graph in Figure 4.13(C) (Martin and Sedra, 1978). Also observe that inverting and noninverting integrators alternate so that all loops have negative feedback (the loop-gain is negative) and are stable. In low-pass filters, the boxes, together with the summing junctions, form summing integrators that now have to be implemented.

The integrators can be obtained from the circuits n Figure 4.2 by adding a second input. As drawn in Figure 4.13(C), the inverting integrators point upward and the noninverting integrators downward. We used this orientation for the circuits in Figure 4.14. Apart from the sign, both circuits realize the same two-input lossy integrator functions,

$$V_2 = \pm \frac{a_1 V_{11} + a_2 V_{12}}{s\tau + q}, \qquad (4.34)$$

where the minus sign is for the inverting integrator in Figure 4.14(A), and the plus sign for the noninverting integrator in Figure 4.14(B). We used a scaling resistor R_a to define $\tau = C_A R_a$, $q = R_a/R_q$, the gain constants $a_1 = R_a/R_1$, and $a_2 = R_a/R_2$ that multiply the two input voltages V_{11} and V_{12}. These gain constants can be adjusted to maximize the dynamic range of the active filter, but the treatment goes beyond the scope of this chapter. We will for simplicity set $a_1 = a_2 = 1$ by selecting $R_a = R_1 = R_2 = R$ to get $\tau = C_A R$ and $q = R/R_q$. Remember still that the LC ladder is lossless. All *internal* integrators are, therefore, lossless (i.e. $q = 0$, $R_q = \infty$). A finite value for R_q is needed only for the first and last ladder arms where R_q serves to realize source and load resistors.

As an example for the signal-flow graph technique, consider the low-pass ladder in Figure 4.15(A). The component values are $R_S = R_L = 1\text{k}\Omega$, $C_1 = C_3 = 20\,\text{nF}$, and $L_2 = 30\,\text{mH}$. The filter has a flat passband; the 1-dB passband corner is at 9.6 kHz.

The first step in the realization is a Norton source transform to convert the voltage source into a current source, so that the source resistor is placed in parallel to C_1. This transformation removes one mesh from the circuit and simplifies the design as in Figure 4.15(B). Let us write the describing equations to understand how the components in the active circuit are derived from the ladder. Choosing as the scaling resistor R_S, we obtain

$$V_1 = \frac{R_S(V_{\text{in}}/R_S) + (-I_L)R_S}{R_S G_S + sC_1 R_S},$$

$$-I_L R_S = \frac{V_1 + (-V_2)}{sL_2/R_S}, \quad -V_2 = \frac{-I_L R_S}{R_S G_L + sC_3 R_S}.$$

These equations need to be compared with those of the integrators, equation 4.34, to determine the element values. Since $C_1 = C_3$ and $R_S = R_L$, the first and last lossy integrators are the same. The comparison yields $C_1 R_S = C_3 R_S = \tau = C_A R_a$, $q_1 = q_3 = G_S/R_S = 1$, $C_2 R_S = \tau_2 = L_2/R_S$, and $q_2 = 0$. If we select[3] $R_a = R_S = 1\,\text{k}\Omega$, we have $C_1 = C_3 = 20\,\text{nF}$ and $C_2 = L_2/R_S^2 = 30\,\text{nF}$. The value of r is unimportant; let us choose $r = 1\,\text{k}\Omega$ so that all resistors have the same value. The final circuit is shown in Figure 4.15(C). Notice that each loop combines the inverting and noninverting integrators, which we used earlier to construct the Ackerberg-Mossberg

[3] Alternatively, we could choose different resistor values and arrive at identical capacitors.

biquad (see Figure 4.6 without the summer). As a result, we conclude that the performance of this simulated ladder can be expected to be similarly insensitive to the op-amp's finite gain-bandwidth products. Using 741-type op-amps with $f_t \approx 1.5\,\text{MHz}$, the performance of the active circuit is acceptable to over 300 kHz, and the performance of the two circuits in Figure 4.15(A) and 4.15(C) is experimentally indistinguishable until about 90 kHz when the op-amp effects begin to be noticeable. As a final comment, observe that the output V_{out} in the active realization is inverting. If this phase shift of 180° is not acceptable, the output may be taken at the node labeled V_2.

4.2.3 Transconductance-*C* (OTA-*C*) Filters

The finite value of the op-amp's gain-bandwidth product ω_t causes the frequency range of the active filters discussed so far to be limited to approximately $0.1\,\omega_T$. Using inexpensive op-amps in which f_t is of the order 1.5 to 3 MHz is not sufficient because the frequency range is too low for most communications applications. Although relatively economical wide-band amplifiers are available with f_t values up to about 100 MHz, a different solution is available that is especially attractive for filter circuits compatible with integrated-circuit (IC) technology. For these cases, gain is not obtained from operational voltage amplifiers but from operational transconductance amplifiers, also labeled OTAs or transconductors. These circuits are voltage-to-current converters characterized by their transconductance parameter g_m that relates the output current to the (normally differential) input voltage:

$$I_{\text{out}} = g_m(V_{\text{in}}^+ - V_{\text{in}}^-). \tag{4.35}$$

Simple transconductors with bandwidths in the GHz range have been designed in standard CMOS technology (Szczepanski *et al.*, 1997); in turn, they permit communication filters to be designed with operating frequencies in the hundreds of megahertz. There are several additional reasons for the popularity of the use of transconductors in filter design. Among them are the small OTA circuitry, the particularly easy filter design techniques that normally permit all OTA cells to be identical, and the compatibility with digital (CMOS) integrated-circuit technology: "OTA-*C*" filters use no resistors.

A small-signal model of the OTA is shown in Figure 4.16(A) including parasitic input and output capacitors (of the order 0.01 to 0.05 pF) and the finite output resistance (of the order of 0.1 to 2 MΩ). We have shown the lower output terminal grounded because for simplicity we shall assume that designs are single-ended for the sake of this discussion. In practice, IC analog circuitry is designed in differential form for better noise immunity, linearity, and dynamic range. Conversion to differential circuitry is straightforward. The customary circuit symbol for the OTA is shown in Figure 4.16(B).

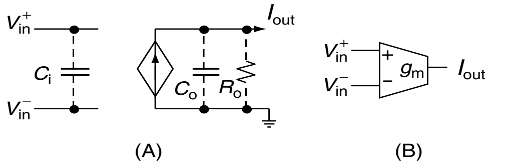

FIGURE 4.16 (A) Small-Signal Model of a Transconductor: $I_{out} = g_m(V_{\text{in}}^+ - V_{\text{in}}^-)$ (B) Circuit Symbol

Apart from minor differences having to do largely with IC implementation, active filter design with OTAs is the same as filter design with op-amps. As before, we have available the cascade method with first and second-order sections, or we can use ladder simulations. For the latter, it can be shown that element replacement and the signal flow-graph technique lead to identical OTA-*C* filter structures, so only one of the two methods needs to be addressed.

Cascade Design

The only difference between this cascade design method and the one presented earlier (in Section 4.2.1) is the use of only OTAs and capacitors. In this case, the filter sections do not normally have low output impedance, but the input impedance[4] is as a rule very large, so cascading remains possible. General first- and second-order sections are shown in Figure 4.17. The circuit in Figure 4.17(A) realizes the function:

$$T_1(s) = \frac{V_{\text{out}}}{V_{\text{in}}} = \frac{saC + g_{m1}}{sC + g_{m2}}, \tag{4.36}$$

and the second-order section in Figure 4.17(B) implements:

$$T_2(s) = \frac{V_{\text{out}}}{V_{\text{in}}} = \frac{s^2 bC_1C_2 + s(bC_2g_{m2} - aC_1g_{m3}) + g_{m1}g_{m3}}{s^2C_1C_2 + sC_2g_{m2} + g_{m3}g_{m4}}. \tag{4.37}$$

Normally, one selects $g_{m3} = g_{m4} = g_m$; the pole frequency and pole quality factor are then:

$$\omega_0 = \frac{g_m}{\sqrt{C_1C_2}}, \quad Q = \frac{\omega_0 C_1}{g_{m2}} = \sqrt{\frac{C_1}{C_2}}\frac{g_m}{g_{m2}}. \tag{4.38}$$

Since ω_0 is proportional to g_m, which in turn depends on a bias current or voltage, the pole frequency can be tuned by varying the circuit's bias. Automatic electronic tuning techniques have been developed for this purpose. In addition, note that Q, as a dimensionless parameter, is set by ratios of like components

[4] The input of an OTA-*C* filter is normally a parasitic capacitor (≈ 0.05 pF) of a CMOS transistor. Thus, even at 100 MHz, the input impedance is still larger than 30 kΩ. Furthermore, as the topology of the first- and second-order circuits in Figure 4.17 indicates, these input capacitors can be absorbed in the circuit capacitors of the previous filter section.

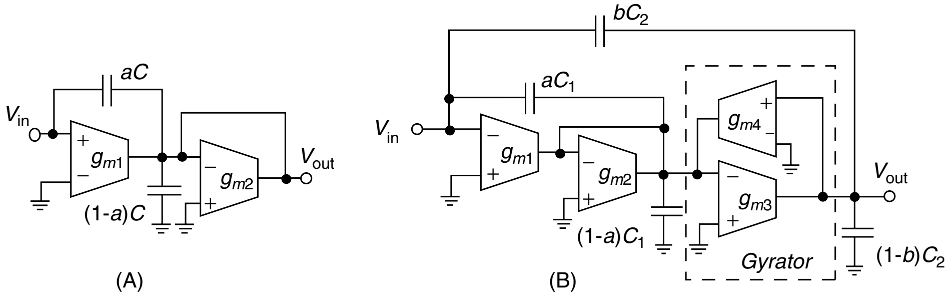

FIGURE 4.17 General OTA-C Filter Sections. (A) First-order. (B) Second-order.

and, therefore, is designable quite accurately. Difficulties arise only for large values of Q where parasitic effects can cause large deviations and tuning must be used.

Evidently, a variety of transfer functions can be realized by choice of the components, the coefficients a and b, and the values and signs of the transconductances, g_{mi}. For instance, comparing equation 4.37 with T_2 in equation 4.12 shows that the second-order functions can be realized with arbitrary coefficients. Negative values of g_{mi} are obtained by simply inverting the polarity of their input connections; this must be done with caution, of course, to make certain that the transfer functions' denominator coefficients stay positive.

An interesting observation can be made about the two circuits in Figure 4.17. Notice that all internal nodes of the circuits are connected to a circuit capacitor. This means that the input and output capacitors of all transconductance cells (see Figure 4.16(A)) can be absorbed in a circuit capacitor and do not generate parasitic poles or zeros, which could jeopardize the transfer function. The designer must, however, "predistort" the capacitors by reducing their nominal design values by the sum of all parasitic capacitors appearing at the capacitor nodes. Thus, if a high-frequency design calls for $C = 1.1\,\text{pF}$ and the sum of all relevant parasitics equals 0.2 pF, for example, the circuit should be designed with $C = (1.1 - 0.2)\text{pF} = 0.9\,\text{pF}$. The unavoidable parasitics will restore the effective capacitor to its nominal value of 1.1 pF.

An additional interesting observation can be made related to the structure of the second-order circuit in Figure 4.17(B). We have labeled the circuit in the dashed box a **gyrator**. A gyrator is a circuit whose input impedance is proportional to the reciprocal of the load impedance. Figure 4.18(A) shows the situation for a load capacitor. From this circuit, we derive that the input impedance equals:

$$Z_{\text{in}} = \frac{V_1}{I_1} = \frac{1}{g_m^2} sC = s\frac{C}{g_m^2} \Rightarrow sL. \tag{4.39}$$

That is, it realizes an inductor of value $L = C/g_m^2$. Consequently, we recognize that the second-order OTA-C circuit is derived from the passive RLC band-pass stage in Figure 4.7(A) in the same way as the GIC filter in Figure 4.7(C). Assume[5] for the following discussion that $a = b = 0$ in the circuit in Figure 4.17(B). We observe then that g_{m1} converts the input voltage V_{in} into a current that flows through C_1 and the resistor[6] $1/g_{m2}$. In parallel with the capacitor, C_1, is the inductor $L = C_2/(g_{m3}g_{m4})$. The parallel RLC connection of $1/g_{m2}$, C_1, and $L = C_2/(g_{m3}g_{m4})$ is driven by the current $g_{m1}V_{\text{in}}$. The OTA-based grounded inductor can be used in any filter application in the same way as the GIC-based inductor of Figure 4.10(A), except that the OTA-based circuit can be employed at much higher frequencies.

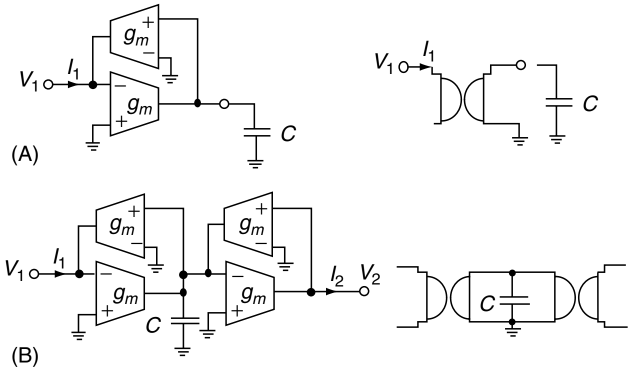

FIGURE 4.18 Capacitor-Loaded Gyrators and their Symbols. (A) Grounded Inductor. (B) Floating Inductor.

Ladder Simulation

The analogy of the present treatment with the one summarized in Figure 4.10 should let us suspect that floating inductors can be simulated as well by appropriate gyrator connections. Indeed, we only need to connect two gyrators with identical g_m values to a grounded capacitor as shown in Figure 4.18(B) to obtain a floating inductor of value $L = C/g_m^2$. For example,

[5] The fractions a and b of the capacitors C_1 and C_2 are connected to the input to generate a general numerator polynomial from the band-pass core circuit. The method is analogous to the one used in Figure 4.8 for the resistors R_1 and KR.

[6] It is easy to show that a transconductor g_m with its output current fed back to the inverting input terminal acts like a resistor $1/g_m$.

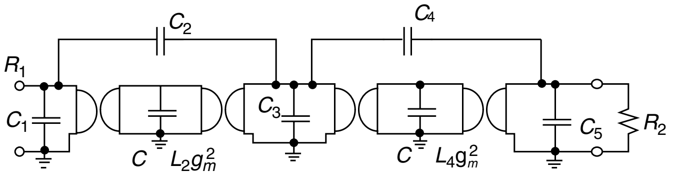

FIGURE 4.19 OTA-*C* Realization of the LC Ladder in Figure 4.9: Note the similarity with the circuit in Figure 4.11. Each gyrator symbol represents the circuit enclosed in the dashed box in Figure 4.16 (B).

using this approach on the ladder in Figure 4.9 results in the circuit in Figure 4.19, in complete analogy with the GIC circuit in Figure 4.11. Notice that all g_m cells in the simulated ladder are the same, a convenience for matching and design automation. The circuits in Figures 4.11 and 4.19 have identical performance in all respects, except that the useful frequency range of the OTA-based design is much larger. Even when using fast amplifiers with, say, $f_t \approx 100\,\text{MHz}$, the useful operating frequencies of the GIC filter in Figure 4.11 will be less than about 10 MHz, whereas it is not difficult to achieve operation at several 100 MHz with the OTA-based circuit. A signal-flow graph method need not be discussed here because, as we stated, the resulting circuitry is identical to the one obtained with the element replacement method.

The treatment of transconductance-*C* filters in this chapter has necessarily been brief and sketchy. Many topics, in particular the important issue of automatic tuning, could not be addressed for lack of space. The reader interested in this important modern signal processing topic is referred to the literature in the References section for further details.

Junction Diodes and Bipolar Junction Transistors

5.1 Junction Diodes

Applications of junction diodes are possible for switches, demodulators, rectifiers, limiters, (variable) capacitors, nonlinear resistors, level shifters, and frequency generation. Special diode types exist that are optimized for the particular application. The cross-section of a discrete diode is shown in Figure 5.1(A); diode structures in integrated circuits also contain a parasitic junction.

5.1.1 Basic Equations

The *pn*-junction and *pn*-diode can be treated theoretically by applying the basic semiconductor equations (Sze, 1981; Selberherr, 1984) consisting of Poisson's equation as well as the continuity equations for electrons and holes; these are complemented by material equations for carrier transport, recombination, and generation. Sufficiently simple analytical equations describing the direct current (dc) and small-signal high-frequency terminal behavior are then obtained by simplifications, such as the **regional approach** (Schilling, 1969). The latter corresponds to a partitioning of the device structure into space-charge regions (SCR) and neutral regions (NR) in which only a subset of the basic equations needs to be solved. $V$and V_j are the applied dc terminal voltage and the dc voltage across the junction, respectively; a (possible) time dependence is indicated by lowercase letters (i.e., v and v_j).

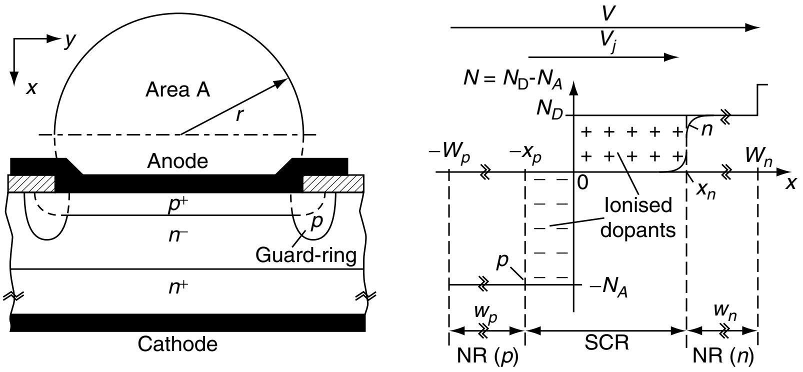
For the sake of clarity, the regional approach is applied here to the one-dimensional (1-D) structure of a *pn*-junction, assuming an abrupt doping profile as shown in Figure 5.1(B) that also contains the respective dimensions used in the subsequent analysis. The lateral (y-) dimensions of the junction define the diode area A shown in Figure 5.1(A).

Space Charge Region

Contacting a p- and n-doped region leads to a large gradient of the carrier densities at the junction. The result is a diffusion current across the junction and an electric field in the opposite direction, due to the ionized doping atoms left behind, which form the SCR. Therefore, in thermal equilibrium ($V = 0$), the corresponding drift current equals the diffusion current, resulting in a zero net current through the junction. The occurring electric field leads to a built-in voltage:

$$V_D = V_T \ln \frac{N_D N_A}{n_{i0}^2}, \tag{5.1}$$

with V_T as the thermal voltage and n_{i0} as intrinsic carrier density. An applied voltage across the junction (positive in the direction defined in Figure 5.1) either decreases ($V > 0$) or increases ($V < 0$) the internal junction voltage, which is then given by superposition as $V_D - V_j$ (with $V_j = V$ here).



(A) Discrete Diode Cross-Section

(B) Schematic Doping Profile

FIGURE 5.1 Junction Diodes. (A) This figure shows a cross-section of a discrete pn-diode with a guard-ring for preventing perimeter breakdown. (B) Illustrated here is a schematic doping profile (assuming an abrupt junction) along a one-dimensional (1-D) cut through the center with definitions of neutral region (NR), space-charge region (SCR), and the respective dimensions.

Important properties of the junction can be calculated from solving Poisson's equation in the SCR (Lindmayer and Wrigley, 1965; Sze, 1981). From this and overall space-charge neutrality, one obtains the width of the SCR

$$w = \sqrt{\frac{2\varepsilon}{q}\left(\frac{N_A + N_D}{N_A N_D}\right)(V_D - V_j)} = w_0\sqrt{1 - \frac{V_j}{V_D}} \qquad (5.2)$$

and the maximum electric field that determines the breakdown characteristics of a diode:

$$E_m = \sqrt{\frac{2q}{\varepsilon}\left(\frac{N_A N_D}{N_A + N_D}\right)(V_D - V_j)}. \qquad (5.3)$$

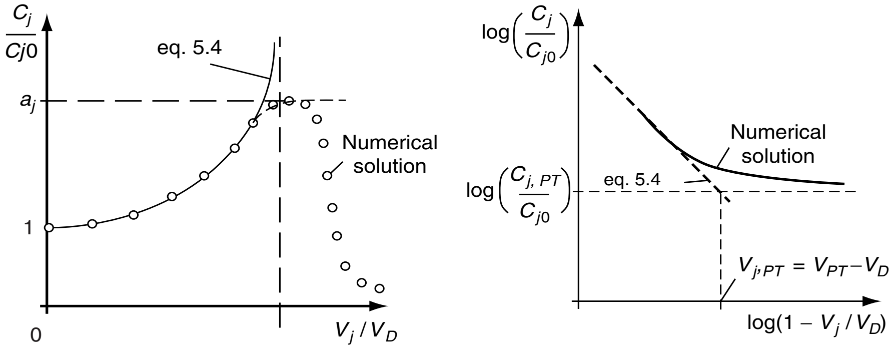
At a forward bias that is not too high ($V_j < 0.7V_D$), the depletion capacitance can be calculated by considering the SCR as two plates with opposite charges and located the distance w apart:

$$C_j(V) = \frac{\varepsilon}{w}A = A\sqrt{\frac{q\varepsilon}{2}\left(\frac{N_A N_D}{N_A + N_D}\right)\frac{1}{V_D - V_j}} = \frac{C_{j0}}{(1 - V_j/V_D)^z}, \qquad (5.4)$$

with $z = 0.5$ in this case of an abrupt doping profile and with C_{j0} as zero-bias capacitance. For the often occurring case of highly nonsymmetrical profiles (e.g., $N_A \gg N_D$), $w_0 = \sqrt{2\varepsilon V_D/(qN_D)}$, and $C_{j0} = A\sqrt{\varepsilon q N_D/(2V_D)}$. The corresponding depletion charge can be described by:

$$Q_j(V) = \int_0^{V_j} C_j dV = \frac{C_{j0}V_D}{1 - z}\left[\left(1 - \frac{V_j}{V_D}\right)^{1-z} - 1\right]. \qquad (5.5)$$

At high forward bias, the depletion charge eventually becomes completely neutralized and disappears, leading to a drop of $C_j(V_j)$; a typical curve is shown in Figure 5.2(A),



(A) Forward Bias

(B) Reverse Bias ($V_j - V$)

FIGURE 5.2 Normalized Depletion Capacitance Characteristics

containing the numerical solution of Poisson's equation as reference. At high reverse bias, the SCR of the lightly-doped side of the junction extends to the highly doped access region; this **punchthrough effect** results in an (almost) constant depletion capacitance $C_{j \cdot PT} = \varepsilon A/W_n$ (for $N_A \gg N_D$) and is easily visible in a log-plot shown in Figure 5.2(B); $V_{PT} = qN_A W_n^2/(2\varepsilon)$ is the punchthrough voltage.

Current–Voltage Relationship (Direct Current)

Consider, for instance, the NR of the n-side of the junction. With applied bias, $V > 0$ holes are injected into the NR at x_n. Using the law-of-mass and the neutrality condition (for low injection, i.e., $V_j = V$), the injected excess minority (hole) carrier density is $\Delta p_n(x_n) = p_{n0}[\exp(V_j/V_T) - 1]$, with p_{n0} as equilibrium carrier density. Combining continuity and transport equations of holes yields a second-order differential equation for calculating the spatial dependence of Δp_n (Lindmayer and Wrigley, 1965; Sze, 1981). Under the assumption of a finite width $w_n (= W_n - x_n)$ of the NR, the solution is:

$$\Delta p_n = p_{n0}\left[\exp\left(\frac{V_j}{V_T} - 1\right)\right] \left[\sinh\left(\frac{W_n - x}{L_p}\right) / \sinh\left(\frac{w_n}{L_p}\right)\right]. \tag{5.6}$$

Because there is no electric field in the considered case of abrupt doping profiles, the hole current density equals the diffusion component; the current density, injected at x_n, is then given by:

$$J_p(x_n) = -qD_p \frac{dp}{dx}\bigg|_{x_n} = \frac{qD_p p_{n0}}{L_p} \coth\left(\frac{w_n}{L_p}\right)\left[\exp\left(\frac{V_j}{V_T}\right) - 1\right]. \tag{5.7}$$

A similar expression can be derived for the electron component. Combination yields the well-known diode equation:

$$I_d = I_S\left[\exp\left(\frac{V_j}{mV_T}\right) - 1\right], \tag{5.8}$$

with an ideality factor m (= 1 here) and the saturation current:

$$I_S = Aq\left[\frac{D_p P_{n0}}{L_p} \coth\left(\frac{w_n}{L_p}\right) + \frac{D_n n_{p0}}{L_n} \coth\left(\frac{w_p}{L_n}\right)\right] \tag{5.9}$$

as parameters. For real devices, m is usually slightly larger than one due to recombination loss and nonabrupt doping profiles, for example. A typical characteristic is shown in Figure 5.3 where the various bias regions are indicated. At very low forward bias recombination dominates and results in $m = 2$. At high-current densities and high injection, respectively, deviations from the ideal I–V behavior of equation 5.8 occur because of conductivity modulation, resulting in $m = 2$, as well as because of series resistances (see later sections in this chapter). At certain reverse bias $V < 0$, the current starts to increase again due to avalanche breakdown at lower doping concentrations or tunneling at higher doping concentrations (e.g., Zener diodes) (Sze, 1981).

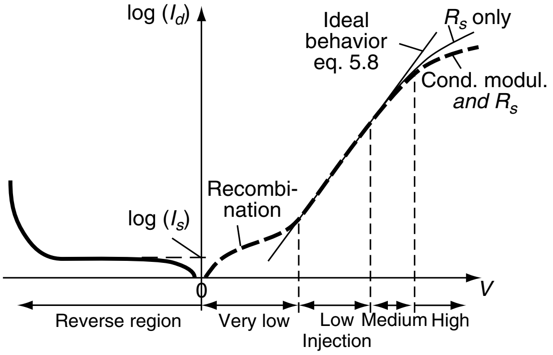


FIGURE 5.3 Typical Current–Voltage Relationship. The V is the terminal voltage applied from anode to cathode.

Diffusion Charge and Capacitance

Minority carriers injected into a NR result in a diffusion charge Q_d and an associated diffusion capacitance of C_d. These are strong functions of bias and can become much larger than Q_j and C_j, respectively, at high forward bias. Combining continuity and transport equation, assuming the small-signal case, with transformation into frequency domain ($\partial/\partial t \to j\omega$) yields again a second-order differential equation that enables the calculation of the frequency and spatially dependent injected excess carrier densities as well as the corresponding injected small-signal terminal current densities. Adding both the hole and electron current components yields the total small-signal terminal current $I_d(\omega)$. Division by the applied small-signal voltage $V(\omega)$ gives the small-signal admittance $Y_d(\omega) = G_d + j\omega C_d$ of the pn-diode. For the most interesting case of a strongly nonsymmetrical junction (e.g., $N_A \gg N_D$) with a short NR width w_n and frequencies that are not too high (i.e., $j\omega\tau_n \ll 1$), one obtains for the case of low injection (Lindmayer and Wrigley, 1965), assuming $V > 4V_T$, with the dc bias current I_d:

$$G_d = \frac{I_d}{mV_T}$$

and

$$C_d = \frac{w_n^2}{3D_p} G_d. \tag{5.10}$$

The diffusion charge is $Q_d = \tau_d I_d$ if the storage time $\tau_d = w_n^2/(3D_p)$ is current independent.

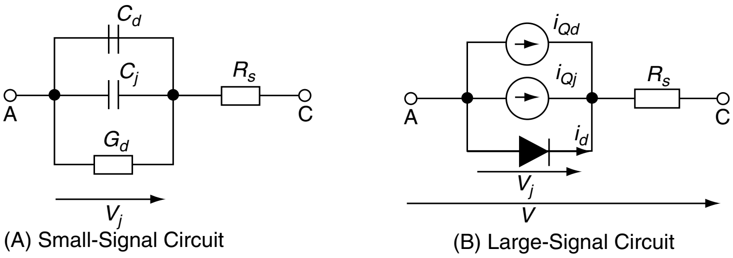

FIGURE 5.4 Equivalent Circuits. (A) This figure shows a small-signal equivalent circuit of a *pn*-diode. (B) Illustrated in this figure is a large-signal equivalent circuit. A and C denote the anode and cathode terminals. $i_{Qd} = dQ_d/dt$ and $i_{Qj} = dQ_j/dt$.

Series Resistances

Both the neutral regions (see Figure 5.1) and the contacts themselves have a finite resistivity, which results in additional parasitic series resistances. Physically, these can be expressed by the sheet resistances of the (access) regions as well as the area-specific contact resistances and the dimensions of the corresponding regions and contacts, respectively.

5.1.2 Equivalent Circuit

A generic small-signal diode-equivalent circuit (EC) is given in Figure 5.4. C_d and the junction conductance G_d have been defined in equation 5.10 and C_j is given by equation 5.4. R_s is the series resistance, which is a lumped representation of all contributing components discussed before. The voltage v_j across the junction is smaller than the applied terminal voltage v due to the voltage drop across R_s. In a realistic diode structure, additional parasitic elements have to be taken into account, such as a sidewall capacitance and—in integrated circuits—a parasitic *pn*-junction that is connected to a different terminal. For tunneling diodes, the effect of a negative differential resistance is usually taken into account in the small-signal EC by an inductance in series to R_s.

5.2 Bipolar Junction Transistor

The generic expression of **bipolar transistor** is used for various types of this device. The most important type is the vertical *npn* bipolar transistor that is available as (a) silicon-based homojunction version (*npn*-BJT) and (b) SiGe or III–V material-based heterojunction version (HBT). Less often employed versions are the lateral *pnp* (LPNP) and vertical *pnp* (VPNP) transistor. In this chapter, emphasis is placed on the *npn*-BJT for presenting a basic theory that can be applied to the other transistor versions with few modifications.

Bipolar transistors are employed wherever speed and drive capability are required. Major application areas include high-speed data links, such as in fiber-optic communications; RF-front-ends, such as mixers and amplifiers in wireless communications; and drivers, bias circuitry, and high-speed logic in general, and in particular in BiCMOS technologies. Both discrete and integrated solutions can be found. An example for a standard integrated BJT implemented in a self-aligning double-polysilicon process is shown in Figure 5.5 (Klose *et al.*, 1993; Yamaguchi *et al.*, 1994). The self-alignment scheme allows submicron emitter window widths b_{E0} with a μm-lithography yielding transit frequencies f_T of 25 GHz and beyond for present production processes. Due to the recent trend to integrate BJTs and silicon-germanium (SiGe) into BiCMOS processes, bipolar transistors benefit from the advanced CMOS lithography tools. The tools enable a significant reduction in parasitics and size and, as a result, the transistors increase in speed ranging from $f_T \approx 30$ GHz (Racanelli *et al.*, 1999) up to ≈ 90 GHz (Freeman *et al.*, 1999), thus possibly even obviating the need for self-alignment schemes. The structure in Figure 5.5 can be divided into the internal transistor T_i (s. blow-up), the peripheral transistor T_p, and the external transistor regions.

Figure 5.6(A) contains the typical doping profile under the emitter for the transistor in Figure 5.5. Two versions are possible: constant collector doping N_C, which yields a high-voltage device, and a selectively implanted collector (SIC), which yields a high-speed device. The transistor speed can be further increased by (a) employing an epitaxial base and (b) adding a graded Ge profile. Both measures significantly reduce the base transit time. A further improvement is achieved by forming a Ge step at the BE junction in Figure 5.6(B) that prevents holes from being back-injected into the emitter and results in a "real" HBT. Here, the BE profile can be inverted without affecting the current gain despite a much higher base doping. The latter allows a significant reduction in base resistance.

The basic operation principle can be derived already for the 1-D structure under the emitter. Classical transistor theory is discussed first; however, it becomes invalid at medium to high current densities because in all practical transistors, $N_C \ll N_B$, so that more general equations are also presented. To allow a generic representation of the typical characteristics and a comparison of technologies, a collector current **density** $J_C = I_C/A_E$ is used in the following considerations, where A_E is the (effective) emitter area that is larger than the emitter window area A_{E0}. The controlling terminal voltages of the 1-D transistor are denoted as $V_{B'E'}$ and $\mathrm{V}_{B'C'}$.

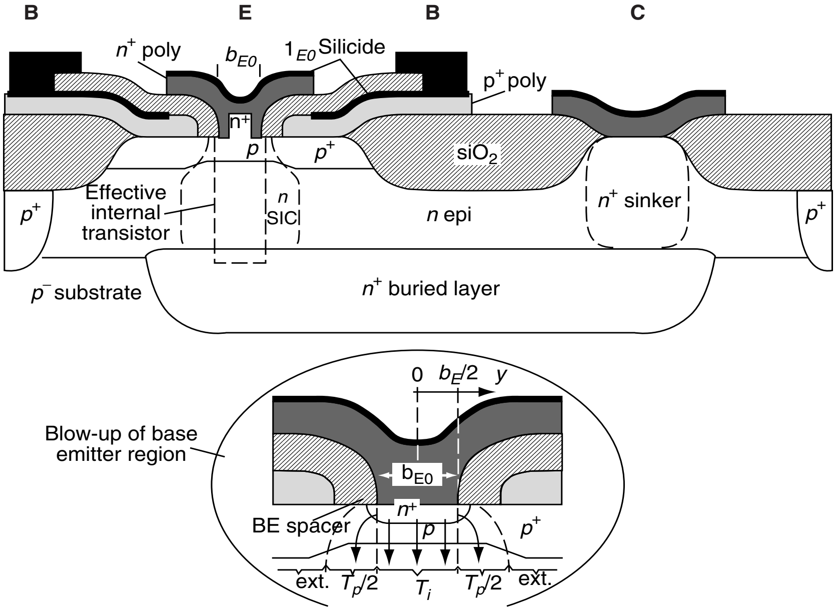

FIGURE 5.5 Schematic Cross-Section of a Self-Aligned Double-Polysilicon Bipolar Transistor Structure. The emitter window area is $A_{E0} = b_{E0|E0}$, and the effective (electrical) internal transistor and its effective emitter width b_E are defined later.

(B) Shown here is a SiGe HBT (typical Ge content ≈ 20–30%) transistor. The location x = 0 defines the surface of the monosilicon and the E′ terminal; w_{Bm} and w_C are the metallurgical widths of base and collector, respectively; x_c is the C′ terminal. Scales are approximate numbers. The SIC does not exist in the external transistor region. The collector substrate junction is not shown here

5.2.1 Basic Equations

Based on the 1-D structure, the basic BJT action can be explained as follows. For normal forward operation ($V_{B'E'} > 0$ and $V_{B'C'} < 0$), electrons are injected from the emitter across the BE SCR into the neutral base. The carriers traverse the base by a combination of drift and diffusion, the partition of which depends on the electric field in the base, and then enter the BC SCR, where they are pulled toward the collector with high velocity. Since in today's processes, recombination of minorities (electrons in this case) in the base can be neglected, the (1-D) current I_C at the collector ($x = x_c$) equals the current injected into the base and, for useful bias conditions $V_{B'E'}$, even the current entering the BE SCR at the emitter side; this current component is often called forward **transfer current** I_{Tf}. Similarly, holes are injected from the base across the BE SCR into the neutral emitter, constituting the base current I_B; a portion of the associated holes recombine in the emitter (Auger recombination), while the remaining portion arrives at the emitter contact. Under practically useful bias conditions $V_{B'E'}$, recombination in the BE SCR is negligible. The emitter current is then $I_E = I_C + I_B$, and the dc common-emitter current gain is $B = I_C/I_B$, which becomes bias dependent at low and high injection (or J_C).

For the theoretical treatment of the BJT, the basic semiconductor equations can be employed (cf., *pn*-diode). Once again, a regional approach is useful for arriving at reasonably simple analytical equations that describe the electrical behavior. Results of classical transistor theory are presented first to provide a feeling for the basic analytical formulations of various characteristics (Lindmayer and Wrigley, 1965; Pritchard, 1967; Philips, 1962).

Direct Current Behavior of a BJT

It is a fair assumption in present technologies to neglect recombination in the base of a "useful" bipolar transistor. According to equation 5.6, the excess electron density injected into the base of a transistor with a simplified box doping profile $\overline{N}_B$ reads, after series expansion of the sinh:

$$\begin{aligned}\Delta n(x) &= \frac{n_{iB}^2(w_B - x)}{\overline{N}_B w_B}\left[\exp\left(\frac{V_{B'E'}}{V_T}\right) - 1\right] \\ &= n_{Be}\left(1 - \frac{x}{w_B}\right).\end{aligned} \tag{5.11}$$

The corresponding (quasistatic) electron current flowing through the base to the collector is represented by:

$$i_{Tf} = I_S\left[\exp\left(\frac{v_{B'E'}}{m_f V_T}\right) - 1\right], \tag{5.12}$$

with an ideality coefficient $m_f = 1$ for the considered assumptions. The saturation current is as follows:

$$I_S = \frac{qA_E D_n n_{iB}^2}{\overline{N}_B w_B}. \tag{5.13}$$

The current depends on base doping and neutral base width. The variation of the latter with the applied voltages $v_{B'C'}$ and $v_{B'E'}$ is known as forward and reverse **Early effect**. In most transistor models, $m_f > 1$ is supposed to account for the reverse Early effect (variation of w_B with $v_{B'E'}$), whereas the $v_{B'C'}$ dependence is approximated analytically, such as $w_B = w_{B0}(1 + v_{B'C'}/V_{Ef})$ with w_{B0} as neutral base width in equilibrium and V_{Ef} as forward **Early voltage**.

At high-injection, a solution for i_{Tf} exists that is similar to the one above, but with 2D$_n$ and $m_f = 2$ rather than D_n and $m_f = 1$. Unfortunately, such a discontinuous description of the transfer current is not very useful for compact models and circuit simulation.

In classical theory, similar equations as above are also derived for reverse operation, leading to $i_{Tr} = -I_S(\exp[v_{BCi}/(m_r V_T)] - 1)$, which is superimposed with i_{Tf} to yield i_T. Since in practically useful transistors $N_C \ll \overline{N_B}$, the control voltage v_{BCi} differs from the terminal voltage $v_{B'C'}$ by a voltage drop that results from the strongly nonlinear bias dependent internal epicollector resistance. Similarly, the base charge and transit time are controlled by v_{BCi}, which is very difficult to model accurately. This together with the high-injection problem mentioned before requires an improvement of classical theory, which is described next.

"Modern" bipolar transistor models employ, one way or the other, the integral charge-control relation (ICCR), which was first proposed by Gummel (1970). Under the assumption of a negligible time dependence $\partial n/\partial t$ in the 1-D electron continuity equation, the (electron) transfer current from the emitter contact $x = 0$ to the internal collector contact at x_c can be written in a simple form (Rein *et al.*, 1985):

$$i_T = I_S \frac{\exp(v_{B'E'}/V_T) - \exp(v_{B'C'}/V_T)}{Q_p/Q_{p0}} = i_{Tf} - i_{Tr}, \tag{5.14}$$

with the saturation current:

$$I_S = (qA_E)^2 V_T \frac{\overline{\mu_n n_i^2}}{Q_{p0}}. \tag{5.15}$$

The hole charge at equilibrium ($V_{B'E'} = V_{B'C'} = 0$) is:

$$Q_{p0} = qA_E \int_0^{x_e} p_0\, dx \approx qA_E \int N_B\, dx = qA_E \overline{N_B} w_{B0}. \tag{5.16}$$

The last two terms containing the base doping concentration N_B and its average value $\overline{N_B}$, respectively, and the zero-bias width w_{B0} of the neutral base show the correspondence to the classical solution of equation 5.13.

The bias-dependent total hole charge in the (1-D) transistor is as follows:

$$Q_p = Q_{p0} + Q_{jEi} + Q_{jCi} + Q_f + Q_r. \tag{5.17}$$

This equation 5.17 can be expressed by several components, namely the base-emitter depletion charge and base-collector depletion charge, respectively:

$$Q_{jEi} = \int_0^{V_{B'E'}} C_{jEi}\, dV \quad \text{and} \quad Q_{jCi} = \int_0^{V_{B'C'}} C_{jCi}\, dV, \tag{5.18}$$

as well as the "forward" and "reverse" minority charge:

$$Q_f = \int_0^{V_{B'E'}} C_{dE} dv = \int_0^{I_{Tf}} \tau_f di \quad \text{and} \qquad (5.19)$$
$$Q_r = \int_0^{V_{B'C'}} C_{dC} dv = \int_0^{I_{Tr}} \tau_r di.$$

In the above integrands, C_{jEi} and C_{jCi} are the BE and BC depletion capacitance, C_{dE} and C_{dC} are the BE and BC diffusion capacitance, and τ_f and τ_r are the minority storage times, which are often called transit times. The latter are strongly bias-dependent small-signal quantities, which will be discussed later in more detail. From a comparison of equations 5.14 and 5.12, it becomes obvious that there is no single Early voltage (i.e., the Early voltage is bias-dependent and modeled by Q_{jCi}).

At this point, it is important to note that the ICCR permits a self-consistent description of nonideal effects via those small-signal quantities that can (a) be measured quite easily with standard methods and equipment and (b) also determine the dynamic (i.e., frequency and large-signal transient) behavior of the transistor. Moreover, from a circuit simulation and numerical point of view, the ICCR provides the basis of a continuous description of the transfer current via a single-piece equation *if* the charges are modeled continuously differentiable. For Si-based HBTs, certain extensions of equation 5.17 are required, which are discussed in Schröter *et al.* (1993) and Friedrich and Rein (1999).

Figure 5.7(A) shows the schematic dependence of the forward dc transfer current density on $V_{B'E'}$. In a "useful" process, I_T/A_E behaves almost ideally at low current densities and is often described in compact models in the form:

$$i_T \cong I_S \exp\left(\frac{v_{B'E'}}{m_f V_T}\right), \qquad (5.20)$$

where m_f is an ideality factor close to 1. For Si bipolar processes, however, this equation is only valid over a fairly small bias range because m_f changes with bias according to the ICCR. At high current densities, the curve bends downward due to so-called high-current effects that are discussed later in more detail.

The base current i_{jBEi} across the BE junction of a modern bipolar transistor can be described by two components:

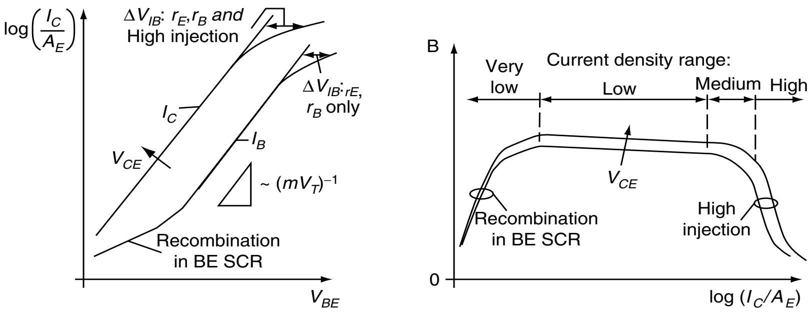
$$i_{jBEi} = I_{BEiS}\left[\exp\left(\frac{v_{B'E'}}{m_{BEi} V_T}\right) - 1\right] + I_{REiS}\left[\exp\left(\frac{v_{B'E'}}{m_{REi} V_T}\right) - 1\right], \qquad (5.21)$$

which are shown in Figure 5.7(A). The first component represents the back injection into the (neutral) emitter, with an ideality factor m_{BEi} that is usually slightly larger than one. This component dominates at low- to high-current densities and remains unaffected by high-current effects for many processes; that is, it keeps increasing almost ideally with $V_{B'E'}$. The second component represents the recombination loss in the BE SCR, with an ideality factor m_{REi} that is close to two. This component dominates for Si BJTs only at very low-current densities. The component i_{jBCi} across the BC junction can be described similarly. The total internal dc base current is then $I_{Bi} = I_{jBEi} + I_{jBCi}$.

The dc current gain B is (obviously) a derived quantity rather than a basic physical parameter of a transistor. Therefore, for modeling purposes, it is easier to describe separately the collector and base current rather than B, as is still often attempted in compact models. For circuit design purposes, only an average value of B is usually required and can be readily provided.

Depletion Capacitances

For reverse and forward biases the capacitances C_{jEi} and C_{jCi} follow the classical voltage dependence given in equation 5.4. For typical capacitance curves as a function of bias, see Figure 5.2. In BJTs, the correct description of C_{jEi} is of most importance for the forward bias region up to the peak value



(A) Forward *I-V* Curves

(B) Current Gain B

FIGURE 5.7 Sketch of the dc Characteristics and Definition of Various Bias Regions. (A) This schematic diagram shows forward $I - V$ curves with total base current I_B (see later). (B) This diagram shows current gain B. The arrow indicates an increase in V_{CE}. Typical units: I_C/A_E in $mA/\mu m^2$.

($a_j C_{jEi0}$), since C_{jEi} strongly determines the charge storage and dynamic behavior in that region. At higher bias, the diffusion capacitance starts to dominate, and the exact modeling of C_{jEi} becomes academic. C_{jEi} is modeled differently in the various transistor models (Schröter, 1998). For the above mentioned reasons, a voltage-independent approximation after the peak (shown by dashed line in Figure 5.2(A)) is sufficient and numerically efficient as well as consistent with the determination of τ_f from f_T. An accurate description of C_{jCi} is usually most important at reverse and low forward bias of the BC junction. For transistors with a lightly doped collector (around $10^{16}\,\text{cm}^{-3}$), the SCR can already punch through the collector at quite low reverse bias, leading to an almost voltage-independent value of C_{jCi} and, therefore, a deviation from the classical equation (refer to Figure 5.2(B). At high collector current densities, the mobile carriers start to compensate for the ionized doping in the collector. As a result, the electric field distribution in the BC SCR changes, and C_{jCi} becomes dependent on i_T in a complicated way. Since in this bias region the minority charge storage dominates the dynamic behavior, an accurate modeling of the above effect on C_{jCi} is usually of little importance for practical applications.

Minority Charge and Transit Time

Classical theory assumes that minority charge storage only occurs in the neutral base; according to equation 5.11, the injected electron density decreases linearly, leading to the stored minority charge $Q_{nB} = qA_E n_{Be}(w_B/2)$. Derivative with respect to I_{Tf} gives the base transit time of a diffusion transistor (i.e., a transistor with a spatially constant base doping) operated at low current densities:

$$\tau_{nB} = \frac{w_B^2}{2D_{nB}}. \tag{5.22}$$

In advanced transistors, τ_{nB} is about two to three times smaller due to a built-in drift field and, thus, is only a portion of the total transit time τ_{f0}. The result of a more detailed analysis, which additionally takes into account both Early effect and delay time through the BC SCR, yields (Schröter, 1998).

$$\tau_{f0} = \tau_0 + \Delta\tau_{0h}(c-1) + \tau_{Bfvl}\left(\frac{1}{c} - 1\right), \tag{5.23}$$

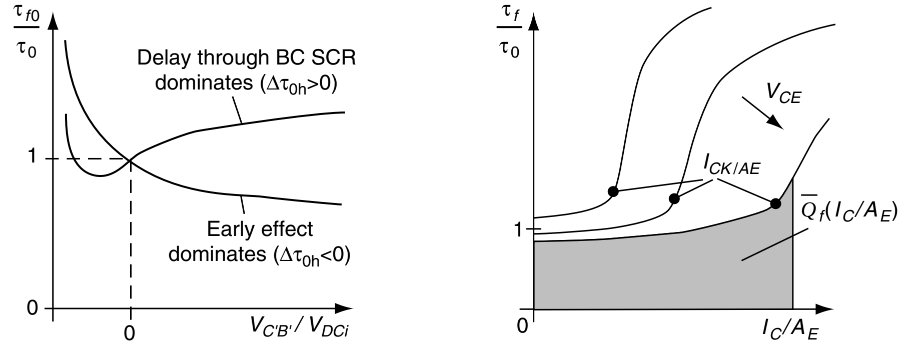
with $c = C_{jCi0}/C_{jCi}(V_{B'C'})$ and τ_0, $\Delta\tau_{0h}$, and τ_{Bfvl} as time constants. Figure 5.8(A) shows the possible voltage dependence of τ_{f0} for the two different cases mentioned previously.

With increasing collector current density, so called high-current effects (e.g., high-injection in the collector region) occur, leading to additional charge storage (Kirk, 1962; Schröter and Lee, 1999). Figure 5.8(B) contains typical characteristics of the transit time $\tau_f = \tau_{f0}(V_{C'B'}) + \Delta\tau_f(I_C, V_{C'E'})$ as a function of collector current density. The sharp increase of τ_f due to high-current effects can be described by a critical current I_{CK} (Schröter and Walkey, 1996) that also serves as a useful aid for designing high-speed switching circuits (Rein, In press). A rough approximation of the corresponding maximum value of the τ_f increase is $\Delta\tau_{f,\,\max} \approx w_C(w_{Bm} + w_C/2)/(2D_{nC})$. (Kirk, 1962). Beyond I_{CK}, a drop in current gain and transit frequency f_T also occur. The latter can be used to determine $\tau_f(I_C, V_{C'E'})$. (Rein, 1983). The total minority charge for forward also operation is given by $Q_f(I_C, V_{C'E'}) = \int_0^{I_{Tf}} \tau_f\, di$ (= area under the τ_f curve), from which the BE diffusion capacitance can be calculated as $C_{dE} = \partial Q_f/\partial V_{B'E'} = \tau_f g_m$ with the transconductance $g_m = \partial I_T/\partial V_{B'E'}$ at constant $V_{C'E'}$.

5.2.2 Internal Transistor and Base Resistance

The base region under the emitter has a finite resistivity that is characterized by the internal base sheet resistance r_{SBi}. The bias dependence of the latter can be reasonably well approximated by:

$$r_{SBi} = r_{SBi0}Q_{p0}/Q_p, \tag{5.24}$$



(A) Low-Current Component (B) Current Dependence

FIGURE 5.8 Bias Dependence of the Forward Transit Time. (A) This graph shows the low-current component for different cases ($V_{C'B'} = V_{CB}$). (B) Notice the current dependence shown here; high-current effects start for $I_C > I_{CK}$. Typical units: τ_f in ps; $\overline{Q}_f$ in fC/μm^2.

with r_{SBi0} as zero-bias value. This automatically includes changes due to the changes of the SCRs and conductivity modulation at high collector current densities (Rein and Schröter, 1991).

The base current entering the internal base region horizontally from the side at $y = \pm b_E/2$ (see Figure 5.5) causes a voltage drop in the direction of the center ($y = 0$) that is called **emitter current crowding**. Because the hole injection into the emitter is distributed laterally, the associated lumped internal base resistance r_{Bi} has to be calculated from a differential equation (Ghosh, 1965; Rein and Schröter, 1989). The formulation for r_{Bi} depends on both the mode of operation (e.g., dc transient and small-signal low or high-frequency) and the emitter geometry (e.g., rectangular, square, and circular). The various cases are discussed below.

Direct Current Operation ($\omega = 0$)

A set of equations describing the geometry dependence and emitter current crowding is given in (Schröter, 1991). The relations are based on analytical solutions for both a long rectangular emitter stripe (used in high-speed applications, for example) and a small square emitter geometry (used in low-power applications, for example):

$$r_{Bi} = r_{SBi}\frac{b_E}{l_E}g_i(b_E,\ l_E)\psi(\eta), \tag{5.25}$$

where the basic expression for the dc current crowding function and factor, respectively, are taken from the square-emitter case for simplicity reasons:

$$\psi(\eta) = \frac{\ln(l+\eta)}{\eta} \quad \text{and} \quad \eta = \frac{r_{SBi}}{g_\eta(b_E,\ l_E)}\frac{b_E}{l_E}\frac{I_{Bi}}{V_T}. \tag{5.26}$$

The functions $g_i = 1/12 - (1/12 - 1/28.6)b_E/l_E$ and $g_\eta = 21.8(b_E/l_E)^2 - 13.5b_E/l_E + 20.3$ describe in a smooth form the geometry dependence of the various possible cases. The results are valid for transistors with n_E emitter and $n_B = n_E + 1$ base contacts (then: $I_{Bi} \rightarrow I_{Bi}/n_B$). For example, $g_i = 12$ for a long stripe and $g_i = 28.6$ for a square emitter window. An extension to the case of a single base contact (i.e., $n_E = n_B = 1$) is given in (Schröter, 1992). Note that in advanced high-speed transistors with narrow emitter widths, dc current crowding becomes negligible.

Small-Signal High-Frequency Operation

At sufficiently high frequencies (hf) the ac base current shunts the center region under the emitter; this effect is called **hf emitter current crowding** (Pritchard, 1958). The small-signal resistance at low frequencies is the following:

$$r_{bi} = r_{Bi} + I_{Bi}\frac{dr_{Bi}}{dI_{Bi}}. \tag{5.27}$$

Assuming negligible dc emitter current crowding and $l_E \gg b_E$, the distributed charging of the capacitances can be represented by a distributed RC network. The solution of the corresponding linear differential equation yields an infinite series for the admittance as a function of frequency. Truncating after the first frequency term leads to the impedance:

$$z_{bi} = r_{Bi}(1 - j\omega r_{Bi}C_{rBi}) \approx r_{Bi}(1 + j\omega r_{Bi}C_{rBi})^{-1}. \tag{5.28}$$

The last expression corresponds to a parallel circuit with a lumped representation of hf emitter current crowding that is modeled by a capacitance $C_{rBi} = (C_{jEi} + C_{jCi} + C_{dE} + C_{dC})/5$ and the dc resistance r_{Bi}.

Large-Signal Transient Operation

During (fast) switching, the base resistance can change significantly over time. At the beginning of a switching process, only the portion at the emitter edge is charged or discharged, leading initially to a small value of the effective internal base resistance $z_{Bi}(t)$. With a continuing turn-on process, the region toward the center starts to get charged, too, and z_{Bi} increases with time, until it approaches the dc value at the end of the turn-on process. For the turn-off process, the discharge of the emitter edge region continues, thus making this region high-ohmic compared to the center region that acts as a conducting transistor. Therefore, z_{Bi} not only starts to become larger than r_{Bi} but also keeps increasing during the remainder of the turn-off process. Overall, for switching:

$$z_{Bi}(t)|_{\text{turn-on}} \leq r_{Bi} \leq z_{Bi}(t)|_{\text{turn-off}}. \tag{5.29}$$

In circuit simulators, usually the dc value is employed for r_{Bi}, which has turned out to be a reasonable approximation for differential-type switching circuits (Schröter and Rein, 1995; Rein, In press).

5.2.3 Emitter Periphery Effects

The lateral outdiffusion of the emitter doping forms the emitter periphery junction with an associated depletion capacitance C_{jEp}. In addition, a portion of the base current, I_{jBEp}, coming from the base contact is back-injected into the emitter already across the peripheral junction. Electrons injected across the emitter periphery junction pass through the external base region under the BE spacer before they enter the external BC depletion region (refer to Figure 5.5). The associated carrier transport and charge storage lead to a perimeter transfer current I_{Tp} and a corresponding diffusion capacitance. Therefore, in most cases, the emitter periphery acts like a second transistor almost in parallel to the internal one but with lower performance. To avoid a two-transistor model, one can combine I_{Ti} and I_{Tp} into a single transfer current source, $I_T = I_{Ti} + I_{Tp} = \overline{I}_{Ti}A_{E0} + I'_{Tp}P_{E0}$, by defining an effective electrical emitter width (for $l_{E0} \gg b_{E0}$) and area, respectively (Rein, 1984):

$$b_E = b_{E0} + 2\gamma_C \quad \text{and} \quad A_E = A_{E0}(1 + \gamma_C P_{E0}/A_{E0}), \qquad (5.30)$$

with the emitter window perimeter P_{E0}. The ratio $\gamma_C = I'_{Tp}/\bar{I}_{Ti}$ is bias-independent at low-current densities. Employing the effective emitter dimensions in all geometry-dependent equations of the internal transistor defines a procedure for constructing a consistent one-transistor model (Schröter and Walkey, 1996). Merging I_{Ti} and I_{Tp} together with the corresponding minority charges into single elements I_T and C_{dE} requires a modification also of r_{Bi} into r^*_{Bi} to obtain the correct time constants (Koldehoff *et al.*, 1993).

5.2.4 Extrinsic Transistor Regions

The regions outside of the (effective) internal transistor are usually described by lumped elements, which will be discussed briefly (see Figures 5.5 and 5.9). For dc operation, the series resistances of the emitter (r_E) as well as of the external base (r_{Bx}) and collector (r_{Cx}) have to be taken into account besides possible current components across the junctions (such as i_{jBCx}); r_{Cx} results from the buried layer and sinker; advanced bipolar transistors r_{Bx} is dominated by the component under the BE spacer (refer to blow-up in Figure 5.5).

For hf operation, the junction capacitances of the external BC region (C_{jCx}) and the collector–substrate region (C_{jS}) are required. With shrinking device dimensions, bias-independent isolation (partially oxide) capacitances caused by the BE spacer (C_{Eox}) as well as by the B-contacting region over the epicollector (C_{Cox}) are of increasing importance. As frequencies increase, a substrate coupling resistance (r_{su}) and—for lightly doped substrate material—the capacitance (C_{su}) that is associated with the substrate permittivity become important (Lee, 1999; Pfost, 1996). In some processes, a parasitic substrate transistor can turn on; however, only a simple transport model (i_{TS}, i_{jSC}, C_{dS}) is usually required to indicate this undesired action to the designer.

From a processing point of view, the goal is to reduce the dimensions of the parasitic regions as much as possible to minimize their impact on electrical performance.

5.2.5 Other Effects

Depending on the operation, a number of other effects can occur that may have to be taken into account for certain applications. Increasing the speed of bipolar transistors comes partially at the expense of lower breakdown voltages in the BC and BE junctions due to larger doping concentrations and shallower junction depths. Therefore, the corresponding effect of BC avalanche breakdown (i_{AVL} in Figure 5.9), which usually occurs in the internal transistor, often needs to be taken into account (Maes *et al.*, 1990; Rickelt and Rein, 1999; Schröter *et al.*, 1998). For some applications, such as varactors, a BE breakdown current (i_{BEt}), which in high-speed transistors is mostly determined by tunneling across the BE periphery junction, can also become important for circuit design (Schröter *et al.*, 1998).

Temperature variations or self-heating in the device cause most characteristics to change more or less significantly with temperature. The corresponding shift in dc *I–V* characteristics and depletion capacitances is mostly determined by the temperature dependence of the bandgap. For instance, typical values for $\partial V_{BE}/\partial T$ at constant I_C and the temperature coefficient (TC) of built-in voltages are in the range of -1.5 to -2.5 mV/K (for silicon). The TC of the current gain is positive for most Si–BJTs, about zero for SiGe bipolar transistors, and negative for III–V (e.g., AlGaAs) HBTs. Changes in series resistances and transit time are predominantly determined by the temperature dependence of the respective mobilities and the thermal voltage V_T. Self-heating occurs at bias points where a high power $P \approx I_C V_{CE}$ is generated and can be described to first-order by a separate network consisting of thermal resistance, R_{th}, and thermal capacitance, C_{th}.

For many applications, such as low-noise amplifiers and oscillators, noise plays an important role. Fundamental noise mechanisms are thermal noise in series resistances, shot noise in junction and transfer currents, and flicker noise. The latter is a phenomenological model for taking into account (physically usually not well described) low-frequency noise sources at surfaces and interfaces (Markus and Kleinpenning, 1995; Deen *et al.*, 1999; Chen *et al.*, 1998). The high-frequency (hf) noise performance of modern bipolar transistors is mostly determined by the noise in $r_B(= r^*_{Bi} + r_{Bx})$, I_{jBE}, and I_T as well as by the parasitic capacitances.

5.2.6 Equivalent Circuits

Figure 5.9 shows a physics-based large-signal equivalent circuit (EC) of a bipolar transistor, containing the elements that were discussed before (Koldchoff *et al.*, 1993; Schröter and Rein, 1995; Schröter and Lee, 1998.). The BC capacitance $C_{BCx} = C_{jCx} + C_{Cox}$ has been split across r_{Bx} to account for distributed hf effects in the external BC region in as simple as possible EC topology (Π-representation). In practice, the full complexity of the EC is often not required and certain effects (i.e., their associated elements, such as those for the substrate transistor or i_{BEt}) can be turned off. In many cases, the transistors are even operated outside any critical bias regions, such as the high-current and breakdown regions, so that a simplified EC [refer to Figure 5.9(B)] and a set of model equations are satisfactory and enable a better analytical insight into the circuit performance for the designer. The simplified model can be constructed from the physics-based model by merging elements and simplifying equations at the expense of a smaller bias, geometry, and temperature validity range. A scalable modeling approach is described in Schröter *et al.* (1999).

5.2.7 Some Typical Characteristics and Figures of Merits

This chapter contains a brief overview and discussion of the typical behavior of some of the most important characteristics of a bipolar transistor. Due to the lack of space, the overview is by no means complete, and the reader is referred to the literature in the Reference list at the end of the chapter. To facilitate in practice an easier understanding for circuit designers and a meaningful comparison of processes, it is recommended to choose the collector current density $J_C = I_C/A_E$ and the voltage V_{CE} as independent variables for defining the bias points of a figure of merit (FoM).

The forward dc ("Gummel") characteristics and the current gain were already shown in Figure 5.7. For most processes, the voltage drop ΔV_{IB} is caused by only r_E and r_B, whereas ΔV_{IC} contains in addition the influence of high-current effects, causing B to drop at higher J_C. Therefore, $I_C(V_{BE})$ should *not* be used for determining the series resistances!

Figure 5.10 shows typical forward output characteristics for constant I_B (with linear spacing ΔI_B). The thin solid line (labeled with $I_{CK}|A_E$) indicates the boundary between the quasisaturation region and the **normal** forward operation. The slope of the curves determines the dc output conductance. At sufficiently high V_{CE}, avalanche breakdown in the BC SCR causes J_C to increase rapidly; this effect is more pronounced in $J_C(V_{CE})$ if I_B rather than V_{BE} is held constant. Often the *CE* breakdown voltage for an open base, BV_{CEO}, is used to characterize the breakdown performance of a process. At high J_C *and* V_{CE}, self-heating occurs that leads J_C to increase (in Si) or decrease (in GaAs) already before the onset of breakdown.

The most important FoMs characterizing the high-frequency performance of a transistor are discussed next. For those frequencies of f that are not too high, the small-signal current gain in common-emitter (CE) configuration (i.e., E-grounded with the signal applied to either B or C) can be described quite accurately as a function of frequency by:

$$\underline{\beta} = \frac{\beta_0}{1 + j(f/f_\beta)} = \frac{\beta_0}{1 + j(\beta_0 f/f_T)}, \tag{5.31}$$

with f_β as 3-dB-corner frequency, f_T as (quasistatic) transit frequency, and β_0 as low-frequency current gain. The above

FIGURE 5.10 Sketch of the Output Characteristics. The impact of self-heating is shown by the dashed lines. Si-based transistors possess a much smaller BV_{CEO} value than GaAs based transistors of comparable performance. Typical units: I_C/A_E in mA/μm^2; V_{CE} in V.

equation allows a simple method for determining f_T (Gummel, 1969):

$$f_T = f\, Im^{-1}\left(\frac{1}{\underline{\beta}(f)}\right), \tag{5.32}$$

which—in addition—can be performed at fairly low frequencies (down to $f \approx f_\beta$), thus avoiding sophisticated de-embedding methods (Koolen, *et al.* 1991). The following is a quite accurate analytical expression for f_T:

$$f_T = \frac{1}{2\pi}\frac{g_m}{C_{BE} + C_{BC} + g_m[\tau_f + r_{Cx}C_{BC} + (r_E + r_B/\beta_0)(C_{BC} + C_{Eox})]}, \tag{5.33}$$

where the transconductance g_m is proportional to I_C at low-current densities.

The maximum frequency of oscillation, $f_{\max}$, depends on the power gain chosen for its extraction. According to theory, though, the magnitude of only the unilateral power gain, G_U, is expected to show a 20 dB per decade decrease in frequency in a certain frequency range. In practice, a deviation of G_U (and also of $|\underline{\beta}|$) from this ideal behavior occurs at higher frequencies due to parasitics, such as C_{BC} and nonquasistatic effects (TeWinkel, 1973; Schröter and Rein, 1995). From G_U, the following equation can be derived for CE configuration (Armstrong and French, 1995):

$$f_{\max} = \frac{f_T}{1 + C_L/C_{BC}}\sqrt{2\left[\sqrt{1 + \frac{(1 + C_L/C_{BC})^2}{8\pi f_T C_{BC}(r_B + 1/g_m)}} - 1\right]}. \tag{5.34}$$

C_L is the capacitive load at the transistor output and includes C_{jS}. For small ratios C_L/C_{BC}, the simple classical equation $f_{\max} = \sqrt{f_T/(8\pi C_{BC} r_B)}$ is obtained. The typical bias dependence of f_T and $f_{\max}$ is shown in Figure 5.11(A). Although f_T shows a moderate dependence on emitter geometry, $f_{\max}$ is a strong function of the emitter dimensions and is usually evaluated for transistors with $l_{E0} \gg b_{E0}$. An important FoM characterizing the noise behavior of a transistor is the noise factor F that can also be calculated as a function of frequency if the EC topology and element noise sources are given (Vendelin, 1990). F depends on a number of transistor parameters as well as on the generator impedance Z_G and increases at high frequencies as shown in Figure 5.11(B). Toward low frequencies, F increases again due to flicker noise. For Si and SiGe bipolar transistors, typical values of the corner frequency f_{fn} are in the order of 1 to 10 kHz, which is much lower than in MOS transistors, for example. Of particular interest for circuit applications is the minimum noise factor $F_{\min}$ at high frequencies, which is obtained by determining the minimum of F with respect to real and imaginary parts of Z_G. At high frequencies, $F_{\min}$ can be expressed analytically as a function of dc bias, transistor parameters, and frequency dependent y-parameters (Voinigescu *et al.*, 1997); a reasonable simplification is as follows:

$$F_{\min} \cong 1 + \frac{m_f}{\beta_0} + \frac{f}{f_T}\sqrt{\frac{2I_C}{V_T}(r_E + r_B)\left(1 + \frac{f_T^2}{\beta_0 f^2}\right) + \frac{m_f^2 f_T^2}{\beta_0 f^2}}. \tag{5.35}$$

5.2.8 Other Types of Bipolar Transistors

Heterojunction bipolar transistors (HBTs) show excellent high-frequency behavior and are in many respects superior to BJTs. Conventionally, HBTs have been fabricated in III–V materials such as GaAs (Ali and Gupta, 1991); major applications of those HBTs are power amplifiers. More recently, also SiGe HBTs have started entering into applications that used to be dominated by III–V semiconductors; however, so far the majority of those "HBTs" are actually transistors with an increased drift field in the base (Harame *et al.*, 1995) rather than "true" HBTs (Schüppen *et al.*, 1996) as shown in Figure 5.6(B).

Besides vertical *npn* transistors, variants of *pnp* transistors are offered in processes, since they are required for certain circuit applications, such as bias networks or push-pull stages. Only few truly complementary bipolar processes do exist (Yamaguchi *et al.*, 1994); that is, in most cases the *pnp*

transistors have a much lower performance than their *npn* counterparts. Lateral *pnp* transistors usually are quite slow (f_T around 0.2 to 1 GHz) and consume significant space on a chip. Vertical *pnp* transistors can be about a factor of 10 faster than LPNPs but suffer often from a large collector series resistance and associated high-current effects already at quite low collector current densities.

In all cases, the fundamental transistor action is the same, so that the same basic modeling approach can be used. For accurate circuit simulation, however, modifications or extensions of both the EC and some of the element equations are required.

Semiconductors

Michael Shur
Department of Electrical, Computer, and Systems Engineering, Rensselaer Polytechnic Institute, Troy, New York, USA

6.1 History of Semiconductors

In 1821, the German physicist Tomas Seebeck first noticed unusual properties of semiconductor materials, such as lead sulfur (PbS). In 1833, the English physicist Michael Faraday reported that resistance of semiconductors decreased as temperature increased (opposite to what happens in metals, in which resistance increases with temperature).

In 1873, the British engineer Willoughby Smith discovered that the resistivity of selenium, a semiconductor material, is very sensitive to light. In 1875, Werner von Siemens invented a selenium photometer, and, in 1878, Alexander Graham Bell used this device for a wireless telephone communication system. The discovery of a bipolar junction transistor by the American scientists John Bardeen, Walter Houser Brattain, and William Bradford Shockley in 1947 led to a revolution in electronics, and, soon after, semiconductor devices largely replaced electronic tubes.

6.2 Dielectrics, Semiconductors, and Metals

When atoms form solids, their electron energy states split into many close energy levels that form allowed **energy bands.** In each energy band, allowed energy levels are very close to each other, and the electron energy can vary continuously. These bands are separated by **forbidden energy gaps** as shown in Figure 6.1. The position and extent of allowed and forbidden energy gaps determine the properties of solids.

The important property of electrons is determined by the rule that is called the **Pauli exclusion principle**. According to this principle, not more than two electrons with different spins can occupy each energy state. Electrons occupy the lowest energy levels first. In semiconductors and dielectrics, almost all the states in the lowest energy bands are filled by electrons, whereas the energy states in the higher energy bands are, by and large, empty. The lower energy bands with mostly filled energy states are called the **valence bands**. The higher energy bands with mostly empty energy states are called **conduction**

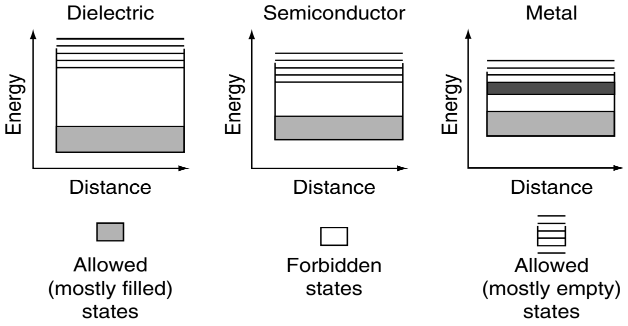

FIGURE 6.1 Band structures of a Dielectric, a Semiconductor, and a Metal. The shaded regions represent energy levels filled with electrons (two per state to satisfy the Pauli exclusion principle).

bands. The difference between the highest valence band and the lowest conduction band is called the **energy band gap** or the **energy gap**. An electron in a valence band needs the energy equal to or higher than the energy gap to experience a transition from the valence to the conduction band.

In a dielectric, the energy gap, E_g, is large so that the valence bands are completely filled and conduction bands are totally devoid of electrons. Typically for a dielectric, E_g is larger then 5 to 6 eV. For semiconductors, energy band gaps vary between 0.1 eV and 3.5 eV. The energy gap of **silicon** (Si), which is the most important semiconductor material, is approximately 1.12 eV at room temperature. The energy gap of silicon dioxide—the most widely used dielectric material in microelectronics—is 9 eV. In a metal, the lowest conduction band is partially filled with many electrons (usually one electron per atom), and the metal's resistance is very small.

6.2.1 Chemical Bonds and Crystal Structure

The most important semiconductor is silicon. Silicon belongs to the fourth column of the Periodic Table. Elements belonging to the fourth column of the Periodic Table, such as Si, Ga, As, Ge, and N, have only *s* and *p* electrons in their valence shells (shells with the largest value of the principal quantum number, *n*, for a given atom). It takes eight valence electrons to fill up all the states in these two valence subshells (two *s* electrons and six *p* electrons). In the Periodic Table, the elements with completely filled *s* and *p* valence subshells correspond to inert gases. When atoms are combined together in a solid, they may share or exchange valence electrons, forming **chemical bonds**. In silicon, germanium, and related compound semiconductors, these bonds are formed in such a way that neighboring atoms share their valence electrons having (on average) completed *s* in the valence shell. In these semiconductors, each atom forms four bonds with four other atoms (four nearest neighbors) and shares two valence electrons with each of them (i. e., an atom shares eight valence electrons with all four nearest neighbors). Since each atom has four nearest neighbors, it is **tetrahedrally coordinated** as shown in Figure 6.2.

If all atoms in a crystal are identical (as in Si or Ge, for example) the electrons shared in a bond must spend, on average, the same time on each atom. This corresponds to a purely homopolar (covalent) bond. In a compound semiconductor, such as GaAs, bonding electrons spend a greater fraction of time on the anions (i. e., negatively charged atoms). This situation corresponds to a partially heteropolar (partially ionic) bond.

The quantitative measure of the type of a chemical bond is ionicity, f_i. The ionicity is zero for a purely covalent bond and unity for a purely heteropolar bond. The ionicity values $0 < f_i < 1$ can be assigned to any binary chemical compound. Elemental semiconductors, such as Si, Ge, or diamond, have zero ionicity. According to the ionicity scale proposed by Phillips in 1973, $f_i = 0.177$ for silicon carbide (SiC) and $f_i = 0.31$ for GaAs.

There are very few elemental semiconductors (e.g., Si, Ge, and C). Many compound materials (such as GaAs, InP, AlGaAs, and GaN), however, also have the tetrahedral bond configuration seen in Figure 6.3 and exhibit semiconducting properties.

Some of these semiconductors, such as GaAs and AlGaAs or GaN and AlGaN, can be grown as films on top of each other to form heterostructures. Hence, very many different material combinations with different properties are available to a semiconductor device designer. As can be seen from Figure 6.2, each silicon atom is located at the center of the tetrahedron formed by four other silicon atoms. In Si, such an arrangement is formed by two interpenetrating face-centered cubic sublattices of silicon atoms, shifted with respect to each other by one fourth of the body diagonal. A diamond crystal (one of the crystalline modifications of carbon) has the same crystal structure, which is traditionally called the **diamond crystal structure** (see Figure 6.4). Another important semiconductor—germanium (Ge)—also has the diamond crystal structure.

Most compound semiconductors have the **zinc blende** crystal structure seen in Figure 6.5 that is very similar to the diamond structure. This structure contains two kinds of atoms, A and B, with each species forming a face-centered cubic lattice. These mutually penetrating face-centered cubic (fcc) lattices of element A and element B are shifted relative to each other by a quarter of the body diagonal of the unit cell cube.

6.2.2 Electrons and Holes

In the absence of an electric field, electrons in a semiconductor move randomly because of thermal motion. The average velocity of this motion is called thermal velocity. An electric field accelerates electrons and causes a component of the electron velocity to go in the direction of the electric field. This velocity of the directed electronic motion in the electric field is called the **drift velocity**. This drift velocity results in an electric current.

To the first order, the difference between the motion of conduction band electrons and free electrons can be approximately described by introducing an electron **effective mass**, m_n, which is different from the **free electron mass**, $m_e = 9.11 \times 10^{-31}$ kg. For example, in gallium arsenide (GaAs), $m_n \sim 0.067\, m_e$.

A valence band electron can change its energy and velocity if and only if it can be promoted to an empty energy level. The vacant levels in the valence band allow electrons in the valence band to move as shown in Figure 6.6.

The motion of a vacant energy level in the valence band can be visualized as the motion of a fictitious particle (called a **hole**). The absence of a negative electronic charge, $-q$, corresponds to a positive charge $q = -(-q)$. Hence, the hole has a positive charge with a magnitude equal to the electronic charge. To the first order, holes can be treated as particles with a certain effective mass, m_p.

6.2.3 Band Diagrams

Usually, conducting electrons occupy states in the conduction band that are close to the lowest energy in the conduction band, E_c, which is called the **conduction band edge** or the **bottom of**

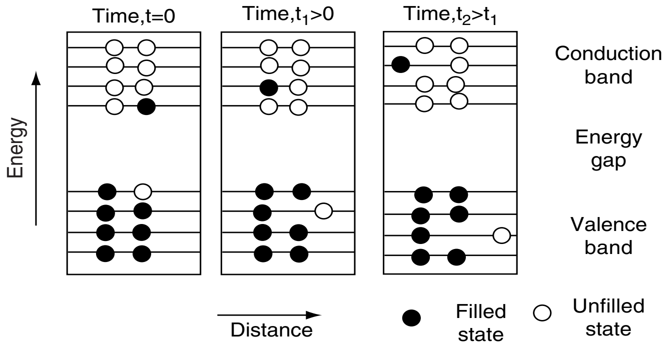

FIGURE 6.6 Motion of Electrons in an Electric Field. Solid circles represent electrons occupying energy levels; open circles represent energy levels available for electrons.

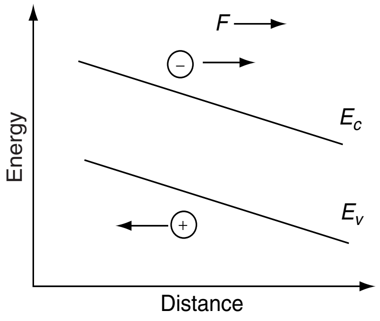

FIGURE 6.7 Band Diagram of a Semiconductor in an Electric Field

the conduction band. Holes occupying states in the valence band are close to the highest energy in the valence band, E_v. E_v is called the **valence band edge** or the **top of the valence band**. The dependencies of E_c and E_v in a semiconductor device on position are called **band diagrams.** Band diagrams are very useful for illustrating properties and understanding behavior of semiconductor materials and devices. As an example, Figure 6.7 shows a band diagram of a semiconductor in an electric field.

In an electric field, F, the bands are tilted, with the slope $-qF$. The arrows in Figure 6.7 represent the directions of forces exerted on the electrons and holes by the electric field. (Since electrons are charged negatively and holes are charged positively, they move in opposite directions.)

In free space, an electron energy is as follows:

$$E = m_e v^2/2, \tag{6.1}$$

where m_e is the free electron mass and v is the electron velocity. According to the basics of quantum mechanics, an electron has both particle-like and wave-like properties and its momentum, $p = m_e v$, can be related to its wave vector, k:

$$p = \hbar k, \tag{6.2}$$

where $\hbar = 1.055 \times 10^{-34}$ js is the Planck constant. Hence, equation 6.1 can be rewritten as:

$$E = \hbar^2 k^2/2m_e. \tag{6.3}$$

In semiconductor materials, $E(k)$ dependence is more complex (see Figure 6.8). Near the lowest point of the conduction band, the dependence of the electron energy on the wave vector can still be approximated by a parabolic function similar to that for an electron in free space (see equation 6.3 and Figure 6.8). The curvature of this dependence, however, is usually quite different from that for an electron in free space. Moreover, different crystallographic directions are not equivalent, and this curvature may depend on direction. These features can be accounted for by introducing an inverse effective mass tensor with components defined as follows:

$$\frac{1}{m_{i,j}} = \frac{1}{\hbar^2}\frac{\partial^2 E_n}{\partial k_i \partial k_j}, \tag{6.4}$$

k_i and k_j are the projections of the wave vector $\boldsymbol{k}$. When $E(k)$ depends only on the magnitude of $\boldsymbol{k}$, and not on the k direction, this tensor reduces to a scalar inverse effective mass, $1/m_n$. This is the case for GaAs, where dependence of the electron energy on the wave vector near the lowest point of the conduction band can be approximated by the following function:

$$E_n(k) = E_c + \frac{\hbar^2 k^2}{2m_n}. \tag{6.5}$$

In Si, however, the lowest minimum point of the conduction band is quite anisotropic. In this case, the simplest equation for $E(k)$ is obtained by expressing k in terms of two components: k_l and k_t, which is perpendicular to k_l. These components are called **longitudinal and transverse components** of k, respectively. (This takes into account the crystal symmetry, which makes all possible directions of k_t equivalent.) Now the inverse effective mass tensor reduces to two components: $1/m_l$ and $1/m_t$, where m_l and m_t are called the **longitudinal effective mass** and **transverse effective mass**, respectively. In this case, the equation for $E(k)$ is given by:

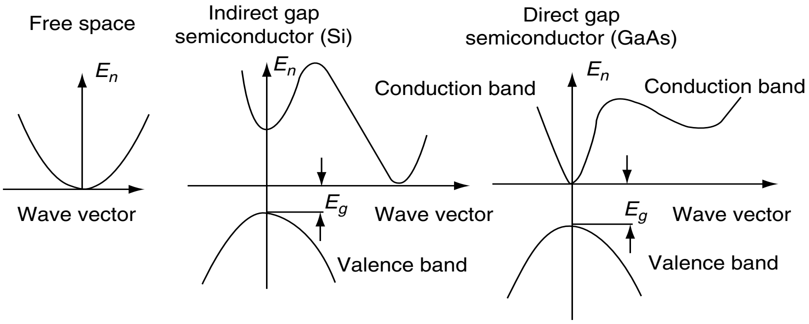

FIGURE 6.8 Qualitative Energy Spectra for Electrons in Free Space. Si and GaAs. Shaded states in valence bands are filled with valence electrons. Figure adapted from Shur (1996).

$$E_n(k) = E_c + \frac{\hbar^2}{2}\left(\frac{k_l^2}{m_l} + \frac{k_t^2}{m_t}\right). \tag{6.6}$$

For Si, $m_l \sim 0.98\, m_e$ and $m_t \sim 0.189\, m_e$, where m_e is the free electron mass, so that these two effective masses are quite different indeed!

For holes, an equation similar to equation 6.5 is written as:

$$E_p(k) = E_v - \frac{\hbar^2 k^2}{2m_p}. \tag{6.7}$$

Equation 6.7 can be used for the valence bands in cubic semiconductors. Here E_v is the energy corresponding to the top of the valence band, and m_p is called a **hole** effective mass.

Doping

In a pure semiconductor, the electron concentration in the conduction band and the hole concentration in the valence band are usually very small compared to the number of available energy states. These concentrations can be changed by many orders of magnitude by **doping**, which means adding to a semiconductor impurity atoms that can "donate" electrons to the conduction band (such impurities are called donors) or "accept" electrons from the valence band creating holes (such impurities are called acceptors). Both donors and acceptors are referred to as **dopants**. A donor atom has more electrons available for bonding with neighboring atoms than is required for an atom in the host semiconductor. For example, a silicon atom has four electrons available for bonding and forms four bonds with the four nearest silicon atoms. A phosphorus atom has five electrons available for bonding. Hence, when a phosphorus atom replaces a silicon atom in a silicon crystal, it can bond with the four nearest neighbors and "donate" one extra electron to the conduction band.

An acceptor atom has fewer electrons than are needed for chemical bonds with neighboring atoms of the host semiconductor. For example, a boron atom has only three electrons available for bonding. Hence, when a boron atom replaces a silicon atom in silicon, it "accepts" one missing electron from the valence band, creating a hole.

A semiconductor doped with donors is called an ***n*-type** semiconductor. A semiconductor doped with acceptors is called a ***p*-type** semiconductor. Often, especially at room temperature or elevated temperatures, each donor in an *n*-type semiconductor supplies one electron to the conduction band, and the electron concentration, n, in the conduction band is approximately equal to the donor concentration, N_d. In a similar way, at room temperature or elevated temperatures, each acceptor creates one hole in the valence band, and the hole concentration, p, in the valence band of a *p*-type semiconductor is approximately equal to the acceptor concentration, N_a. If both donors and acceptors are added to a semiconductor, they "compensate" each other, since electrons supplied by donors occupy the vacant levels in the valence band created by the acceptor atoms. In this case, the semiconductor is called **compensated**. In a compensated semiconductor, the largest impurity concentration "wins": if $N_d > N_a$, the compensated semiconductor is *n*-type with the effective donor concentration, $N_{deff} = N_d - N_a$; if $N_d < N_a$, the compensated semiconductor is *p*-type with the effective acceptor concentration, $N_{aeff} = N_a - N_d$.

6.3 Electron and Hole Velocities and Mobilities

Electrons and holes experience a chaotic random thermal motion. The average kinetic energy of thermal motion per one electron is $3k_BT/2$, where T is temperature in degrees Kelvin and k_B is the Boltzmann constant. The electron **thermal velocity**, v_{thn}, is found by equating the electron kinetic energy to $3k_BT/2$:

$$\frac{m_n v_{thn}^2}{2} = \frac{3k_BT}{2}, \tag{6.8}$$

where m_n is the electron effective mass. From equation 6.8:

$$v_{thn} = \left(\frac{3k_BT}{m_n}\right)^{1/2}. \tag{6.9}$$

Thermal velocities v_{thn} and v_{thp} represent average magnitudes of electron and hole velocities caused by the thermal motion. Since the directions of this thermal motion are random, the same number of carriers crosses any device cross-section in any direction so that the electric current is equal to zero.

In an electric field, the electrons and holes acquire an additional drift velocity caused by the electric field, which is superimposed on the chaotic thermally induced velocities. In a uniform semiconductor and in a weak electric field, F, the drift velocities, v_n and v_p, of the electrons and holes are proportional to the electric field:

$$v_n = -\mu_n \mathbf{F}. \tag{6.10}$$

and

$$v_p = \mu_p \mathbf{F}. \tag{6.11}$$

The μ_n and μ_p are called the electron and hole mobilities, respectively. (The direction of v_p coincides with the direction of the electric field, and the direction of v_n is opposite to the direction of the electric field, since holes are positively charged and electrons are negatively charged.) The total charge of the electrons crossing a unit area of a semiconductor per second is qnv_n, where n is the electron concentration in the conduction band. The charge of the holes crossing a unit area of a semiconductor per second is qpv_p, where p is the hole concentration in the valence band. Hence, using equations 6.1 and 6.2, we obtain the following expressions for the current density, j, and conductivity, σ for a semiconductor:

$$j = \sigma F, \tag{6.12}$$

where

$$\sigma = q\mu_n n + q\mu_p p. \tag{6.13}$$

Often, the hole contribution to the conductivity of an n-type semiconductor can be neglected because the hole concentration is many orders of magnitude smaller than the electron concentration. Likewise, the electron contribution to the conductivity of a p-type semiconductor can often be neglected.

Equation 6.12 is called **Ohm's law**. We can rewrite this equation in a more familiar form:

$$I = V/R, \tag{6.14}$$

where $I = jS$ is the total current, S is the sample cross-section, $V = FL$ is the potential difference across the sample (here a constant electric field is assumed), and L is the sample length. The **sample resistance** is the following:

$$R = \frac{L}{\sigma S}. \tag{6.15}$$

Remember that, in semiconductors, Ohm's law is only valid when an electric field is weak, which is rarely the case in modern semiconductor devices.

To the first order, equation 6.10 can be interpreted by using the second law of motion for an electron in the conduction band:

$$m_n \frac{dv_n}{dt} = -qF - m_n \frac{v_n}{\tau_{np}}. \tag{6.16}$$

The first term in the right-hand side of equation 6.16 represents the force from the electric field. The second term in the right-hand side of the same equation represents the loss of the electron momentum, $m_n v_n$, due to electron collisions with impurities and/or lattice vibrations; τ_{np} is called the momentum relaxation time. From equation 6.16, in a steady state:

$$v_n = -\mu_n F,$$

where

$$\mu_n = \frac{q\tau_{np}}{m_n}. \tag{6.17}$$

The τ_{np} is an average time between random collisions interrupting these free electron flights. The average distance that an electron travels between two collisions is called the **mean free path**. In relatively weak electric fields when the electron drift velocity is much smaller than the thermal velocity, the mean free path is given by:

$$\lambda_n = v_{thn}\tau_{np}. \tag{6.18}$$

The momentum relaxation time, τ_{np}, can be approximately expressed as:

$$\frac{1}{\tau_{np}} = \frac{1}{\tau_{ii}} + \frac{1}{\tau_{ni}} + \frac{1}{\tau_{\text{lattice}}} + \ldots, \tag{6.19}$$

where the terms on the right-hand side represent momentum relaxation times due to different scattering processes such as **ionized impurity scattering** (τ_{ii}), **neutral impurity scattering** (τ_{ni}), and **lattice vibration scattering** (τ_{lattice}).

In a low electric field, τ_{np} and m_n are independent of the electric field, and the electron drift velocity, v_n, is proportional to the electric field. However, in high electric fields when electrons may gain considerable energy from the electric field, τ_{np} and, in certain cases, m_n become strong functions of the electron energy and, hence, of the electric field. In a high electric field, electrons gain energy from the field, and their average energy exceeds the thermal energy (they become "hot").

Hot electrons transfer energy into thermal vibrations of the crystal lattice. Such vibrations can be modeled as harmonic oscillations with a certain frequency, ω_l. The energy levels of a harmonic oscillator are equidistant with the energy difference between the levels equal to $E_l = \hbar\omega_l$. Hence, the scattering process for a hot electron can be represented as follows. The electron accelerates in the electric field until it gains enough energy to excite lattice vibrations:

$$\frac{m_n v_{n\max}^2}{2} = E_n - E_o \approx \hbar\omega_l, \tag{6.20}$$

where $v_{n\max}$ is the maximum electron drift velocity. Then the scattering process occurs, and the electron loses all the excess energy and all the drift velocity. Hence, the electron drift velocity varies between zero and $v_{n\max}$, and average electron drift velocity ($v_n = v_{n\max}/2$) becomes nearly independent of the electric field:

$$v_n \approx \sqrt{\frac{\hbar\omega_l}{2m_n}} = v_{sn}. \tag{6.21}$$

The v_{sn} is called the **electron saturation velocity**.

Figure 6.9 shows the dependencies of the electron drift velocity on the electric field for several semiconductors.

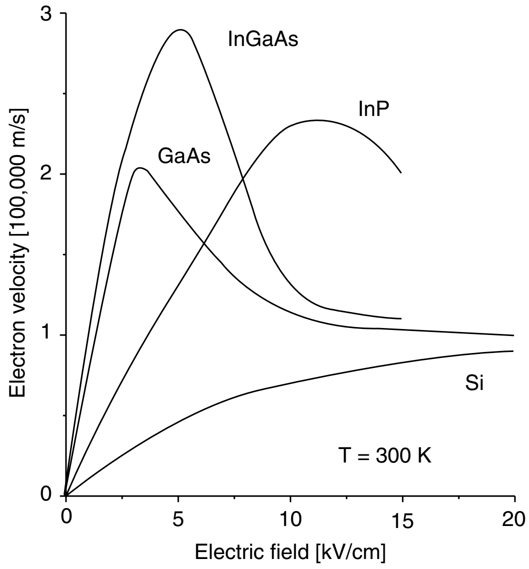

FIGURE 6.9 Velocity Versus Electric Field for Several Semiconductors. Figure adapted from Shur (1996).

As can be seen from Figure 6.9, in Si, the drift velocity saturates in high electric fields, as expected. In many compound semiconductors, such as GaAs, InP, and InGaAs, the electron velocity decreases with an electric field in a certain range of high electric fields. (In this range of the electric fields, the electron differential mobility, $\mu_{dn} = dv_n/dF$, is negative.) In these semiconductors, the central valley of the conduction band (Γ) is the lowest as shown in Figure 6.8. In high electric fields, hot electrons acquire enough energy to transfer from the central valley of the conduction band (where the effective mass and, hence, the density of states is relatively small) into the satellite valleys, where electrons have a higher effective mass and, hence, a larger density of states but a smaller drift velocity.

As can be seen from Figure 6.9, compound semiconductors have a potential for a higher speed of operation than silicon because electrons in these materials may move faster. The negative differential mobility observed in many compound semiconductors can be used for generating microwave oscillations at very high frequencies.

Modern semiconductor devices are often so small that their dimensions are comparable to or even smaller than the electron mean free path. In this case, electrons may acquire higher velocities than those shown in Figure 6.9, since transient effects associated with acceleration of carriers become important. In the limiting case of very short devices, the electron transit time may become so small that most electrons will not experience any collisions during the transit. Such a mode of electron transport is called **ballistic transport**.

Figure 6.10 shows the dependence of the electron and hole mobilities in Si on temperature for different electron concentrations.

6.3.1 Impact Ionization

In high electric fields, electron-hole pairs in a semiconductor are often generated by **impact ionization**. In this process, an electron (or a hole) acquires enough energy from the electric field to break a bond and promote another electron from the valence band into the conduction band. The electron impact ionization generation rate, G_{ni}, is proportional to the electron concentration, n, to the electron velocity, v_n, and to the **impact ionization coefficient**, α_{ni}:

$$G_{ni} = \alpha_{ni} n v_n, \tag{6.22}$$

where α_{ni}, is given by the following empirical expression:

$$\alpha_{ni} = \alpha_{no} \exp[-(F_{in}/F)^{m_{in}}]. \tag{6.23}$$

In a similar fashion, when the impact ionization is caused by holes, the result is as follows:

$$G_{pi} = \alpha_{pi} p v_p. \tag{6.24}$$

$$\alpha_{pi} = \alpha_{po} \exp\left[-(F_{ip}/F)^{m_{ip}}\right]. \tag{6.25}$$

Here F is an electric field and α_{no}, α_{po}, F_{in}, F_{ip}, m_{in}, and m_{ip} are constants that depend on semiconductor material and, in certain cases, even on the direction of the electric field. The impact ionization coefficients for Si calculated by using

6.3.2 Optical Properties

Generation of electron-hole pairs in a semiconductor can be achieved by illuminating a semiconductor sample with light with photon energies larger than the energy gap of the semiconductor. The light is partially reflected from the semiconductor surface and partially absorbed in the semiconductor (see Figure 6.12).

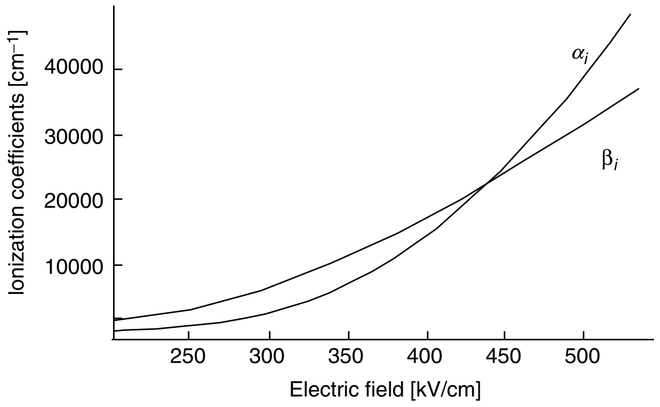

FIGURE 6.11 Impact Ionization Coefficients for Si; $\alpha_0 = 3,\ 318\,\text{cm}^{-1}$, $F_{no} = 1,174\,\text{kV/cm},\ m_{in} = 1$. Figure adapted from Shur (1996).

The light intensity P_l (measured in W/m^2) is given by:

$$P_l = P_o \exp(-\alpha x), \tag{6.26}$$

where P_o is the light intensity at the surface. The distance $1/\alpha$ is called the **light penetration depth** (see Figure 6.12(B)). If $1/\alpha \gg L$, where L is the sample dimension, the generation rate of electron-hole pairs is nearly uniform in the sample. Absorption coefficient, α, is a strong function of the wavelength. (Typically, α is measured in the range from 10^2 to $10^6\,\text{cm}^{-1}$.) The number of generated electron-hole pairs is proportional to the number of absorbed photons. Since the energy of each photon is $\hbar\omega$, the generation rate is given by:

$$G = Q_e \frac{\alpha P_l}{\hbar\omega}, \tag{6.27}$$

where Q_e is equal to the average number of electron-hole pairs produced by one photon. Q_e is called the **quantum efficiency**.

FIGURE 6.13 Recombination Processes According to Electron-Hole Pair Generation. The figures show (A) direct (band-to-band) radiative recombination, (B) radiative band-to-impurity recombination, (C) nonradiative recombination via impurity (trap) levels, and (D) surface recombination. Figure adapted from Shur (1996).

For $\hbar\omega > E_g$, the quantum efficiency Q_e is often fairly close to unity.

Under equilibrium conditions, $G = R$, where R is the recombination rate; that is, the generation of electron-hole pairs is balanced by different recombination processes that include **direct** (**band-to-band**) **radiative recombination**, **radiative band-to-impurity recombination**, **nonradiative recombination via impurity (trap) levels**, **Auger recombination**, and **surface recombination**. These processes (except for the Auger recombination discussed below) are schematically shown in Figure 6.13.

In the radiative recombination processes, recombining electron-hole pairs emit light, and the energy released during this recombination process is transformed into the energy of photons. Since during band-to-band recombination, the energy released by each recombining electron-hole pair is either equal to the energy gap or is slightly higher, the frequency of the emitted radiation can be estimated as:

$$\hbar\omega = E_g. \tag{6.28}$$

The radiative band-to-band recombination rate is proportional to the np product:

$$R = A\left(np - n_i^2\right), \tag{6.29}$$

since both electrons and holes are required for the band-to-band recombination (just like the number of marriages in a city should be proportional to both the number of eligible men and to the number of eligible women). In practical light-emitting semiconductor devices, radiative band-to-impurity recombination may be more important than radiative band-to-band recombination. The radiative band-to-impurity recombination rate is given by:

$$R = p/\tau_r, \tag{6.30}$$

where p is the concentration of the electron-hole pairs, $\tau_r = 1/(B_r N_t)$, N_t is the concentration of impurities involved in this radiative recombination process, and B_r is a constant.

In many cases, the dominant recombination mechanism is recombination via traps, especially in indirect semiconductors such as silicon. Shockley and Reed were first to derive the famous (but somewhat long) expression for the recombination rate related to traps:

$$R = \frac{pn - n_i^2}{\tau_{pl}(n + n_l) + \tau_{nl}(p + p_l)}. \tag{6.31}$$

Here, n_i is the intrinsic carrier concentration, and τ_{nl}, τ_{pl} are electron and hole lifetimes given by:

$$\tau_{nl} = \frac{1}{v_{thn}\sigma_n N_t} \text{ and } \tau_{pl} = \frac{1}{v_{thp}\sigma_p N_t}, \tag{6.32}$$

where v_{thn} and v_{thp} are electron and hole thermal velocities, σ_n and σ_p are effective capture cross-sections for electrons and holes, and N_t is the trap concentration. The carrier concentrations corresponding to the position of the Fermi level coinciding with the trap level can be written as follows:

$$n_l = N_c \exp\left(\frac{E_t - E_c}{k_B T}\right) \text{ and } p_l = N_v \exp\left(\frac{E_v - E_t}{k_B T}\right). \tag{6.33}$$

Here N_c and N_v are the effective densities of states in the conduction and valence bands, respectively, and E_t is the energy of the trap level. When electrons are minority carriers ($n = n_p \ll p \approx N_a = p_p$, where N_a is the concentration of shallow ionized acceptors, $p \gg p_l$, $p \gg n_l$), equation 6.31 reduces to:

$$R = \frac{n_p - n_{po}}{\tau_{nl}}, \tag{6.34}$$

where $n_{po} = n_i^2/N_a$. When holes are minority carriers ($p = p_n \ll n \sim N_d = n_n$, where N_d is the concentration of shallow ionized donors, $n \gg n_l$, $n \gg p_l$:

$$R = \frac{p_n - p_{no}}{\tau_{pl}}, \tag{6.35}$$

where $p_{no} = n_i^2/N_d$. The electron lifetime, τ_{nl}, in p-type silicon and the hole lifetime, τ_{pl}, in n-type silicon decrease with increasing doping. At low doping levels, this decrease may be explained by higher trap concentrations in the doped semiconductor. We can crudely estimate electron and hole lifetimes in Si as follows:

$$\tau_{nl}(\mathrm{s}) = \frac{10^{12}}{N_a(\mathrm{cm}^{-3})} \text{ and } \tau_{pl}(\mathrm{s}) = \frac{3 \times 10^{12}}{N_d(\mathrm{cm}^{-3})}. \tag{6.36}$$

At high doping levels, however, the lifetimes decrease faster than the inverse doping concentration. The reason is that a different recombination mechanism, called **Auger recombination**, becomes important. In an Auger process, an electron and a hole recombine without involving trap levels, and the released energy (of the order of the energy gap) is transferred to another carrier (a hole in p-type material and an electron in n-type material). Auger recombination is the inverse of impact ionization, where energetic carriers cause the generation of electron-hole pairs. Since two electrons (in n-type material) or two holes (in p-type material) are involved in the Auger recombination process, the recombination lifetime associated with this process is inversely proportional to the square of the majority carrier concentration; that is:

$$\tau_{nl} = \frac{1}{G_p N_a^2} \text{ and } \tau_{pl} = \frac{1}{G_n N_d^2}, \tag{6.37}$$

for p-type material and for n-type material, respectively, where $G_p = 9.9 \times 10^{-32}\,\mathrm{cm}^6/\mathrm{s}$ and $G_n = 2.28 \times 10^{-32}\,\mathrm{cm}^6/\mathrm{s}$ for silicon.

As stated previously, in many cases the recombination rate can be presented as $R = (p_n - p_{no})/\tau_{pl}$ (in n-type material in which holes are minority carriers). In this case, the diffusion of the minority carriers can be described by the **diffusion equation**:

$$D_p \frac{\partial^2 p_n}{\partial x^2} - \frac{p_n - p_{no}}{\tau_{pl}} = 0. \tag{6.38}$$

The solution of this second-order linear differential equation is given by:

$$\Delta p = A \exp(x/L_p) + B \exp(-x/L_p), \tag{6.39}$$

where $\Delta p = p_n - p_{no}$, A and B are constants to be determined from the boundary conditions, and

$$L_p = \sqrt{D_p \tau_{pl}} \tag{6.40}$$

is called the **hole diffusion length**. A similar diffusion equation applies to electrons in p-type material, where electrons are minority carriers. The **electron diffusion length** is then given by:

$$L_n = \sqrt{D_n \tau_{nl}}. \tag{6.41}$$

6.4 Important Semiconductor Materials

Today, most semiconductor devices are made of silicon. However, submicron devices made of compound semiconductors, such as gallium arsenide or indium phosphide, successfully compete for applications in microwave and ultra-fast digital circuits. Other semiconductors, such as mercury cadmium telluride are utilized in infrared detectors. Silicon carbide, aluminum nitride, and gallium nitride promise to be suitable for power devices operating at elevated temperatures and in harsh environments. Hydrogenated amorphous silicon and related compounds have found important applications in the display industry and in photovoltaics. Ternary compounds, quaternary compounds, and heterostructure materials provide another important dimension to semiconductor technology. Developing new semiconductor materials and using their unique properties in electronic industry is a major challenge that will exist for many years to come.

Power Semiconductor Devices

7.1 Introduction

Power semiconductor devices are used as switches in power electronics applications. Ideal switches arbitrarily block large forward and reverse voltages, with zero current flow in the off-state, arbitrarily conduct large currents with zero voltage drop in the on-state, and have negligible switching time and power loss. Material and design limitations prevent semiconductor devices from operating as ideal switches. It is important to understand the operation of these devices to determine how much the device characteristics can be idealized. Available semiconductor devices could be either controllable or uncontrollable. In an **uncontrollable device**, such as the diode, on-and off-states are controlled by circuit conditions. Devices like BJTs, MOSFETs, and their combinations can be turned on and off by control signals, and hence, are **controllable devices**. **Thyristors** belong to an intermediate category defined by latch-on being determined by a control signal and turn-off governed by external circuit conditions. This chapter presents a summary of the design equations, terminal characteristics, and the circuit performance of contemporary and emerging power devices.

7.2 Breakdown Voltage

Figure 7.1(A) shows the cross-section of a typical **power diode**. A *p*-*n* junction is formed when an *n*-type region in a semiconductor crystal abuts a *p*-type region in the same crystal. Rectification properties of the device result from the presence of two types of carriers in a semiconductor: electrons and holes. Power devices are required to block high voltage when the anode is biased negative with respect to the cathode. Application of a reverse bias removes carriers from the junction and creates a depletion region devoid of majority carriers. The width of the depletion layer depends on the applied bias, V_R, and doping of the region, N_D, as:

$$W_D = \sqrt{\frac{2\varepsilon(V_R + V_{bi})}{qN_D}}, \tag{7.1}$$

where V_{bi} is the built-in potential. A high electric field is formed in the depletion layer. This field rises as the reverse voltage is increased until a critical electric field, E_C, is reached, at which point the device breaks down. The critical electric field for Si is roughly $2 \times 10^5\,\mathrm{V/cm}$. A nonpunchthrough diode has drift region doping (N_D) and width $(W_{D,pp})$ parameters such that the critical electric field is reached before the entire region is depleted. In such cases, the breakdown voltage, V_{BD}, and depletion width at breakdown, W_D, for a given doping level are expressed as:

$$V_{BD} = 5.34 \times 10^{13} N_D^{-3/4} \tag{7.2a}$$

and

$$W_{D,pp} = 2.67 \times 10^{10} N_D^{-7/3}. \tag{7.2b}$$

In some power devices, it is preferable to use a punchthrough structure to support the voltage. In this case, the entire drift region is depleted at the time of breakdown. The breakdown voltage of a punchthrough device with a certain doping (N_D) and width $W_D(< W_{D,pp})$ is given as:

$$V_{BD} = E_C W_D - \frac{qN_D W_D^2}{2\varepsilon}. \tag{7.3}$$

The thickness, W_D, of the punchthrough structure is smaller than that of the nonpunchthrough device with the same breakdown voltage. A thinner drift region is preferable for bipolar power devices, such as P-i-N diodes operating under high-level injection conditions.

Planar diodes are formed by implantation and diffusion of impurities through a rectangular diffusion window. A cylindrical junction is formed at the straight edges of the diffusion window, and a spherical junction is formed at each of the corners. The breakdown voltage of practical devices can be significantly lower than the ideal values by the occurrence of high electric fields at the device edges. With respect to the parallel-plane breakdown voltage, $V_{BD,pp}$, the breakdown voltage of cylindrical $(V_{BD,CYL})$ and spherical $(V_{BD,SP})$ junctions with a junction depth x_j is given as the following two equations:

$$\frac{V_{BD,CYL}}{V_{BD,PP}} = \frac{1}{2}\left[\left(\frac{x_j}{W_D}\right)^2 + 2\left(\frac{x_j}{W_D}\right)^{6/7}\right] \ln\left[1 + 2\left(\frac{x_j}{W_D}\right)^{8/7}\right] - \left(\frac{x_j}{W_D}\right)^{6/7}. \tag{7.4a}$$

$$\frac{V_{BD,SP}}{V_{BD,PP}} = \left(\frac{x_j}{W_D}\right)^2 + 2.14\left(\frac{x_j}{W_D}\right)^{6/7} - \left[r\left(\frac{x_j}{W_D}\right)^3 + 3\left(\frac{x_j}{W_D}\right)^{13/7}\right]^{2/3}. \tag{7.4b}$$

FIGURE 7.1 Typical Power Diode (P-i-N)

EXAMPLE 7.1. The asymmetrically doped p^+n diode shown in Figure 7.1 should be designed to support a reverse voltage of 500 V by forming a p^+ junction 5 μm deep into the n-type material. For avalanche breakdown at the parallel-plane junction, the drift region doping and maximum depletion width at breakdown are obtained using equation 7.3 to yield $5 \times 10^{14}\,\mathrm{cm}^{-3}$ and 36 μm respectively.

Considering that the p^+ junction is 5 μm deep into the n-type drift region, the diode forms a cylindrical junction at the edge, with a radius of 5 μm. This gives a ratio of 0.14 with the ideal parallel plane breakdown depletion width. Then, using equation 7.4a, the finite device will have a cylindrical breakdown voltage that is 40% of the ideal parallel plane breakdown. In this case, the finite device has a breakdown voltage of 200 V.

Special device termination structures have been devised to reduce the electric field strength at the device edge and to raise the breakdown voltage close to the ideal value. These include floating field rings, field plates, bevelled edges, ion-implanted edge terminations, and so forth.

7.3 P-i-N Diode

The **P-i-N diode** has a punchthrough structure as described earlier and has an n^+ region at the end of the drift region opposite from the rectifying junction. The n^+ region provides an ohmic cathode contact and injects electrons into the drift region under high-level injection. When the diode is forward biased, the p^+ anode injects minority holes into the drift region, resulting in current flow. The forward bias current flow is determined by recombination of the minority carriers injected into the drift region. The device conducts in low-level injection regime when the injected minority carrier density is much lower than background doping. The magnitude of this current is written as:

$$J_F = \frac{qD_p p_{on}}{L_p}\left(e^{\frac{qVF}{kT}} - 1\right), \tag{7.5}$$

where V_F is the voltage drop across the rectifying junction.

Away from the junction in the drift region, current flow is dominated by majority carriers under the influence of an electric field. This causes a resistive voltage drop. During on-state current flow, when injected minority carrier density exceeds background doping concentration, the device is said to be conducting in high-level injection. The current flow in high-level injection is given by:

$$J_F = \frac{2qL_a n_i}{\tau_a}\tan\mathrm{h}\left(\frac{W_D}{2L_a}\right)\left(e^{\frac{qVF}{kT}} - 1\right), \tag{7.6}$$

where τ_a and L_a are the ambipolar carrier lifetime and diffusion length, respectively.

7.3.1 Switching Characteristics

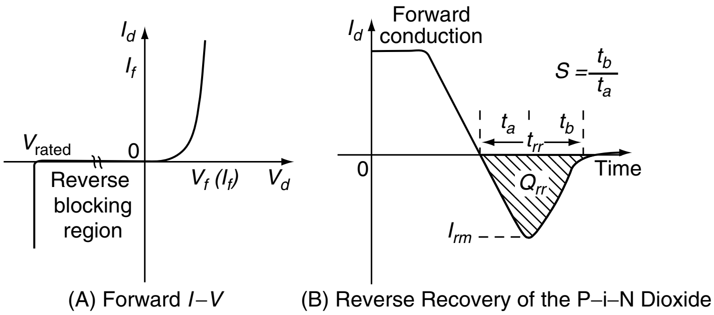
A power diode requires a finite time to switch from the blocking state (reverse bias) to the on-state (forward bias) and vice versa. This is because of the finite time required for establishment and removal of steady-state carrier distribution in the drift region. During turn-on, the terminal voltage, V_A, first rises to a value V_{FP} that is much higher than the static forward drop before decaying to the steady-state value, V_F, determined by the static characteristics. This process is called forward recovery, and V_{FP} is known as the forward recovery voltage. When the diode is turned off, the current changes at a rate dI/dt determined by the external circuit conditions. The diode current displays a negative peak before decaying to zero. Correspondingly, device voltage rises to the off-state voltage, $\mathrm{V_R}$. The process of negative current flow during device turn-off is referred to as the **reverse recovery process**. The current, I_{rr}, is the reverse recovery current peak, and t_{rr} is the reverse recovery time. These quantities are expressed as:

$$I_{rr} = \sqrt{\frac{2Q_{rr}(di_R/dt)}{S+1}} \tag{7.7a}$$

and

$$t_{rr} = \sqrt{\frac{2Q_{rr}(S+1)}{di_R/dt}}, \tag{7.7b}$$

where S is the "snappiness" factor defined in Figure 7.2. The variable Q_{rr} represents the reverse charge extracted out of the diode and is indicated by the shaded area in Figure 7.2.



(A) Forward I–V (B) Reverse Recovery of the P–i–N Dioxide

FIGURE 7.2 Reverse and Forward Biases of a Power Node

The extracted charge, Q_{rr}, is a fraction of the total charge $Q_F(=\tau_F I_F)$ stored in the diode during forward bias.

EXAMPLE 7.2. The diode designed in example 7.1 has a high-level carrier lifetime of 500 ns. At a current density of 100 A/cm^2, assuming conduction in high-level injection, the voltage drop across the diode is roughly given by equation 7.2, where $L_a = \sqrt{(D_a\tau_a)}$. The ambipolar diffusion constant, D_a, for a diode at room temperature is 9 cm^2/V-s. Then, for a lifetime of 500 ns, the ambipolar diffusion length, L_a, is 21 μm, and the forward voltage of the diode is 0.82 V.

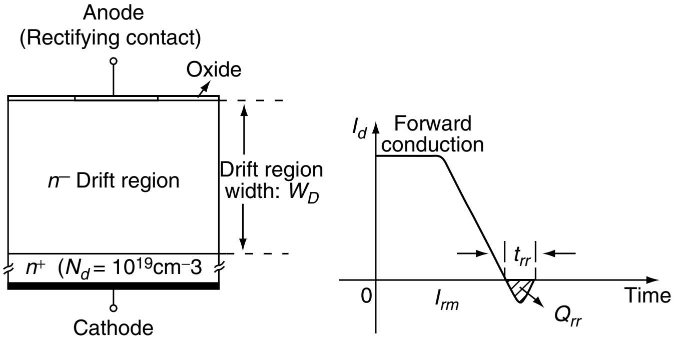
This diode is turned off from an on-state current density of 100 A/cm^2 with a turn-off dJ/dt of 100 A/cm^{2}μs. Assuming that all the excess charge is removed from the device, $Q_{rr} \sim Q_F = \tau_F J_F$. Thus, a charge of 50 μC is removed from the device. For a diode with S = 1, the reverse recovery current has a magnitude of 71 A/cm^2 and a duration of 0.7 μs.

7.4 Schottky Diode

A P-i-N diode displays large reverse recovery transients because of charge accumulation in the drift region brought about by bipolar current flow. A majority carrier diode may be formed by making a rectifying junction between a metal and the semiconductor. Such a device, as shown in Figure 7.3, is referred to as the **Schottky diode**. The rectifying characteristics of a Schottky diode are identical to a P-i-N diode, although the fundamental physics of operation are quite different. The forward current of a Schottky diode is expressed as:

$$J_F = A^* T^2 e^{\frac{q^{\cdot}Bo}{kT}}\left(e^{\frac{qV_F}{kT}} - 1\right), \tag{7.8}$$

where A^* is the effective Richardson's constant and where ϕ_{Bo} is the metal-semiconductor barrier height defined as the difference between the metal and semiconductor work



(A) Cross-Section (B) Typical Reverse Recovery

FIGURE 7.3 A Schottky Diode

functions. Current flow is dominated by majority carriers. The Schottky diode has a negligible stored charge in the drift region because of a lack of minority carriers. The switching transients do not include forward and reverse recovery. A finite transient recovery is observed because of the capacitance associated with the depletion region. However, the reverse leakage current is considerably higher than for P-i-N diodes. Furthermore, at higher voltage rating, the Schottky diode has a considerable voltage drop in the drift region, expressed as:

$$V_{dr} = \frac{J_F W_D}{q\mu_n N_D}. \tag{7.9}$$

EXAMPLE 7.3. A Schottky diode is designed with the same drift region parameters indicated in example 7.1. The Schottky contact has a barrier height of 0.8 eV. Conduction in a Schottky diode takes place by majority carriers. Forward voltage drop of the diode is obtained from equations 7.8 and 7.9 as:

$$V_F = \frac{kT}{q}\ln\left(\frac{J_F}{A^* T^2 e^{q^{\phi}Bo/kT}}\right) + R_s J_F = 0.49 + 3.1 = 3.59\,\text{V},$$

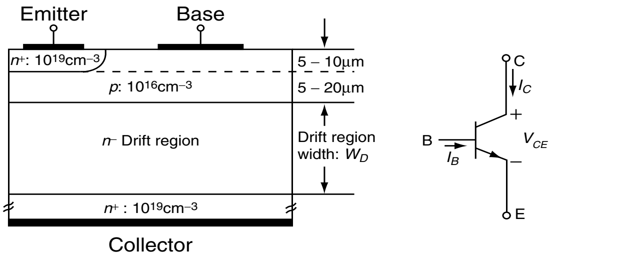
where $R_s = \frac{W_D}{q\mu_n N_D}$ is the specific series resistance of the drift region and $A^* = 146\,\text{Å}/\text{cm}^2\text{-K}^2$ for Si. A 200-V Schottky diode requires a drift region with a doping of $1.7 \times 10^{15}\,\text{cm}^{-3}$ and thickness of 12.5 μm. For a barrier height identical to the previous case, the forward voltage of this diode is $V_F = 0.49 + 0.32 = 0.81\,\text{V}$.

The voltage drop across the series resistor in the Schottky diode rises rapidly with the breakdown voltage rating. This restricts the operating voltage range of Schottky diodes even as reverse recovery limits high-frequency operation of P-i-N diodes. Hybrid devices such as junction barrier Schottky and merged P-i-N–Schottky diodes have been developed to expand the operating range of power diodes by taking advantage of the properties of Schottky and P-i-N diodes.

7.5 Power Bipolar Transistor

The vertical power bipolar junction transistor (BJT) has a four-layer structure of alternating *p*-type and *n*-type doping as shown in Figure 7.4. The transistor has three terminals labeled **collector, base**, and **emitter**. The need for a large off-state blocking voltage and high on-state current-carrying capability is responsible for the changes in structure over the logic-level counterpart. The transistor is commonly operated in a common emitter mode. The steady-state static *I–V* characteristics of the power BJT are shown in Figure 7.5. The BJT is turned on by injecting current in the base terminal and is a current-controlled device. This causes electrons to flow from the emitter to collector. The maximum collector current for a given base current is determined by the current gain, $I_{C,\,\max} = \beta I_B$:

$$I_C = \frac{A_q D_n N_B}{W_B}\exp\left(\frac{qV_{BE}}{kT}\right). \tag{7.10}$$



(A) Cross-Section (B) Circuit Representation

FIGURE 7.4 Power Bipolar Junction Transistor

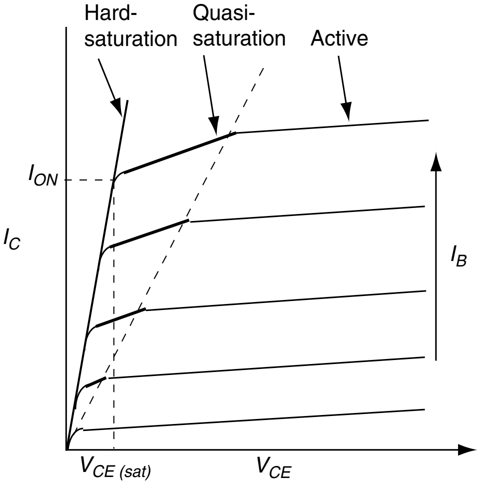


FIGURE 7.5 Output Characteristics of Power BJT

The static output characteristics of the BJT has three distinct regimes of conduction. From its off-state current, the transistor enters a forward active region when the base–emitter (B–E) junction is forward biased by a base current. With the base-collector (B–C) junction reverse biased, a collector current of magnitude $\beta_F I_B$ flows through the device. For the same base current, if the collector voltage is reduced such that the B–C junction is barely forward biased, the device enters the quasisaturation mode of operation. The boundary for this transition is $V_{CE} = V_{BE,on} + I_C R_D$, where R_D is the resistance of the drift region. Forward biasing the B–C junction results in minority carrier injection into the collector drift region. The increase in effective base width reduces the transistor current gain and, hence, the collector current. The device conducts in hard saturation when the entire collector drift region is in high-level injection. Any additional reduction in collector voltage drives the transistor further into hard saturation. The transistor has very little on-state voltage in hard saturation and quasisaturation and is operated in this condition for practical application.

Since BJTs are controlled by current, base current must be supplied continuously to maintain conduction, resulting in power loss. Power BJTs have a low current gain ($\beta \sim 5 - 20$). The gain can be enhanced by connecting the transistors in Darlington configuration, as shown in Figure 7.6. The output of one transistor drives another transistor, resulting in higher overall current gain. The current capability, however, is accompanied by a deterioration in forward voltage and switching speed.

7.5.1 Switching Characteristics

The **clamped inductive load circuit**, a typical switching application of a controllable power switch, is shown in Figure 7.7. The switching waveforms of the power BJT, used as a switch in the circuit, are shown in Figure 7.8. A large inductor represents a typical inductive load that is driven by the circuit. The inductor is approximated as a constant current source I_O. For a given collector current, the base current should be high enough to ensure conduction in hard or quasisaturation.

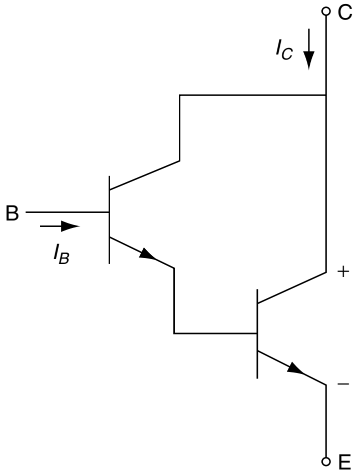

FIGURE 7.6 Darlington Configuration

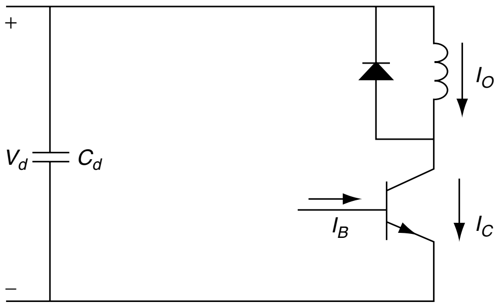

FIGURE 7.7 Clamped Inductive Load Circuit

After an initial delay because of the B–E capacitance, the charge in the base begins to buildup, and the collector current rises to its on-state value with the voltage clamped to V_d by the diode. The voltage beings to fall rapidly once the device attains on-state current. As the charge is injected into the drift region, the gain of the transistor reduces and slows down the rate of fall of voltage. This phase increases the overall device turn-on time. The turn-off process involves removal of all the stored charge in the transistor. The base current is driven negative to remove the charge during turn-off. The negative base current rapidly removes excess charge from the device. The base current reversal is usually achieved gradually because abrupt reversal leads to a long current tail, thus increasing switching loss. When the base current is reversed, the collector current remains constant for a storage time, t_s, until the drift region comes out of high-level injection at one of its ends. After this interval, the device enters quasisaturation, and voltage starts rising slowly. Once the charge distribution reduces to zero at the collector-base junction, the voltage rises rapidly until the diode clamps it to the bus voltage. The collector current then falls off toward zero and device is cut off.

For higher current or voltage-handling capability, devices can be connected in parallel or series. Connecting BJTs in parallel can lead to instabilities because of a negative temperature coefficient of the on-state resistance. During conduction, if the temperature of one device rises, its resistance reduces, causing it to pass more current than other transistors. This, in turn, leads to a further rise in current, eventually resulting in a thermal runaway condition that destroys the device.

7.6 Thyristor

The vertical cross-section and symbol of a thyristor are shown in Figure 7.9. The thyristor is a three-junction *p-n-p-n*

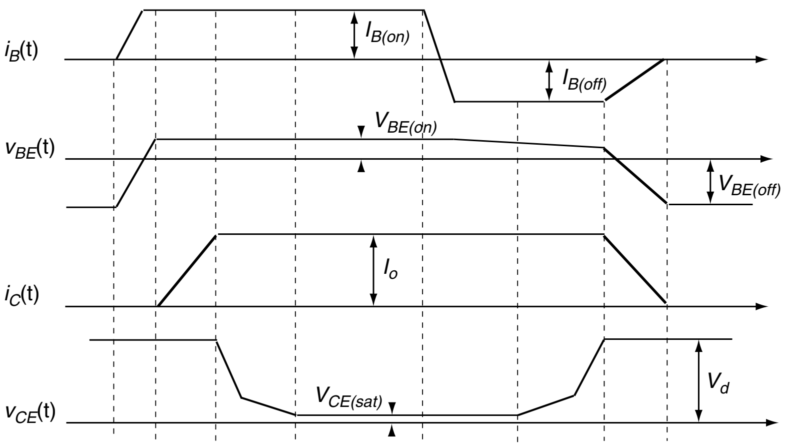

FIGURE 7.8 Switching Waveforms of a Power BJT During Clamped Inductive Turn-Off

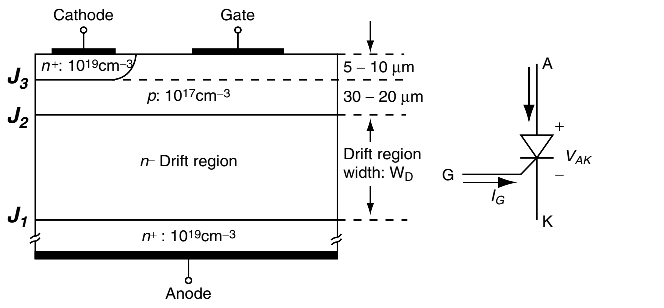

(A) Cross-Section (B) Circuit Representation

FIGURE 7.9 Diagram of a Thyristor

structure. The thyristor may be viewed as two bipolar transistors connected back to back. The collector current of one transistor provides base current to the other transistor. In the reverse direction, the thyristor operates similarly to a reverse-biased diode. When a forward polarity volage is applied, the junction J_3 (between the gate and drift region) is reverse biased, and the thyristor is in the forward blocking mode. The device can be triggered into latch-up by injecting a hole current from the gate electrode. Considering I_{CO} to be the leakage current of each transistor in cut-off condition, the anode current can be expressed in terms of gate current as:

$$I_A = \frac{\alpha_2 I_G + I_{CO1} + I_{CO2}}{1 - (\alpha_1 + \alpha_2)}, \qquad (7.11)$$

where α is the common base current gain of the transistor ($\alpha = I_C/I_E$). From equation 7.11, the anode current becomes arbitrarily large as $(\alpha_1 + \alpha_2)$ approaches unity. As the anode–cathode voltage increases, the depletion region expands and reduces the neutral base width of the n_1 and p_2 regions. This causes a corresponding increase in the α of the two transistors. If a positive gate current of sufficient magnitude is applied to the thyristor, a significant amount of electrons will be injected across the forward-biased junction, J_3, into the base of the $n_1p_2n_2$ transistor. The resulting collector current provides base current to the $p_1n_1p_2$ transistor. The combination of the positive feedback connection of the *npn* and *pnp* BJTs and the current-dependent base transport factors eventually turn the thyristor on by regenerative action. Among the power semiconductor devices known, the thyristor shows the lowest forward voltage drop at large current densities. The large current flow between the anode and cathode maintains both transistors in saturation region, and gate control is lost once the thyristor latches on.

7.6.1 Transient Operation

When gate current is injected in the thyristor, finite time is required by the regenerative action to turn the thyristor on under the influence of the gate current (see Figure 7.10). A time delay is observed before the current starts rising. After the delay time, the anode current rapidly rises toward its on-state value at a rate limited only by external current elements, and the device voltage collapses. The finite time required for the charge plasma to spread through the device causes a tail in on-state voltage. The thyristor cannot be turned off by the gate and turns off naturally when the anode current is forced to change direction. A thyristor exhibits turn-off reverse recovery characteristics just like a diode. Excess charge is removed once the current crosses zero and attains a negative value at a rate determined by external circuit elements. The reverse recovery peak is reached when either junction J_1 or J_3 becomes reverse biased. The reverse recovery current starts decaying, and the anode–cathode voltage rapidly attains its off-state value.

Because of the finite time required for spreading or collecting the charge plasma during turn-on or turn-off stage, the maximum *dI*/*dt* and *dV*/*dt* that may be imposed across the device are limited in magnitude. Further, device manufacturers

(B) Transient

FIGURE 7.10 Typical Characteristics of a Thyristor

specify a circuit-commutated recovery time, t_q, for the thyristor, which represents the minimum time for which the thyristor must remain in its reverse blocking mode before forward voltage is reapplied.

Thyristors come in various forms depending on the application requirements. They can be made to handle large voltage and current with low on-state forward drop. Such thyristors typically find applications in circuits requiring rectification of line frequency voltage and currents. Faster recovery thyristors can be made at the expense of increased on-state voltage drop.

7.7 Gate Turn-Off Thyristor

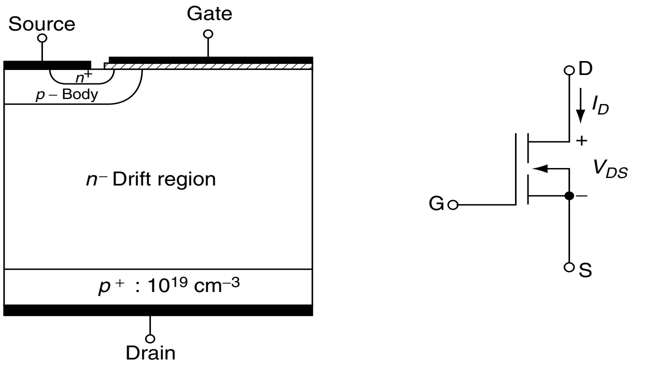
The gate turn-off thyristor (GTO) adds gate-controlled turn-off capability to the thyristor. In a GTO, modifications are made to ensure that the base current of the transistor $n_1p_2n_2$ is briefly made less than the value needed to maintain saturation ($I_{B2} < I_C/\beta$). This forces the transistor to go into the active region. The regenerative action pulls both transistors out of saturation into the active region and eventually into turn-off mode. A GTO requires complex interdigitated layout of gate and cathode. Anode short structures further suppress regeneration. The turn-off capability of a GTO is gained at the expense of on-state performance. Other variations in structure, such as the reverse-conducting thyristor (RCTs), asymmetrical silicon-controlled-rectifier (ASCR), light-triggered thyristor (LTT), and so forth, are applied in many modern power electronic applications.

7.8 Metal-Oxide-Semiconductor Field Effect Transistor

The power metal-oxide-semiconductor field effect transistor (MOSFET) is perhaps the most thoroughly investigated and optimized power semiconductor device. Figure 7.11 shows the cross-section of a vertical n-channel power MOSFET. The MOSFET is a voltage-controlled device as opposed to a BJT that is a current-controlled device. In an off-state mode, the depletion layer expands in the drift region and supports the blocking voltage. As the depletion layer grows, it pinches off the region between the p-wells and isolates the gate oxide from the high voltage appearing at the drain. The channel region is formed by implantation and diffusion of p-type impurities in the window for the source region. The p-type region also isolates the source and the drain. Application of a gate voltage higher than a threshold value creates an inversion channel under the gate oxide that supports current flow from source to the drain. For an ideal metal-oxide-semiconductor structure, the threshold voltage is expressed as:

$$V_{TH} = \sqrt{\frac{4\varepsilon k T N_D \ln(N_D/n_i)}{\varepsilon_{ox}/t_{ox}}} + \frac{2kT}{q} \ln\left(\frac{N_D}{n_i}\right). \qquad (7.12)$$

The maximum current supported per unit cell for a given gate voltage is limited by the threshold voltage and channel length.



(A) Cross-Section

(B) Circuit Representation

FIGURE 7.11 Power MOSFET

Several unit cells of the kind shown in Figure 7.11 are connected in parallel to achieve the desired current rating. The cells are connected in a variety of geometrical layouts, such as stripes, squares, and hexagonal shapes. The source n^+ region and p-body region are shorted. This creates a parasitic diode connected from the drain to the source of the MOSFET. This integral diode is useful in several power electronics applications, such as half-bridge and full-bridge PWM converters.

The MOSFET is a majority carrier device. In the case of the n-channel MOSFET shown in Figure 7.11, the electrons traveling from source to drain have to overcome the resistance offered by the channel, the accumulation region at the surface, the neck or JFET region between the p-wells, the drift region, and the substrate, as indicated in Figure 7.12(A). The overall resistance of the device is determined by the contributions of the individual components. Thus, the following is true:

$$R_{on} = R_{ch} + R_{acc} + R_{neck} + R_{drift} + R_{sub}. \tag{7.13a}$$

$$\frac{L_{ch}}{2ZC_{ox}\mu_{eh}(V_{GS}-V_{TH})} + \frac{L_G}{8ZC_{ox}\mu_{acc}(V_{GS}-V_{TH})} + \frac{x_D}{q\mu_n Z L_G N_D} + R_{on} = \frac{\ln[1+2(W_D/L_G)\tan\alpha]}{q\mu_n Z N_D \tan\alpha} + \frac{W_{sub}}{q\mu_n Z L_{cell} N_{sub}}. \tag{7.13b}$$

The resistance of low-voltage MOSFETs is dominated by the resistance of the channel and neck regions. Higher voltage MOSFETs, however, have thicker drift regions with low doping. The resistance is then dominated by the drift region. This limits the application of MOSFETs at higher voltage levels. The I–V characteristics of the power MOSFET are shown in Figure 7.12(B). Increasing the gate voltage raises the saturation current level as given by:

$$I_{D,\ sat} = \mu_{ch} C_{ox} Z \left(V_{GS} - V_{TH}\right)^2 / L_{ch}. \tag{7.14}$$

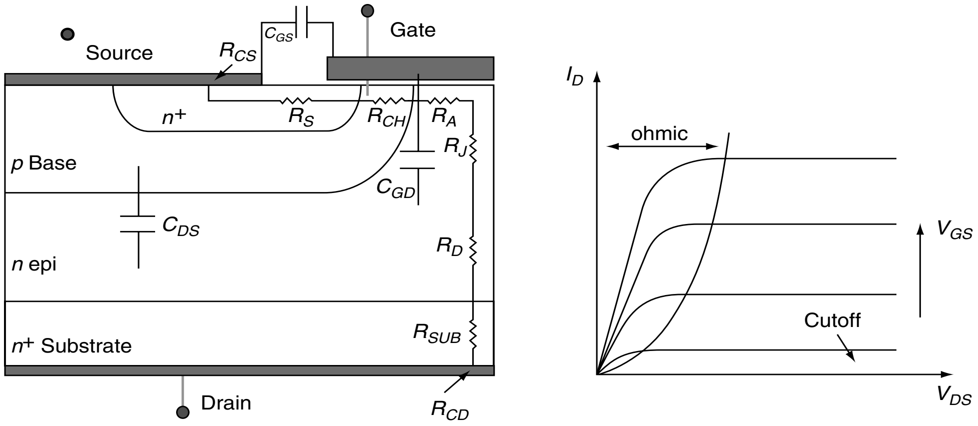
EXAMPLE 7.4. A power MOSFET has a p-base region that is uniformly doped at a concentration of $1 \times 10^{17}\,\text{cm}^{-3}$ with a gate oxide thickness of 1000 A. Using equation 7.14, the threshold voltage of this device is 5.65 V at room temperature. A fixed charge density at the semiconductor–oxide interface introduces additional charge and shifts the threshold voltage of the device by:

$$\Delta V_{TH} = -\frac{Q_{ox}}{C_{ox}}.$$

Thus, a charge density of $1 \times 10^{11}\,\text{cm}^{-2}$ would cause a shift of -0.47 V in the threshold voltage. Saturation current of the MOSFET is determined by the channel. For a MOSFET with channel length of 2 μm, the channel width required to have a saturation current of 1 A at a gate voltage of 7 V can be obtained with the help of equation 7.14 to be 6.4 cm. The channel on-resistance is 0.68 Ω.

7.8.1 Switching Performance

The MOSFETs require continuous application of gate-source voltage above the threshold voltage to be in an on-state mode. The gate is isolated from the semiconductor by the oxide. Gate current flows only during transition from on-to off-state and vice versa when the gate capacitor charges or discharges. This implies reduced power loss in the control circuit and simple gate control. The switching transients are determined by the time required to charge and discharge various capacitors in the MOSFET structure. The capacitors appear where the gate oxide overlaps the semiconductors and junction capacitance because of the depletion layer, as indicated in Figure 7.12.



(A) Parasitics in a Power MOSFET

(B) Typical Output Characteristics

FIGURE 7.12 MOSFET Device

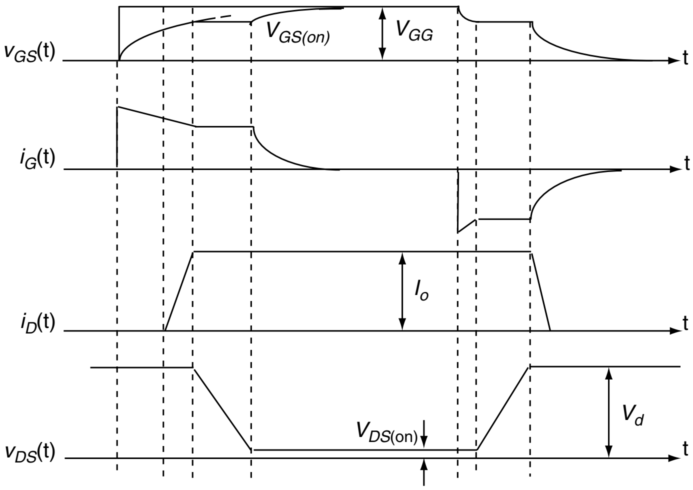


FIGURE 7.13 Switching Waveforms of Power MOSFET

Important switching waveforms of the MOSFET are indicated in Figure 7.13 for an inductive load, similar to the one in Figure 7.7. The gate pulse makes transitions between V_{GP} and V_{GN} through the gate resistor, R_G. Initially, the device is off. When the gate pulse is turned on high, the capacitor C_{GD} and C_{GS} charge exponentially toward V_{GP} through R_G. The MOSFET turns on when the gate-source voltage crosses V_{TH}. The device goes from cut-off to saturation region. As the gate voltage rises, the MOSFET current also increases, as determined by equation 7.14, until it is conducting I_O. The drain voltage remains at V_D as long as the free-wheeling diode is conducting. Once the MOSFET attains the current I_O, the drain current is clamped. Since the device is conducting in saturation, the gate-source voltage is also clamped. The capacitor C_{GD} now starts discharging through the gate resistor. The gate current is given as:

$$I_G = \frac{V_{GP} - V_{GS,\,on}}{R_G} = C_{GD}\frac{dV_{GD}}{dt} = C_{GD}\frac{dV_{CE}}{dt}, \qquad (7.15)$$

where $V_{GS,\,on}$ is the gate-source voltage required to maintain a drain current I_O in saturation. The gate voltage starts rising exponentially again when the drain voltage reduces to on-state value.

The turn-off of the MOSFET involves the inverse sequence of the events that occur during turn-on, and the turn-off waveforms are also shown in Figure 7.16. During the switching transient, the maximum power loss occurs during the crossover between voltage and current states. This power loss originates from the charging and discharging of capacitors. Since these capacitances do not vary with temperature, the switching power loss in MOSFET is independent of temperature. The on-state resistance and, hence, conduction loss, however, do vary with temperature.

Example 7.5. The MOSFET designed in example 7.4 has a parasitic capacitance of $C_{ISS} = 2.5\,\text{nF}, C_{RSS} = 200\,\text{pF}$, and $C_{OSS} = 600\,\text{pF}$. A gate pulse of 10 V is applied through a gate resistor of $10\,\Omega$ to the MOSFET to turn it on from an off-state voltage of 100 V to an on-state current of 500 mA. Based on example 7.4, the $V_{GS,\ on}$ of the MOSFET at this current level is about 7 V. During the turn-off phase, the current rapidly rises to its on-state value. The device voltage then reduces from 100 V to the on-state value in the phase of the Miller plateau. Then, according to equation 7.18, the time required for the device voltage to drop is 67 ns. Accordingly, the turn-on energy loss is as follows:

$$E_{on} = 1/2 I_{on} V_{Bus} t_{on} = 1.7\,\mu\text{J}.$$

7.8.2 Limits of Operation

Static breakdown of power MOSFETs occurs when the reverse voltage exceeds the static breakdown. As explained in equation 7.13, the on-resistance of the power MOSFET increases rapidly with the device blocking voltage because of increased drift region resistance. The dependence of resistance on breakdown voltage is nearly cubic ($\sim V_{BD}^{2.5-2.7}$). The on-resistance has a positive temperature coefficient because of a reduction in carrier mobility at higher temperature. This permits paralleling of MOSFETs without risk of instability. The device conducting higher current heats up and is forced to share its current equitably with the MOSFETs that are in parallel with it.

The MOSFET structure has a parasitic *npn* bipolar transistor, as can be identified from Figure 7.11. The base of this transistor is shorted to the source of the MOSFET through a

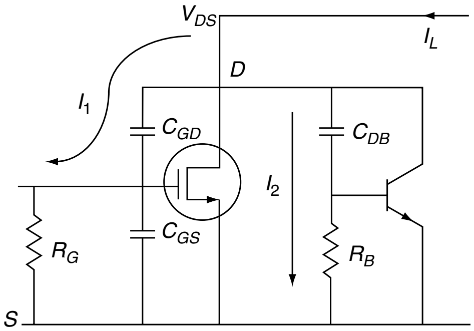

FIGURE 7.14 Circuit Representation of MOSFET with Parasitic Elements

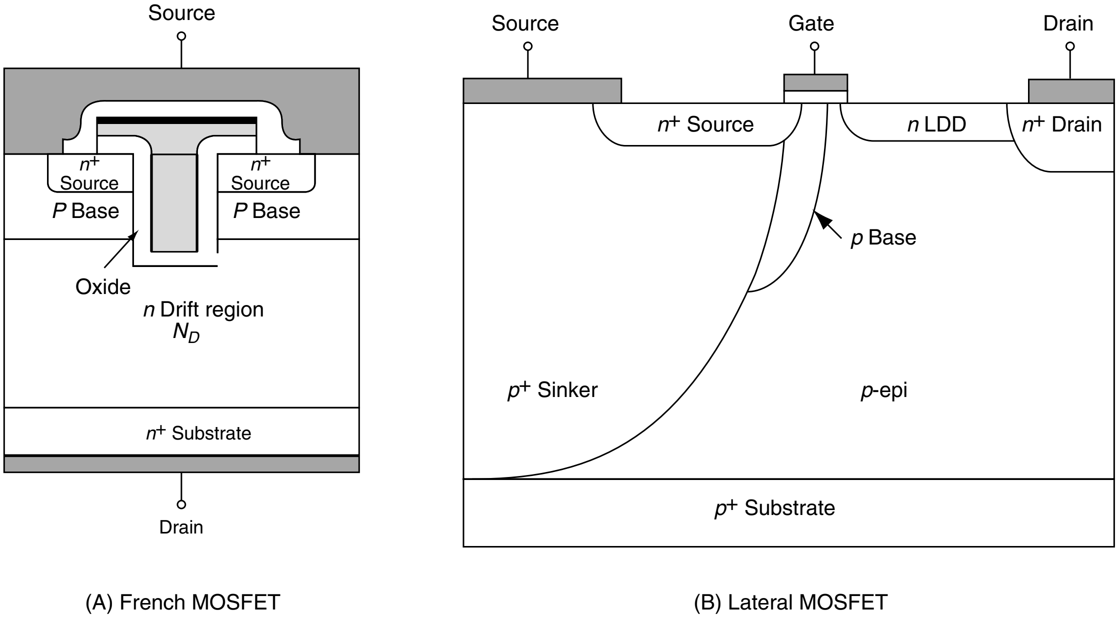
resistor that is the lateral resistance of the *p*-base. The equivalent circuit model of the MOSFET, including the parasitic transistor, is shown in Figure 7.14. Under rapid transients of voltage at the drain, a displacement current is induced through the parasitic capacitors of the MOSFET along two paths, as shown. The current I_1 may rise V_{GS} above V_{TH}, thus causing spurious turn-on of the MOSFET. Likewise, the current I_2 may cause a resistive drop across R_B that is high enough to turn the parasitic bipolar transistor on. This places a limit on the maximum *dV/dt* across the MOSFET. Reliability of MOSFET is also affected by the power dissipation under transient conditions. This power dissipation leads to a temperature rise in the device. The temperature range of operation and highest current and voltage stress are determined by the extent of device self-heating.

7.8.3 Improved Structures

Apart from channel resistance, on-resistance of the MOSFET has contributions from the neck region between the *p*-wells and spreading resistance in the drift region. Various structures have been designed to reduce the on-resistance toward the ideal limit. Two notable device structures are the trench MOSFET and the lateral MOSFET shown in Figure 7.15. The trench MOSFET ensures a nearly one-dimensional current flow and eliminates the neck region. This structure also achieves a much lower cell size and higher packing density. Two of the major markets where power MOSFETs are finding increasing use are portable electronics and automotive applications. In such applications, the power MOSFET must be integrated with other circuit elements for logic-controlled or analog applications. This requires all terminals to be available at the top surface for integration. The lateral MOSFET, shown in Figure 7.15(B) satisfies this requirement.

7.9 Insulated Gate Bipolar Transistor

Although power BJTs have low on-state resistance, their operation involves circuit complexity and significant losses in the control circuitry because of the current-controlled nature of device operation. On the other hand, MOSFETs involve relatively simple gate drive circuits but have significant losses during forward conduction at higher blocking voltages. Improved overall performance is achieved by merging the advantages of bipolar conduction with MOS-gate control. Several hybrid MOS-gate transistors have been introduced. Among



(A) French MOSFET

(B) Lateral MOSFET

FIGURE 7.15 Cross-Sections of MOSFETs

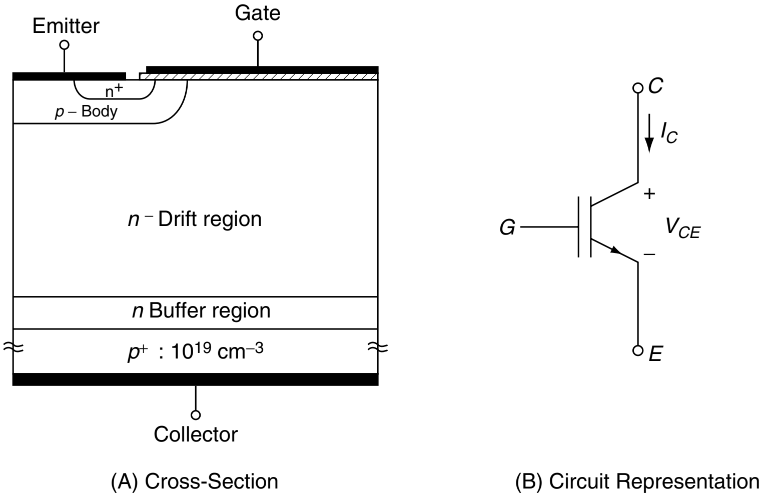


FIGURE 7.16 Insulated Gate Bipolar Transistor

these devices, the insulated gate bipolar transistor (IGBT) is the most popular and widely used device. A vertical cross-section of the IGBT is shown in Figure 7.16(A). The structure is similar to a vertical diffused MOSFET. The main difference is the p^+ layer at the back of the device that forms the collector of the device. This layer forms a *pn* junction, which injects minority carriers into the drift region under normal conduction. The structure at the top of the device is identical to a MOSFET in all respects including processing and cell geometry.

The forward blocking operation of the IGBT is identical to a power MOSFET. The presence of a rectifying junction at the backside also provides the device with reverse voltage blocking capability. A nonpunchthrough (NPT) drift region design has symmetrical forward and reverse blocking capability. The on-state operation of the IGBT can be understood by an equivalent representation of a MOSFET and a power diode connected in series. When a positive gate voltage is applied, an inversion layer is formed under the gate that facilitates the injection of electrons from the emitter into the drift region. Positive voltage at the collector simultaneously induces hole injection into the drift region from the p^+ backside layer. Double injection into the drift region gives the device its excellent on-state properties. Just like a power diode, the drift region conductivity is modulated significantly during conduction, which helps reduce the on-state resistance compared to the power MOSFET. The NPT IGBT has a thick drift region to support the high voltage. The same voltage blocking capability can be achieved by use of a much thinner drift region if an n^+ buffer layer is introduced between the drift region and p^+ substrate. These punchthrough (PT) IGBTs exhibit stronger conductivity modulation by virtue of a thinner drift region.

The on-state characteristics of the IGBT are depicted in Figure 7.17. For a given gate voltage, the saturation current is determined by the MOS channel, as expressed in equation 7.14. The device is operated in the linear region, where the contributions to voltage drop are from the MOS channel, the drift region, and the backside junction drop:

$$V_{CE,\,on} = V_{p-n} + V_{MOS} + V_{drift}. \tag{7.16}$$

Neglecting the voltage drop in the drift region because of conductivity modulation yields:

$$V_{CE,\,on} = \frac{kT}{q}\ln\left(\frac{I_C\tau}{qWL_{cell}Zn_i}\right) + \frac{I_C L_{ch}}{\mu_{ch}C_{ox}Z(V_{GS} - V_{TH})}. \tag{7.17}$$

A more detailed and accurate analysis can be done by treating the IGBT as a power BJT whose base current is provided by a MOSFET. A parasitic thyristor is formed in the

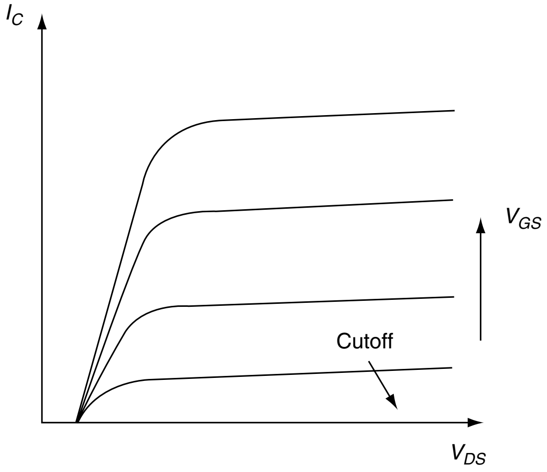

FIGURE 7.17 Output Characteristics of IGBT

IGBT by the junctions between the p^+ substrate, n-type drift, p-base, and n^+ emitter regions. Under normal operation, a fraction of the holes injected into the drift region by the p^+ substrate are collected by the p-base. These holes travel laterally in the p-base before being collected at the emitter contact. The lateral voltage drop may be sufficient to turn on the p-base n^+ emitter junction, eventually latching the parasitic thyristor. Several improvements have been made in the structure of present-day IGBTs to incorporate very high latch-up immunity.

7.9.1 Transient Operation

The switching waveforms of an IGBT in the clamped inductive circuit are shown in Figure 7.18. The turn-on waveforms are similar to those of the MOSFET in Figure 7.13. Two distinct phases are observed while the IGBT turns on. The first is the rapid reduction in voltage as the capacitor C_D discharges, similar to a MOSFET. A finite time is required for high-level injection conditions to set in the drift region. The gate voltage starts rising again only after the transistor comes out of its saturation region into the linear region.

During turn-off, the current is held constant while the collector voltage rises. This is followed by a sharp decline in collector current as the MOS channel turns off. The turn-off transient until this phase is similar to a MOSFET. However, the IGBT has excess charge in the drift region during on-state conduction that must be removed to turn the device off. This high concentration of minority carriers stored in the n-drift region supports current flow even after the MOS channel is cut off. As the minority carrier density decays due to recombination, it leads to a gradual reduction in the collector current and results in a current tail. For an on-state current of I_{ON}, the magnitude of the current tail and turn-off time are roughly expressed as:

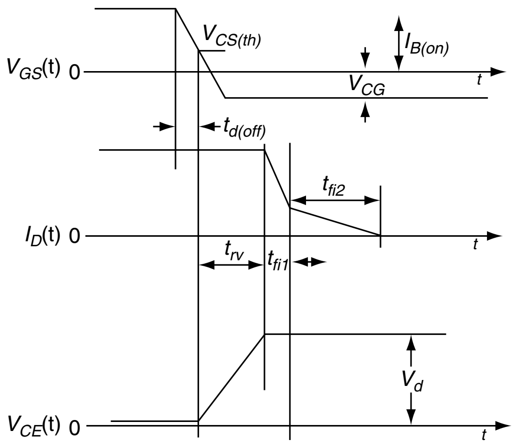

FIGURE 7.18 Typical Switching Waveforms During IGBT Clamped Inductive Load Turn-Off

$$I_C(t) = \alpha_{pnp} I_{on} e^{-t/\tau_{HL}}. \tag{7.18a}$$

$$t_{off} = \tau_{HL} \ln(10\alpha_{pnp}). \tag{7.18b}$$

In these equations, $\alpha_{pnp} = \text{sech}(W_D/L_a)$ is the gain of the bipolar transistor.

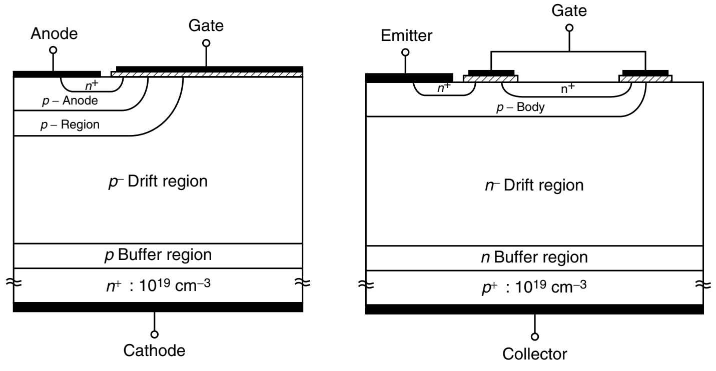
The PT IGBT has a thin drift region and better on-state performance than NPT IGBT. High gain of the *pnp* transistor can lead to potential thyristor latch-up. For this reason, PT IGBT is subjected to lifetime control techniques to reduce the gain of the bipolar transistor. On the other hand, NPT IGBT has a wide drift region, and the gain is low even without lifetime control. Low lifetime and thin drift region make the PT IGBT more sensitive to temperature variation than NPT IGBT. Further, being bipolar in nature, IGBTs are vulnerable to thermal runaway in certain conditions, depending on the relative importance of MOSFET and bipolar transistor parameters. Hence, paralleling IGBTs is a challenge. The delay in turn-on and current tail during turn-off are significant sources of power loss in an IGBT. Several structures have been designed for faster removal of charge from the drift region during turn-off. Controlling the carrier lifetime within a tightly controlled band in the drift region has also been used to obtain a better turn-off between conduction and switching characteristics.

> Example 7.6. An IGBT is designed with the same parameters as the MOSFET in example 7.4 by replacing the n^+ substrate with a p^+ substrate. A symmetrical structure is designed for both devices with a voltage blocking capability of 500 V. The drift region has a minority carrier lifetime of 1 μs. We can compare the on-state performance of the IGBT and the MOSFET.

From Example 7.3, the voltage drop across the drift region at a current density of 100 Å/cm^2 is 3.1 V. With technological limitations and following the design guidelines, the unit cell dimension of a 500 V MOSFET is about 8 μm. Then, considering that the channel has an on-state resistance of 0.68 Ω (example 7.4), the channel drop is 0.35 V. Thus, the overall MOSFET voltage drop is 3.45 V. The IGBT will have the same channel drop. However, the voltage across the diode in the equivalent representation of the IGBT is given by equation 7.19 to be 0.43 V. Thus, the overall voltage-drop of the IGBT is 0.78 V. This illustrates the superior on-state performance of IGBTs over MOSFETs at higher voltage levels.

7.10 Other MOS-Gate Devices

In the on-state, the IGBT operates as a bipolar transistor driven by a MOSFET. The on-state characteristics can be significantly improved by thyristor-like operation. This is achieved by the MOS-controlled thyristor (MCT) shown in Figure 7.19(A). Application of a negative gate voltage creates a p-channel



(A) MOS-Controlled

(B) Emitter-Switched

FIGURE 7.19 Cross-Section of Thyristors

under the gate. This channel provides the gate current to the vertical *n-p-n-p* thyristor that latches due to regenerative feedback and conducts a large forward current with a low forward voltage drop. During on-state conduction, the *p*-channel loses control over MCT performance once the thyristor latches on, and the *I–V* characteristics are independent of gate voltage beyond the threshold voltage V_{TH} of the channel. MCT turn-off is accomplished by applying a high voltage of reverse polarity at the gate. This creates an *n*-channel under the gate. If the resistance of the channel is small enough, it will divert the electron current from the thyristor. This effectively raises the holding current of the thyristor, thus forcing it to turn-off.

Although MCTs have significantly improved current-handling capability, they do not match the switching performance of IGBTs. This is due to the increased resistance in the device during turn-on and higher current density. During the turn-off stage, the thyristor may fail to turn off if resistance of the diverting channel is high. In addition the channel has to be formed uniformly and abruptly to effectively cut off the feedback in the thyristor.

The MCT has an uncontrolled on-state performance; hence, its forward-biased safe operating area (FBSOA) cannot be defined. The emitter-switched thyristor (EST) has been proposed to achieve control over the thyristor on-state conduction. The cross-section of an EST is shown in Figure 7.19(B). The EST has an n^+ floating emitter region in addition to the basic IGBT structure. When the inversion channel is formed on application of a gate voltage, device performance is identical to an IGBT. At higher current levels, hole flow in the *p*-base region under the floating region forward biases the p-n^+ junction, causing latch-up of the vertical thyristor. The thyristor current flows through the MOS channel before reaching the emitter terminal. This provides control over the thyristor current as resistance of the channel can be varied by changing the gate voltage. On-state thyristor operation of EST results in a much higher current density than IGBT. The switching mechanism in an EST is identical to an IGBT. Because of a higher level of drift region conductivity modulation, however, large turn-off power results.

Several other MOS-gated structures, such as base resistance-controlled thyristor (BRT), insulated gate-controlled thyristor (IGCT), injection-enhanced transistor (IEGT), MOS-turn-off thyristor (MTO), and so forth have been introduced in the recent past to further optimize the on-state and switching performance at high voltage and current levels.

7.11 Smart Power Technologies

The development of MOS-gate driven power devices has greatly simplified the gate drive circuits. The devices have made it possible to integrate the gate drive circuit into a monolithic chip. With the current technology, it is also possible to add other functions, such as protection against adverse operating conditions and logic circuits to interface with microprocessors. In a typical smart power control chip, the sensing and protection circuits are usually implemented using analog circuits with high-speed bipolar transistors. These circuits must sense adverse temperatures, currents, and voltages. This circuitry helps detect situations like thermal runaway, impact ionization, insufficient gate drive, and so forth. Present day Smart Power chips are manufactured using a junction isolation technology. Efforts are in progress to make lateral structures with high breakdown voltages and thin epitaxial layers. The dielectric isolation technology is being perfected to replace the junction isolation technology to achieve fewer parasitics, compactness, and a higher degree of integration.

7.12 Other Material Technologies

Numerous power circuit applications exist in which the device temperature can rise significantly above room temperature. Further, several applications require devices that can handle large blocking voltage exceeding 5 kV. Inherent material limitations make it impossible to use silicon-based devices beyond 200°C. These limitations have led to the search for new materials that can handle large voltages. Wide band gap materials with high carrier mobilities are ideally suited for such applications. Presently, SiC appears to be the most promising material to replace Si for high-voltage, high-temperature applications. With the commercial availability of high-quality silicon carbide wafers with lightly doped epitaxial layers, the fabrication of power devices has become viable. Power switches and rectifiers fabricated from silicon carbide offer tremendous promise for reduction of power losses in the device. All the devices discussed in this chapter have been demonstrated using SiC technology. However, the predicted superior performance of SiC devices has not been achieved on a large scale because of limitations in wafer quality and processing technology. Much work needs to be done before a manufacturable technology can be commercialized.

VLSI SYSTEMS

Magdy Bayoumi
The Center for Advanced Computer Studies, University of Louisiana at Lafayette, Lafayette, Louisiana, USA

This Section covers the broad spectrum of VLSI arithmetic, custom memory organization and data transfer, the role of hardware description languages, clock scheduling, low-power design, micro electro mechanical systems, and noise analysis and design. It has been written and developed for practicing electrical engineers in industry, government, and academia. The goal is to provide the most up-to-date information in the field.

Over the years, the fundamentals of the field have evolved to include a wide range of topics and a broad range of practice. To encompass such a wide range of knowledge, the section focuses on the key concepts, models, and equations that enable the design engineer to analyze, design, and predict the behavior of large-scale systems. While design formulas and tables are listed, emphasis is placed on the key concepts and the theories underlying the processes. In order to do so, the material is reinforced with frequent examples and illustrations.

The compilation of this section would not have been possible without the dedication and efforts of the section editor and contributing authors. I wish to thank them all.

Logarithmic and Residue Number Systems for VLSI Arithmetic

Thanos Stouraitis
Department of Electrical and Computer Engineering, University of Patras, Greece

1.1 Introduction

Very large-scale integrated circuit (VLSI) arithmetic units are essential for the operations of the data paths and/or the addressing units of microprocessors, digital signal processors (DSPs), as well as data-processing application-specific integrated circuits (ASICs) and programmable integrated circuits. Their optimized realization, in terms of power or energy consumption, area, and/or speed, is important for meeting demanding operational specifications of such devices.

In modern VLSI design flows, the design of standard arithmetic units is available from design libraries. These units employ binary encoding of numbers, such as one's or two's complement, or sign magnitude encoding to perform additions and multiplications. If nonstandard operations are required, or if high performance components are needed, then the design of special arithmetic units is necessary. In this case, the choice of arithmetic system is of utmost importance.

The impact of arithmetic in a digital system is not only limited to the definition of the architecture of arithmetic circuits. Arithmetic affects several levels of the design abstraction because it may reduce the number of operations, the signal activity, and the strength of the operators. The choice of arithmetic may lead to substantial power savings, reduced area, and enhanced speed.

This chapter describes two arithmetic systems that employ nonstandard encoding of numbers. The logarithmic number system (LNS) and the residue number system (RNS) are singled out because they have been shown to offer important advantages in the efficiency of their operation and may be at the same time more power- or energy-efficient, faster, and/or smaller than other systems.

Although a detailed comparison of performance of these systems to their counterparts is not offered here, one must keep in mind that such comparisons are only meaningful when the systems under question cover the same dynamic range and present the same precision of operations. This necessity usually translates in certain data word lengths, which, in their turn, affect the operating characteristics of the systems.

1.2 LNS Basics

Traditionally, LNS has been considered as an alternative to floating-point representation (Koren, 1993; Stouraitis, 1986). The organization of an LNS word is shown in Figure 1.1.

The LNS maps a linear real number X to a triplet as follows:

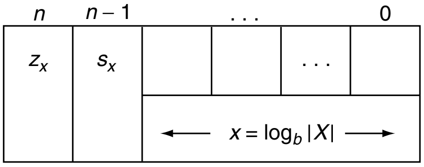

FIGURE 1.1 The Organization of an $(n + 1)$-bit LNS Digital Word

$$X \xrightarrow{\text{LNS}} (z_x,\ s_x,\ x = \log_b |X|), \tag{1.1}$$

where s_x is the sign of X, b is the base of the logarithmic representation, and z_x is a single-bit flag, which, when asserted, denotes that X is zero. A zero flag is required because $\log_b X$ is not a finite number for $X = 0$. Similarly, since the logarithm of a negative number is not a real number, the sign information of X is stored in flag s_x. Logarithm $x = \log_b |X|$ is encoded as a binary number, and it may comprise a number of k integer and l fractional bits.

The inverse mapping of a logarithmic triple $(z_x,\ s_x, x)$ to a linear number X is defined by:

$$(z_x,\ s_x,\ x) \xrightarrow{\text{LNS}^{-1}} X\colon X = (1 - z_x)(-1)^{s_x} b^x. \tag{1.2}$$

1.2.1 LNS and Linear Representations

Two important issues in a finite word length number system are the **range** of numbers that can be represented and the **precision** of the representation (Koren, 1993).

Let $(k,\ l,\ b)$–LNS denote an LNS of integer and fractional word lengths k and l, respectively, and of base b. These three parameters determine the properties of the LNS and can be computed so that the LNS meets certain specifications. For example, for a $(k,\ l,\ b)$–LNS to be considered as equivalent to an n-bit linear fixed-point system, the following two restrictions may be posed:

1. The two representations should exhibit equal average representational error.
2. The two representations should cover equivalent data ranges.

The average representational error, ε_{ave}, is defined as:

$$\varepsilon_{\text{ave}} = \frac{\displaystyle\sum_{X=X_{\min}}^{X_{\max}} \varepsilon_{\text{rel}}(X)}{X_{\max} - X_{\min} + 1}, \tag{1.3}$$

where $X_{\min}$ and $X_{\max}$ define the range of representable numbers in each system and where $\varepsilon_{\text{rel}}(X)$ is the relative representational error of a number X encoded in a number system. This error is, in general, a function of the value of X and it is defined as:

$$\varepsilon_{\text{rel}}(X) = \frac{|X - \hat{X}|}{X}, \tag{1.4}$$

in which X is the actual value and $\hat{X}$ is the corresponding value representable in the system. Notice that $X \neq \hat{X}$ due to the finite length of the words. Assuming that the logarithm of X is represented as a two's complement number, the relative representational error $\varepsilon_{\text{rel, LNS}}$ for a $(k,\ l,\ b)$–LNS is independent of X and, therefore, is equal to the average representational error. It is given by [refer to Koren (1993) for the case $b = 2$].

$$\varepsilon_{\text{ave, LNS}} = \varepsilon_{\text{rel, LNS}} = b^{2^{-l}} - 1. \tag{1.5}$$

Due to formula 1.3, the average representational error for the n-bit linear fixed-point case is given by:

$$\varepsilon_{\text{ave, FXP}} = \frac{1}{2^n - 1} \sum_{i=1}^{2^n - 1} \frac{1}{i}, \tag{1.6}$$

which, by computing the sum on the right-hand side, can be written as:

$$\varepsilon_{\text{ave, FXP}} = \frac{\psi(2^n) + \gamma}{2^n - 1}, \tag{1.7}$$

where γ is the Euler gamma constant and function ψ is defined through:

$$\psi(x) = \frac{d}{dx} \ln \Gamma(x), \tag{1.8}$$

where $\Gamma(x)$ is the Euler gamma function.

In the following, the maximum number representable in each number system is computed and used to compare the ranges of the representations. Notice that different figures could also have been used for range comparison, such as the ratio $X_{\max}/X_{\min}$ (Stouraitis, 1986). The maximum number representable by an n-bit linear integer is $2^n - 1$; therefore the upper bound of the fixed-point range is given by:

$$X_{\max}^{\text{FXP}} = 2^n - 1. \tag{1.9}$$

The maximum number representable by a $(k,\ l,\ b)$-LNS encoding 1.1 is as follows:

$$X_{\max}^{\text{LNS}} = b^{2^k + 1 - 2^{-l}}. \tag{1.10}$$

Therefore, according to the equivalence restrictions posed above, to make an LNS equivalent to an n-bit linear fixed-point representation, the following inequalities should be simultaneously satisfied:

$$X_{\max}^{\mathrm{LNS}} \geq X_{\max}^{\mathrm{FXP}}. \tag{1.11}$$

$$\varepsilon_{\mathrm{ave,\ LNS}} \leq \varepsilon_{\mathrm{ave,\ FXP}}. \tag{1.12}$$

Hence, from equations 1.5 and 1.7 through 1.10 the following equations are obtained:

$$l = \left\lceil -\log_2 \log_b \left(1 + \frac{\psi(2^n) + \gamma}{2^n - 1}\right) \right\rceil. \tag{1.13}$$

$$k = \left\lceil \log_2 \left(\log_b (2^n - 1) + 2^{-l} - 1 \right) \right\rceil. \tag{1.14}$$

Values of k and l that correspond to various values of n for various values of b can be seen in Table 1.1, where for each base, there is a third column (explained next).

Although the word lengths k and l computed via equations 1.13 and 1.14 meet the posed equivalence specifications of equations 1.11 and 1.12, LNS is capable of covering a significantly larger range than the equivalent fixed-point representation. Let n_{eq} denote the word length of a fixed-point system that can cover the range offered by an LNS defined through equations 1.13 and 1.14. Equivalently, let n_{eq} be the smallest integer, which satisfies:

$$2^{n_{\mathrm{eq}}} - 1 \geq b^{2^k + 1 - 2^{-l}}. \tag{1.15}$$

From equation 1.15, it follows that:

$$n_{\mathrm{eq}} = \left\lceil (2^k + 1 - 2^{-l}) \log_2 b \right\rceil. \tag{1.16}$$

It should be stressed that when $n_{\mathrm{eq}} \geq n$, the precision of the particular fixed-point system is better than that of the LNS derived by equations 1.13 and 1.14. Equation 1.16 reveals that the particular LNS, while meeting the precision of an n-bit linear representation, in fact covers the range provided by an n_{eq}-bit linear system.

Of course, the average (relative) error is not the only way to compare the accuracy of computing systems. Especially true for signal processing systems, one may use the signal-to-noise ratio (SNR), assuming that quantization errors represent noise, to compare the precision of two systems. In that case, by equating the SNRs of the LNS and the fixed-point system that covers the required dynamic range, the integer and fractional word lengths of the LNS may be computed.

1.2.2 LNS Operations

Mapping of equation 1.1 is of practical interest because it can simplify certain arithmetic operations (i.e., it can reduce the implementation complexity, also called **strength**, of several operators). For example, due to the properties of the logarithm function, the multiplication of two linear numbers, $X = b^x$ and $Y = b^y$, is reduced to the addition of their logarithmic images, x and y.

The basic arithmetic operations and their LNS counterparts are summarized in Table 1.2, where, for simplicity and without loss of generality, the zero flag z_x is omitted and it is assumed that $X > Y$. Table 2 reveals that, while the complexity of most operations is reduced, the complexity of LNS addition and LNS subtraction is significant. In particular, for $d = |x - y|$, LNS addition requires the computation of the nonlinear function:

$$s_a(d) = \log_b (1 + b^{-d}), \tag{1.17}$$

and subtraction requires the computation of the nonlinear function:

$$s_s(d) = \log_b (1 - b^{-d}). \tag{1.18}$$

Equations 1.7 and 1.8 substantially limit the data word lengths for which LNS can offer efficient VLSI implementations. The

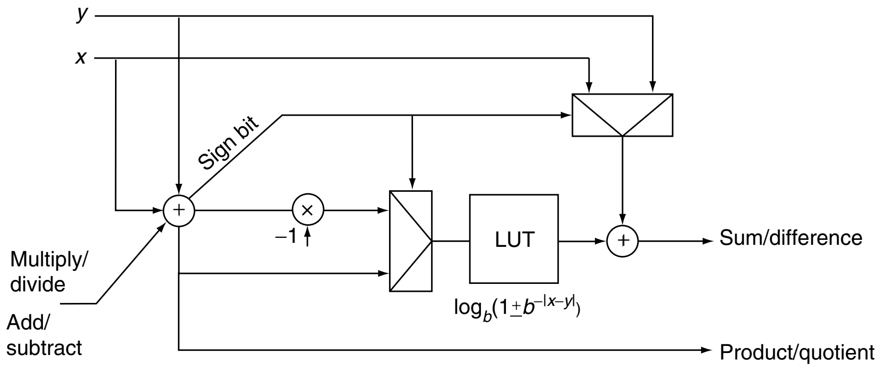

FIGURE 1.2 The Organization of a Basic LNS Processor: the processor comprises an adder, two multiplexers, a sign-inversion unit, a look-up table, and a final adder. It may perform the four operations of addition, subtraction, multiplication, or division.

organization of an LNS processor that can perform the four basic operations of addition, subtraction, multiplication, or division is shown in Figure 1.2. Note that to implement LNS subtraction (i.e., the addition of two quantities of opposite sign) a different memory look-up table (LUT) is required.

The main complexity of an LNS processor is the implementation of the LUTs for storing the values of the functions $s_a(d)$ and $s_s(d)$. A straightforward implementation is only feasible for small word lengths. A different technique can be used for larger word lengths based on the partitioning of an LUT into an assortment of smaller LUTs. The particular partitioning becomes possible due to the nonlinear behavior of the addition and subtraction functions, $\log_b(1 + b^{-d})$ and $\log_b(1 - b^{-d})$, respectively, that are depicted in Figure 1.3 for $b = 2$. By exploiting the different minimal word length required by groups of function samples, the overall size of the LUT is compressed, leading to a LUT organization of Figure 1.4. In addition to the above techniques, reduction of the size of memory can be achieved by proper selection of the base of the logarithms. It turns out that the same bases that yield minimum power consumption for the LNS arithmetic unit by reducing the bit activity, as mentioned in the next section, also result in minimum LUT sizes.

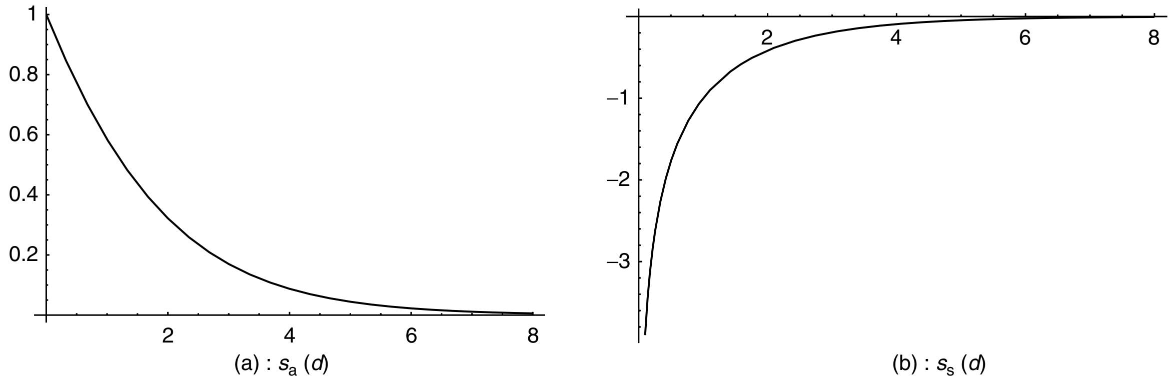
To use the benefits of LNS, a conversion overhead is required in most cases to perform the forward LNS mapping defined by equation 1.1. It is noted that conversions of equations 1.1 and 1.2 are required if an LNS processor receives input or transmits output linear data in digital format. Since all arithmetic operations can be performed in the logarithmic domain, only an initial conversion is imposed; therefore, as the amount of processing implemented in LNS grows, the contribution of the conversion overhead to power dissipation and to area–time complexity becomes negligible because it remains constant.

In stand-alone DSP systems, the adoption of a different solution to the conversion problem is possible. In particular, the LNS forward and inverse mapping overhead can be mitigated by converting the analog data directly into digital logarithms.

LNS Arithmetic Example

Let $X = 2.75,\ Y = 5.65$, and $b = 2$. *Perform the operations* $X \cdot Y$, $X + Y$, $\sqrt{X}$ and Y^2 *using the LNS.*

Initially, the data are transferred to the logarithmic domain as implied by equation 1.1:



(a) : $s_a\ (d)$

(b) : $s_s\ (d)$

FIGURE 1.3 The Functions $s_a(d)$ and $s_s(d)$: Approximations required for LNS addition and subtraction.

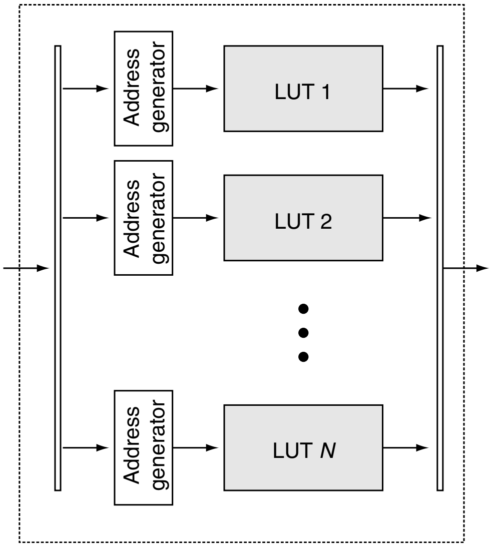


FIGURE 1.4 The Partitioning of the LUT: The partitioning stores the addition and subtraction functions into a set of smaller LUTs, which leads to memory compression.

$$\begin{aligned} X &\xrightarrow{\text{LNS}} (z_x,\ s_x, x = \log_2 |X|) \\ &= (0,\ 0, x = \log_2 2.75) = (0,\ 0,\ 1.4594). \end{aligned} \tag{1.19}$$

$$\begin{aligned} Y &\xrightarrow{\text{LNS}} (z_y,\ s_y,\ y = \log_2 |Y|) \\ &= (0,\ 0,\ y = \log_2 5.65) = (0,\ 0,\ 2.4983). \end{aligned} \tag{1.20}$$

Using the LNS images from equations 1.19 and 1.20, the required arithmetic operations are performed as follows: The logarithmic image w of the product $W = X \cdot Y$ is given by:

$$w = x + y = 1.4594 + 2.4983 = 3.9577. \tag{1.21}$$

As both operands are of the same sign (i.e., $s_x = s_y = 0$), the sign of the product is $s_w = 0$. In addition, because $z_x \neq 1$ and $z_y \neq 1$, the result is non-zero (i.e., $z_w = 0$).

To retrieve the actual result W from equation 1.21, inverse conversion of 1.2 is used as follows:

$$W = (1 - z_w)(-1)^{s_w} 2^w = 2^{3.9577} = 15.5377. \tag{1.22}$$

By directly multiplying X by Y, it is found that $W = 15.5375$. The difference of 0.0002 is due to round-off error during the conversion from linear to the LNS domain.

The calculation of the logarithmic image w of $W = \sqrt{X}$ is performed as follows:

$$w = \frac{1}{2}x = \frac{1}{2}1.4594 = 0.7297. \tag{1.23}$$

The actual result is retrieved as follows:

$$W = 2^{0.7297} = 1.6583. \tag{1.24}$$

The calculation of the logarithmic image w of $W = X^2$ can be done as:

$$w = 2 \cdot 1.4594 = 2.9188. \tag{1.25}$$

Again, the actual result is obtained as:

$$W = 2^{2.9188} = 7.5622. \tag{1.26}$$

The operation of logarithmic addition is rather awkward, and its realization is usually based on a memory LUT operation. The logarithmic image w of the sum $W = X + Y$ is as follows:

$$w = \max(x,\ y) + \log_2 (1 + 2^{\min(x,y) - \max(x,y)}) \tag{1.27}$$

$$= 2.4983 + \log_2 (1 + 2^{-1.0389}) \tag{1.28}$$

$$= 3.0704. \tag{1.29}$$

The actual value of the sum $W = X + Y$ is obtained as:

$$W = 2^{3.0704} = 8.4001. \tag{1.30}$$

1.2.3 LNS and Power Dissipation

Power dissipation minimization is sought at all levels of design abstraction, ranging from software and hardware partitioning down to technology-related issues. The average power dissipation in a circuit is computed via the relationship:

$$P_{\text{ave}} = af_{\text{clk}} C_L V_{\text{dd}}^2, \tag{1.31}$$

where f_{clk} is the clock frequency, C_L is the total switching capacitance, V_{dd} is the supply voltage, and a is the average activity in a clock period.

LNS is applicable for low-power design because it reduces the complexity of certain arithmetic operators and the bit activity.

Power Dissipation and LNS Architecture

LNS exploits properties of the logarithm function to reduce the strength of several arithmetic operations; thus, it leads to complexity savings. By reducing the area complexity of operations, the switching capacitance C_L of equation 1.31 can be reduced. Furthermore, reduction in latency allows for further reduction in supply voltage, which also reduces power dissipation (Chandrakasan and Brodersen, 1995). A study of the impact of the choice of the number system on the QRD-RLS algorithm revealed that LNS offers accuracy comparable to that of floating-point operations but only at a fraction of the switched capacitance per iteration of the algorithm (Sacha and Irwin, 1998). The reduction of average switched capacitance of LNS systems stems from the simplification of basic arithmetic operations, shown in Table 1.2. It can be seen that n-bit multiplication and division are reduced to $(k + l)$-bit addition and subtraction, respectively, while the computation of roots and powers is reduced to division and multiplication by a constant, respectively. For the common cases of square root or square, the operation is reduced to left or right shift respectively. For example, assume that a n-bit carry-save array multiplier, which has a complexity of $n^2 - n$ 1-bit full adders (FAs), is replaced by an n-bit adder, assuming $k + l = n$ has a complexity of n FAs for a ripple-carry implementation (Koren, 1993). Therefore, multiplication complexity is reduced by a factor r_{C_L}, given as:

$$r_{C_L} = \frac{n^2 - n}{n} = n - 1. \tag{1.32}$$

Equation 1.32 reveals that the reduction factor r_{C_L} grows with the word length n.

Addition and subtraction, however, are complicated in LNS because they require an LUT operation for the evaluation of $\log_b(1 \pm b^{y-x})$, although different approaches have been proposed in the literature (Orginos *et al.*, 1995; Paliouras and Stouraitis, 1996). An LUT operation requires a ROM of $n \times 2^n$ bits, a size that can inhibit use of LNS for large values of n. In an attempt to solve this problem, efficient table reduction techniques have been proposed (Taylor *et al.*, 1988). As a result of the above analysis, applications with a computational load dominated by operations of simple LNS implementation can be expected to gain power dissipation reduction due to the LNS impact on architecture complexity.

Since multiplication–additions are important in DSP applications, the power requirements of an LNS and a linear fixed-point adder–multiplier have been compared. It has been reported that approximately a two times reduction in power dissipation is possible for operations with word sizes of 8 to 14 bits (Paliouras and Stouraitis, 2001). Given a sufficient number of consecutive multiplication–additions, the LNS implementation becomes more efficient from the low-power dissipation viewpoint, even when a constant conversion overhead is taken into consideration.

Power Dissipation and LNS Encoding

The encoding of data through logarithms of various bases implies variations in the bit activity (i.e., the a factor of equation 31 and, therefore, the power dissipation) (Paliouras and Stouraitis, 1996, 2001).

Assuming a uniform distribution of linear n-bit input numbers, the distribution of bit assertions of the corresponding LNS words reveals that LNS can be exploited to reduce the average activity. Let $p_{0\to 1}(i)$ be the bit assertion probabilities (i.e., the probability of the ith bit transition from 0 to 1). Assuming that data are temporarily independent, it holds that:

$$p_{0\to 1}(i) = p_0(i)p_1(i) = (1 - p_1(i))p_1(i), \tag{1.33}$$

where $p_0(i)$ and $p_1(i)$ is the probability of the ith bit being 0 or 1, respectively. Due to the assumption of uniform data distribution, it holds that:

$$p_0(i) = p_1(i) = \frac{1}{2}, \tag{1.34}$$

which, due to equation 1.33, gives:

$$p_{0\to 1}(i) = \frac{1}{4}. \tag{1.35}$$

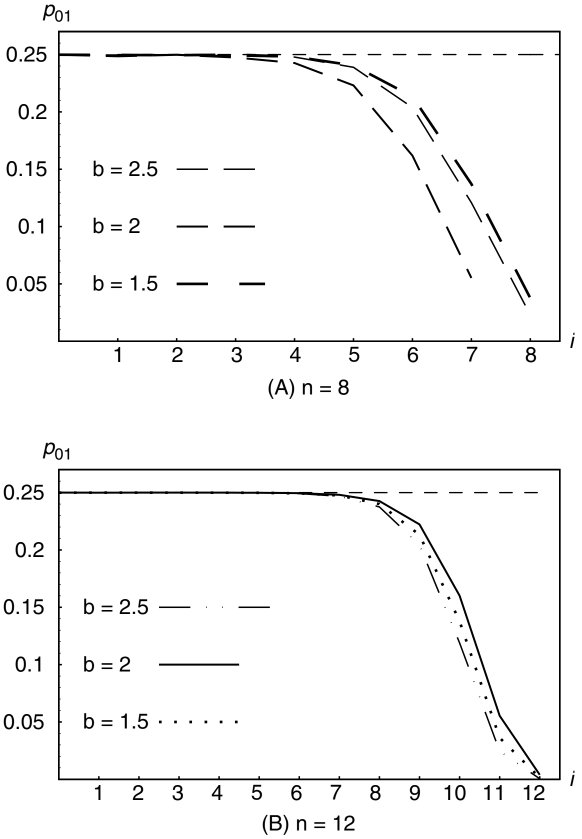
Therefore, all bits in the linear fixed-point representation exhibit an equal $p_{0\to 1}(i)$, $i = 0, 1, \ldots, n - 1$.

Activities of the bits in an LNS-encoded word are quantified under similar assumptions. Since there is an one-to-one correspondence of linear fixed-point values to their LNS images defined by equation 1.1, the LNS values follow a probability function identical to the fixed-point case. In fact, the LNS mapping can be considered as a continuous transformation of the discrete random variable X, which is a word in the linear representation, to the discrete random variable x, an LNS word. Hence, the two discrete random variables follow the same probability function (Peebles, 1987).

The $p_{0\to1}^{\mathrm{LNS}}$ probabilities of bit assertions in LNS words, however, are not constant as $p_{0\to1}(i)$ of equation 1.35; they depend on the significance of the ith bit. To evaluate the probabilities $p_{0\to1}^{\mathrm{LNS}}(i)$, the following experiment is performed. For all possible values of X in a n-bit system, the corresponding $\lfloor \log_b X \rfloor$ values in a (k, l, b)-LNS format are derived, and probabilities $p_1(i)$ for each bit are computed. Then, $p_{0\to1}^{\mathrm{LNS}}(i)$ is computed as in equation 1.33. The actual assertion probabilities for the bits in an LNS word, $p_{0\to1}^{\mathrm{LNS}}(i)$, are depicted in Figure 1.5. It can be seen that $p_{0\to1}(i)$ for the more significant bits is substantially lower than $p_{0\to1}(i)$ for the less significant bits. Moreover, it can be seen that $p_{0\to1}(i)$ depends on b. This behavior, which is due to the inherent data compression property of the logarithm function, leads to a reduction of the average activity in the entire word. The average activity savings percentage, S_{ave}, is computed as:

$$S_{\mathrm{ave}} = \left(1 - \frac{\sum_{i=0}^{k+l-1} p_{0\to1}^{\mathrm{LNS}}(i)}{0.25n}\right)100\%, \qquad (1.36)$$

where $p_{0\to1}^{\mathrm{FXP}}(i) = 1/4$ for $i = 0, 1, \ldots, n-1$; the word lengths k and l are computed via equations 1.13 and 1.14, and n denotes the length of the fixed-point system. The savings percentage S_{ave} is demonstrated in Figure 1.6(A) for various values of n and b, and the percentage is found to be more than 15% in certain cases.



(A) n = 8

(B) n = 12

FIGURE 1.5 Activities Against Bit Significance i (in an LNS Word for $n = 8$ and $n = 12$) and Various Values of the Base b. The horizontal dashed line is the activity of the corresponding n-bit fixed-point system

As implied by the definition of n_{eq} in equation 1.16, however, the linear system that provides an equivalent range to that of a (k, l, b)-LNS, requires n_{eq} bits. If the reduced precision of a (k, l, b)-LNS, compared to an n_{eq}-bit fixed-point system, is acceptable for a particular application, S'_{ave} is used to describe the relative efficiency of LNS, instead of equation 1.36, where:

$$S'_{\mathrm{ave}} = \left(1 - \frac{\sum_{i=0}^{k+l-1} p_{0\to1}^{\mathrm{LNS}}(i)}{0.25n_{\mathrm{eq}}}\right)100\%. \qquad (1.37)$$

Savings percentage S'_{ave} is demonstrated in Figure 1.6(B) for various values of n and b. Savings are found to exceed 50% in some cases. Notice that Figure 1.6 reveals that, for a particular word length n, the proper selection of logarithm base b can significantly affect the average activity. Therefore, the choice of b is important in designing a low-power LNS-based system.

Finally, it should be noted that overhead is imposed for linear-to-logarithmic and logarithmic-to-linear conversion. Conversion overhead contributes additional area and time complexity as well as power dissipation. As the number of operations grows, however, the conversion overhead remains constant; therefore, the overhead's contribution to the overall budget becomes negligible.

1.3 The Residue Number System

A different concept than the nonlinear logarithmic transformation is followed by mapping of data to appropriately selected finite fields. This may be achieved through the use of one of the many available versions of the residue number system (RNS) (Szabo and Tanaka, 1967). RNS arithmetic faces difficulties with sign detection, division, and magnitude comparison. These difficulties may outweigh the benefits it presents for addition, subtraction, and multiplication as far as general computing is concerned. Its use in specialized computations, like those for signal processing, offers many advantages. RNS has been used to offer superior fault tolerance capabilities as well as high-speed, small-area, and/or significant power-dissipation savings in the design of signal processing architectures for FIR filters (Freking and Parhi, 1997) and other circuits (Chren, 1998). RNS may even reduce the computational load in complex-number processing (Taylor *et al.*, 1985), thus

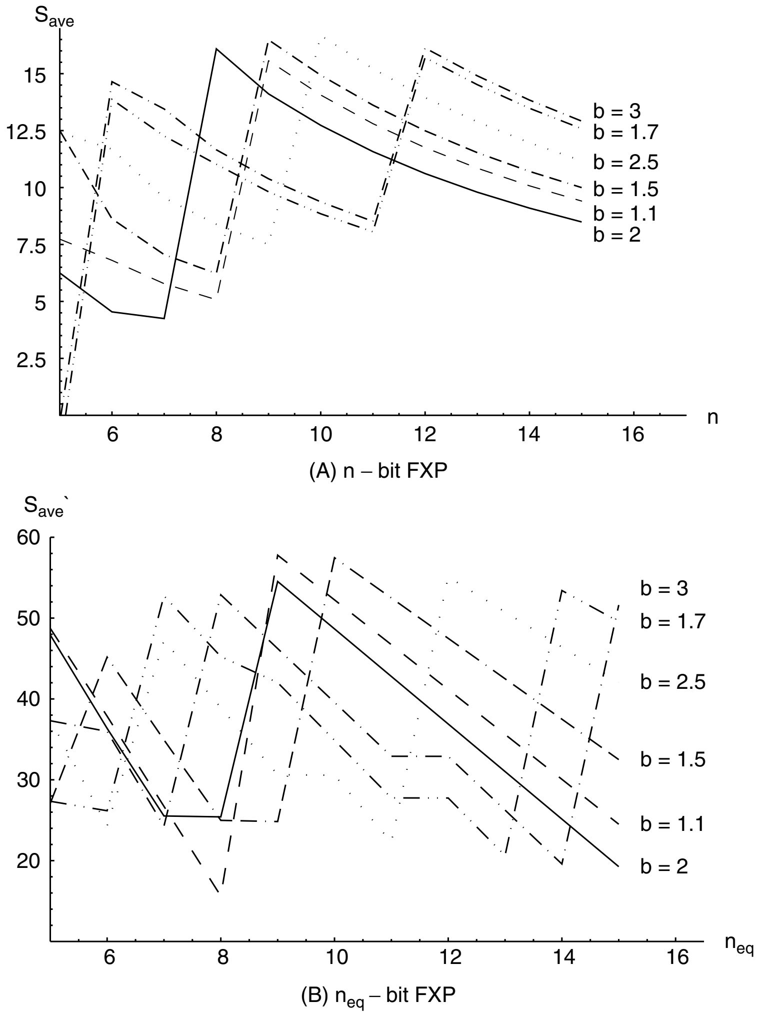


FIGURE 1.6 Percentage of Average Activity Reduction from Use of LNS. The percentage is compared to n-bit and to n_{eq}-bit linear fixed-point system for various bases b of the logarithm. The diagram reveals that the optimal selection of b depends on n, and it can lead to significant power dissipation reduction.

providing speed and power savings at the algorithmic level of the design abstraction.

1.3.1 RNS Basics

The RNS maps a natural number X in the range $[0, \ M-1]$, with $M = \prod_{i=1}^{N} m_i$, to an N-tuple of **residues** x_i:

$$X \xrightarrow{\text{RNS}} \{x_1, \ x_2, \ \ldots, \ x_N\}, \tag{1.38}$$

where $x_i = \langle X \rangle_{m_i}$, $\langle \cdot \rangle_{m_i}$ denotes the mod m_i operation and where m_i is a member of the set of the co-prime integers $B = \{m_1, \ m_2, \ldots, \ m_N\}$ called **moduli**. Co-prime integers' greatest common divisor is $gcd(m_i, \ m_j) = 1, \ i \neq j$. The set of RNS moduli is called the **base** of RNS. The modulo operation $\langle X \rangle_m$ returns the integer remainder of the integer division x div m (i.e., an integer k such that $x = m \cdot l + k$) where l is an integer.

RNS is of interest because basic arithmetic operations can be performed in a digit-parallel carry-free manner, such as in:

$$z_i = \langle x_i \circ y_i \rangle_{m_i}, \tag{1.39}$$

where $i = 1, \ 2, \ldots, \ N$ and where the symbol $\circ$ stands for addition, subtraction, or multiplication. Every integer in the range $0 \leq X < \prod_{i=1}^{N} m_i$ has a unique RNS representation.

Inverse conversion may be accomplished by means of the Chinese remainder theorem (CRT) or the mixed-radix conversion (Soderstrand *et al.*, 1986). The CRT retrieves an integer from its RNS representation as:

$$X = \left\langle \sum_{i=1}^{N} \overline{m_i}\langle \overline{m_i}^{-1} x_i \rangle_{m_i} \right\rangle_M, \tag{1.40}$$

where $\overline{m_i} = \frac{M}{m_i}$, $M = \Pi_{i=1}^{N} m_i$, and $\overline{m_i}^{-1}$ is the multiplicative inverse of $\overline{m_i}$ modulo m_i (i.e., an integer such that $\langle \overline{m_i} \cdot \overline{m_i}^{-1} \rangle_{m_i} = 1$).

Using an associated mixed radix system, inverse conversion may also be performed by translating the residue representations to a mixed radix representation. By choosing the RNS moduli to be the weights in the mixed radix representation, the inverse mapping is facilitated by associating the mixed radix system with the RNS. Specifically, an integer $0 < X < M$ can be represented by N mixed radix digits $(x_1', \ldots, x_N')$ as:

$$\begin{aligned} X = {} & x_N'(m_{N-1}m_{N-2}\ldots m_1) + \ldots + x_3'(m_2 m_1) \\ & + x_2' m_1 + x_1', \end{aligned} \tag{1.41}$$

where $0 \le x_i' < m_i$, $i = 1 \ldots N$, and the x_i' can be generated sequentially from the x_i using only residue arithmetic, such as in:

$$\begin{aligned} x_1' &= \langle X \rangle_{m_1} = x_1 \\ x_2' &= \langle m_1^{-1}(X - x_1') \rangle_{m_2} \\ x_3' &= \langle m_2^{-1}(m_1^{-1}(X - x_1')) - x_2') \rangle_{m_3}, \end{aligned} \tag{1.42}$$

and so on, or as in the following:

$$\begin{aligned} x_1' &= x_1 \\ x_2' &= \langle (x_2 - x_1') m_1^{-1} m_2 \rangle_{m_2} \\ x_3' &= \langle ((x_3 - x_1') m_1^{-1} m_3 - x_2') m_2^{-1} m_3 \rangle_{m_3} \\ &\vdots \\ x_N' &= \langle (\ldots((x_N - x_1') m_1^{-1} m_N - x_2') m_2^{-1} \\ & \quad m_N - \ldots - x_{N-1}') m_{N-1}^{-1} m_N \rangle_{m_N}. \end{aligned} \tag{1.43}$$

The digits x_i' can be generated sequentially through residue subtraction and multiplication by the fixed m_i^{-1}. The sequential nature of calculation increases the latency of the residues conversion to binary numbers.

The set of RNS moduli is often chosen so that the implementation of the various RNS operations (e.g., addition, multiplication, and scaling) becomes efficient. A common choice is the set of moduli $\{2^n - 1,\ 2^n,\ 2^n + 1\}$, which may also form a subset of the base of RNS.

RNS Arithmetic Example

Consider the base $B = \{3,\ 5,\ 7\}$ and two integers $X = 10$ and $Y = 5$. The RNS images of X and *Y are as written here:*

$$\begin{aligned} X \xrightarrow{\text{RNS}} \{x_1,\ x_2,\ x_3\} &= \{\langle 10 \rangle_3,\ \langle 10 \rangle_5,\ \langle 10 \rangle_7\} \\ &= \{1,\ 0,\ 3\}. \end{aligned} \tag{1.44}$$

$$Y \xrightarrow{\text{RNS}} \{y_1,\ y_2,\ y_3\} = \{\langle 5 \rangle_3,\ \langle 5 \rangle_5,\ \langle 5 \rangle_7\} = \{2,\ 0,\ 5\}. \tag{1.45}$$

The RNS image of the sum $Z = X + Y$ is obtained as:

$$\begin{aligned} Z \xrightarrow{\text{RNS}} \{z_1,\ z_2,\ z_3\} &= \{\langle 1 + 2 \rangle_3,\ \langle 0 + 0 \rangle_5,\ \langle 3 + 5 \rangle_7\} \\ &= \{0,\ 0,\ 1\}. \end{aligned} \tag{1.46}$$

To retrieve the integer that corresponds to the RNS representation $\{0,\ 0,\ 1\}$ by applying the CRT of equation 1.40, the following quantities are precomputed: $M = 3 \cdot 5 \cdot 7 = 105$, $\overline{m_1} = \frac{105}{3} = 35$, $\overline{m_2} = \frac{105}{5} = 21$, $\overline{m_3} = \frac{105}{7} = 15$, $\overline{m_1}^{-1} = 2$, $\overline{m_2}^{-1} = 1$, and $\overline{m_3}^{-1} = 1$. The value of the sum in integer form is obtained by applying equation 1.40

$$\begin{aligned} Z = X + Y &= \langle 35\langle 2 \cdot 0 \rangle_3 + 21\langle 1 \cdot 0 \rangle_5 + 15\langle 1 \cdot 1 \rangle_7 \rangle_{105} \\ &= \langle 15 \rangle_{105} = 15. \end{aligned} \tag{1.47}$$

To verify the result of equation 1.46, notice that $X + Y = 10 + 5 = 15$ and that:

$$15 \xrightarrow{\text{RNS}} \{\langle 15 \rangle_3,\ \langle 15 \rangle_5,\ \langle 15 \rangle_7\} = \{0,\ 0,\ 1\} = \{z_1,\ z_2,\ z_3\}, \tag{1.48}$$

which is the result obtained in equation 1.46. The same integer may be retrieved by using an associated mixed radix system defined by equation 1.41 as:

$$Z = z_3' \cdot 15 + z_2' \cdot 3 + z_1',$$

with $0 \le z_1' < 3,\ 0 \le z_2' < 5,\ 0 \le z_3' < 7$ and the following:

$$\begin{aligned} z_1' &= z_1 = 0 \\ z_2' &= \langle 3^{-1}(z_2 - z_1') \rangle_5 = \langle 2 \cdot z_2 \rangle_5 = 0 \end{aligned}$$

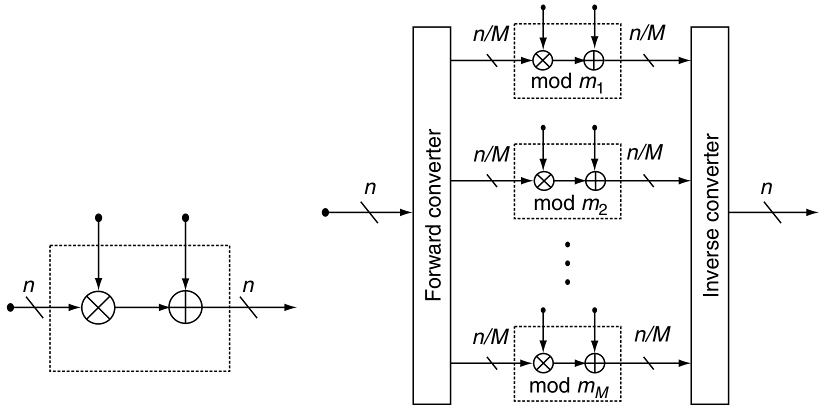
and

$$\begin{aligned} z_3' &= \langle 5^{-1}[3^{-1}(z_3 - z_1') - z_2'] \rangle_7 = \langle (z_3 - z_1') - 3 \cdot z_2' \rangle_7 \\ &= \langle (1 - 0) - 3 \cdot 0 \rangle_7 = 1 \end{aligned} \tag{1.49}$$

so that $Z = 1 \cdot 15 + 0 \cdot 3 + 0 = 15$.

1.3.2 RNS Architectures

The basic architecture of an RNS processor in comparison to a binary counterpart is depicted in Figure 1.7. This figure shows that the word length n of the binary counterpart is partitioned into N subwords, the residues, that can be processed



(A) Structure of a Binary Architecture (B) Corresponding RNS Processor

FIGURE 1.7 Basic Architectures

independently and are of word length significantly smaller than n. The architecture in Figure 1.7 assumes, without loss of generality, that the moduli are of equal word length. The ith residue channel performs arithmetic modulo m_i.

Most implementations of arithmetic units for RNS consist of an accumulator and a multiplier and are based on ROMs or PLAs. Bayoumi *et al.* (1983) have analyzed the efficiency of various VLSI implementations of RNS adders. Moreover, implementations of arithmetic units that operate in a finite integer ring $R(m)$ and that are called AU$_m$s are offered in the literature (Stouraitis, 1993). They are less costly and require less area and lower hardware complexity and power consumption. They are based on continuously decomposing the residue bits that correspond to powers of 2 that are larger than or equal to 2^n, until they are reduced to a set of bits that correspond to a sum of powers of 2 that is less than 2^n, where $n = \lceil \log_2 m \rceil$. This decomposition is implemented by using full adder (FA) arrays. For all moduli, the FA-based AU$_m$s are shown to execute much faster as well as have much smaller hardware complexity and time-complexity products than ROM-based general multipliers. Since the AU$_m$s use full adders as their basic units, they lead to modular and regular designs, which are inexpensive and easy to implement in VLSI.

1.3.3 Error Tolerance in RNS Systems

Because there is no interaction among digits (channels) in residue arithmetic, any errors generated at one digit cannot propagate and contaminate other channels during subsequent operations, given that no conversion has occurred from the RNS to a weighted representation.

In addition, because there is no weight associated with the RNS residues (digits), if any digit becomes corrupted, the associated channel may be easily identified and dealt with.

Based on the amount of redundancy that is built in an RNS processor, the faulty channels may be replaced or just isolated, with the rest of the system operating in a "soft failure" mode, being allowed to gracefully degrade into accurate operations of reduced dynamic range. Provided that the remaining dynamic range contains the results, there is no problem with this degradation.

The more redundant an RNS is, the easier it is to identify and correct errors. A redundant RNS (RRNS) uses a number r of moduli in addition to the N standard moduli that are necessary for covering the desired dynamic range. All $N + r$ moduli must be relatively prime. In an RRNS, a number X is presented by a total of N nonredundant residue digits $\{X_2, \ldots, X_N\}$ plus r redundant residue digits $\{X_{N+1} \ldots, X_{N+r}\}$. Of the total number of states, $M_R = \Pi_{i=1}^{N+r} m_i$ is represented by the RRNS. The $M = \Pi_{i=1}^{N} m_i$ first states constitute its "legitimate range," while any number that lies in the range $(M,\ M_R)$, is called "illegitimate."

Any single error moves a legitimate number X into an illegitimate number X'. Once it is verified that the number being tested is illegitimate, its digits are discarded one by one, until a legitimate representation is found. The discarded digit whose omission results in the legitimate representation is the erroneous one. A correct digit can then be produced by extending the base of the reduced RNS that produced the legitimate representation. The above error-locating-and-correcting procedure can be implemented in a variety of ways. Assuming that the mixed radix representations of all the reduced RNS representations can be efficiently generated, the legitimate one can be easily identified by checking the highest order mixed radix digit against zero. If it is zero, the representation is legitimate.

Mixed radix representations associated with the RNS numbers can be used to detect overflows as well as to detect and correct errors in redundant RNS systems. For example, to detect overflows, a redundant modulus m_{N+1} is added to the base and the corresponding highest order mixed radix digit a_{N+1} is found and compared to zero. Assuming that the number being tested for overflow is not large enough to overflow the augmented range of the redundant system, overflow occurs whenever a_{N+1} is not zero.

1.3.4 RNS and Power Dissipation

RNS may reduce power dissipation because it reduces the hardware cost, the switching activity, and the supply voltage (Freking and Parhi, 1997). By employing binary-like RNS filter structures (Ibrahim, 1994), it has been reported that RNS reduces the bit activity up to 38% in (4×4)-bit multipliers. As the critical path in an RNS architecture increases logarithmically with the equivalent binary word length, RNS can tolerate a larger reduction in the supply voltage than the corresponding binary architecture while achieving a particular delay specification. To demonstrate the overall impact of the RNS on the power budget of an FIR filter, Freking and Parhi (1997) report that a filter unit with 16-bit coefficients and 32-bit dynamic range, operating at 50 MHz, dissipates 26.2 mW on average for a two's complement implementation, while the RNS equivalent architecture dissipates 3.8 mW. Hence, power dissipation reduction becomes more significant as the number of filter taps increases, and a 3-fold reduction is possible for filters with more than 100 taps.

Low-power may also be achieved via a different RNS implementation. It has been suggested to one-hot encode the residues in an RNS-based architecture, thus defining **one-hot RNS** (OHR) (Chren, 1998). Instead of encoding a residue value x_i in a conventional positional notation, an $(m-1)$-bit word is employed. In this word, the assertion of the ith bit denotes the residue value x_i. The one-hot approach allows for a further reduction in bit activity and power-delay products using residue arithmetic. OHR is found to require simple circuits for processing. The power reduction is rendered possible since all basic operations (i.e., addition, subtraction, and multiplication) as well as the RNS-specific operations of scaling (i.e., division by constant), modulus conversion, and index computation are performed using transposition of bit lines and barrel shifters. The performance of the obtained residue architectures is demonstrated through the design of a direct digital frequency synthesizer that exhibits a power-delay product reduction of 85% over the conventional approach (Chren, 1998).

RNS Signal Activity for Gaussian Input

The bit activity in an RNS architecture with positionally encoded residues has been experimentally studied for the encoding of 8-bit data using the base {2, 151}, which provides a linear fixed-point dynamic range of approximately 8.24 bits. Assuming data sampled from a Gaussian process, the bit assertion activities of the particular RNS, an 8-bit sign-magnitude, and an 8-bit two's-complement system are measured and compared. The results are depicted in Figure 1.8 for 100 Monte Carlo runs. It is observed that RNS performs better than two's complement representation for anticorrelated data and slightly worse than sign-magnitude and two's complement representations for uncorrelated and correlated sequences.

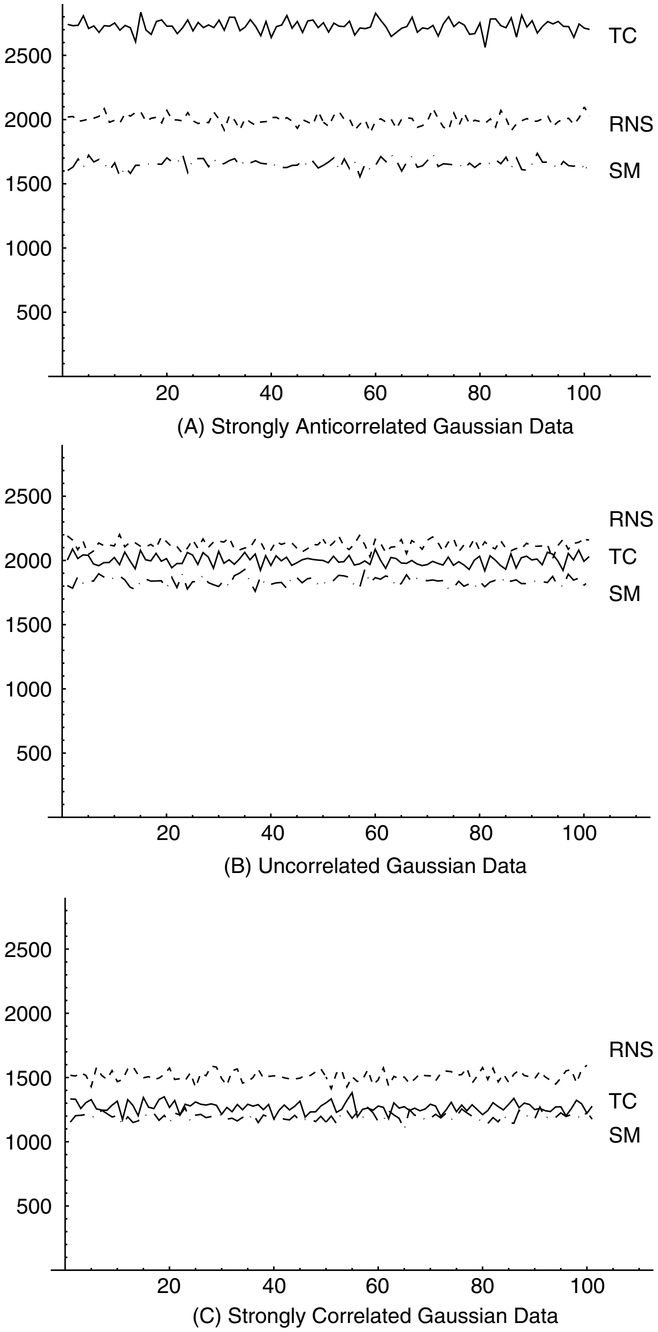


FIGURE 1.8 Number of Low-to-High Transitions. 2.1 Introduction

Because of the eternal push for more complex applications with correspondingly larger and more complicated data types, storage technology is taking center stage in more and more applications (Lawton, 1999), especially in the information technology area, including multimedia processing, network protocols, and telecom terminals. In addition, the access speed, size, and power consumption associated with the available storage devices form a severe bottleneck in these systems, especially in an embedded context. In this chapter, several building blocks for memory storage will be investigated first, with the emphasis on their internal architectural organization. Section 2 presents a general classification of the main memory components for customized organizations, including register files and on-chip SRAM and DRAMs. Next, Section 3. explains off-chip and global hierarchical memory organization issues.

Apart from the storage architecture itself, the way data are mapped to these architecture components is important for a good overall memory management solution. Actually, these issues are gaining in importance in the current age of deep submicron technologies, where technology and circuit solutions are not sufficient on their own to solve the system design bottlenecks. In current practice, designers usually go for the highest speed implementation for most submodules of a complex system, even when real-time constraints apply for the global design. Moreover, the design tools for exploration support (e.g., compilers and system synthesis tools) focus mainly on the performance aspect. The system cost, however can often be significantly reduced by system-level code transformations or trading-off cycles spent in different submodules. Therefore, the last four sections of this chapter are devoted to different aspects of data transfer and storage exploration: code rewriting techniques to improve data reuse and access locality (Section 4), how to meet real-time bandwidth constraints (Section 5), custom memory organization design (Section 6), and data layout reorganization for reduced memory size (Section 7). The main emphasis lies on custom processor contexts. Realistic multimedia and telecom applications are used to demonstrate the impressive effects of such techniques.

2.2 Custom Memory Components

In a custom processing context, many different options are open to the designer for the organization of the data storage and the access to it. Before going into the usually hierarchical organization of this storage (see section 2–3), this section presents the different components that make up the primitives of the hierarchy.

The goal of a storage device is in general to store a number of *n*-bit data words for a short- or long-term period. Under control of the address unit(s), these data words are transferred to the custom processing units (called processors further on) at the appropriate point in time (cycle), and the results of the operations are then written back in the storage device for future use. Due to the different characteristics of storage and access, different styles of devices have been developed.

2.2.1 General Principles and Storage Classification

A very important difference can be made between memories (for frequent and repetitive use) concerning short-term and long-term storage. Short-term storage devices are in general located very close to the operators and require a very small access time. Consequently, they should be limited to a relatively small capacity (less than 32 words typically) and are taken up usually in feedback loops over the operators (e.g., RegfA-BufA-BusA-EXU-RegfA in Figure 2.1) or at the input of execution units. This is typically called foreground memory. The devices for long-term storage are in general meant for (much) larger capacities (from 64- to 16-M words) and take a separate cycle for read or write access (Figure 2.2). Both categories are described in more detail in the next subsections.

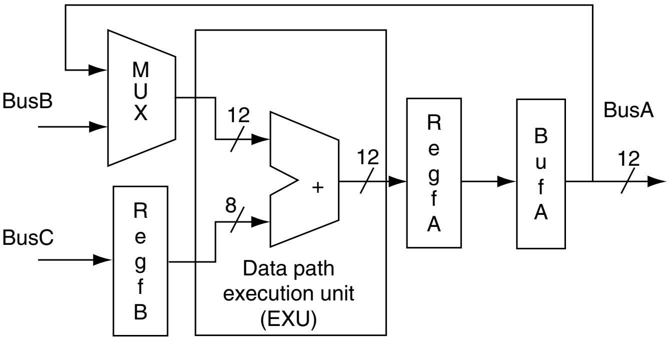

FIGURE 2.1 Register File in Feedback Loop of Custom Data Path

Six other important distinctions between short-term and long-term storage devices can be made using the tree-like "genealogy" of storage devices presented in Figure 2.3:

1. **Read-only and read or write (R/W) access**: Some memories are used only to store constant data, such as read-only memories or ROMs. Good alternatives include programmable logic arrays (PLA) or multilevel logic circuits, especially when the amount of data is relatively small. In most cases, data needs to be overwritable at high speeds, which means that *read* and *write* are treated with the same priority (R/W access),

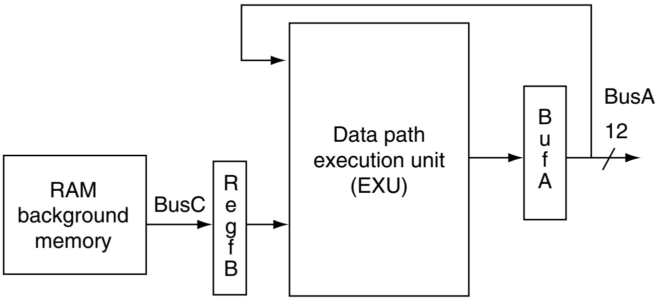

FIGURE 2.2 Large Capacity Background Memory Communicating with Custom Data Path

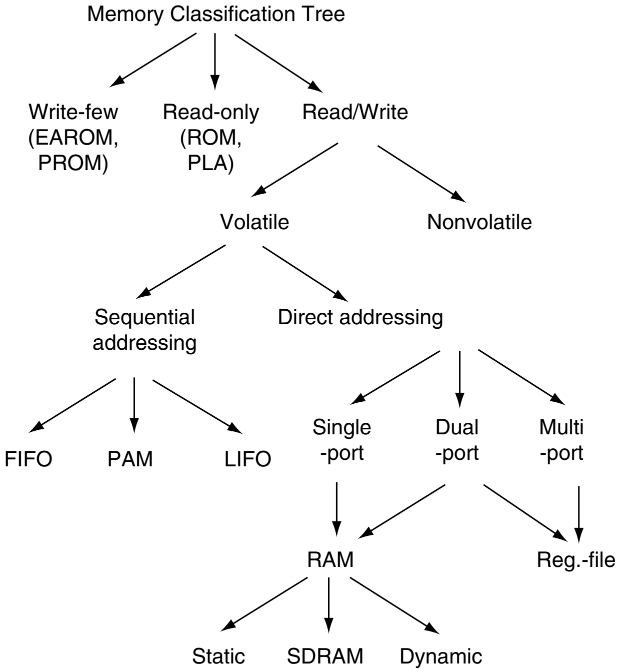

FIGURE 2.3 Storage Classification

such as in random-access memories or RAMs. In some cases, the ROMs can be made electrically alterable (= write-few) with high energies (EAROM) or programmable by means of fuses (PROM), for example. Only the R/W memories will be discussed further on.

2. **Volatile or not**: For R/W memories, the data are usually removed once the power goes down. In some cases, this can be avoided, but these nonvolatile options are expensive and slow. Examples are magnetic media and tapes that are intended for slow access of mass data. This discussion is restricted to the most common case on chip, namely, the volatile one.
3. **Address mechanism**: Some devices require only sequential addressing, such as the first-in first-out (FIFO) queue or first-in last-out (FILO) or stack structures, which put a severe restriction on the order in which the data are read out. Still, this restriction is acceptable for many applications. A more general but still sequential access order is available in a pointer-addressed memory (PAM). In most cases, however, the address sequence should be random (including repetition), which requires a direct addressing scheme. Then, an important requirement is that in this case, the access time should be independent of the address selected.
4. **The number of independent addresses and corresponding gateways (busses) for access**: This parameter can be one (single-port), two (dual-port), or even more (multiport) ports. Any of these ports can be for reading only, writing only, or R/W. Of course, the area occupied will increase considerably with the number of ports.
5. **Internal organization of the memories**: The memory can be meant for capacities that remain small or that can become large. Here, a trade-off is usually involved between speed and area efficiency. The registerfiles in subsection 2.2.2 constitute an example of the fast small capacity organizations that are usually also dual-ported or even multiported. The queues and stacks are meant for medium-sized capacities. The RAMs in subsection 2.2.3 can become extremely large (up to 256 Mb for the state-of-the-art RAM) but are also much slower in random access.
6. **Static or dynamic**: For R/W memories, the data can remain valid as long as Vdd is on (static cell in SRAM), or the data should be refreshed every 1.2 ms (dynamic cell in DRAM). In the dynamic class, high-throughput Synchronous DRAMs (SDRAM) are also available. Circuit level issues are discussed in overview articles concerning SRAMs, such as in Evans (1995), and for DRAMs, such as in Itoh (1997) and Prince (1994).

In the following subsections, the most important R/W-type memories and their characteristics are investigated in more detail.

2.2.2 Register Files and Local Memory Organization

This subsection discusses the register file and local memory organization. An illustrative organization for a dual port register file with two address busses, where the separate read and write addresses are generated from an address calculation unit (ACU), is shown in Figure 2.4. In this case, two data busses (A and B) are used but only in one direction, so the write and read addresses directly control the port access. In general, the number of different address words can be smaller than the number of port(s) when they are shared (e.g., for either read or write), and the busses can be bidirectional. Additional control signals decide whether to write or read and for which port the address applies. The number of address bits per word is $\log_2(N)$. The register file of Figure 2.4 can be used very efficiently in the feedback loop of a data path as already illustrated in Figure 2.1. In general, the file is used only for the storage of temporary variables in the application running on the data path (sometimes also referred to as execution unit). Such register files (regfiles) are also used heavily in most modern general-purpose RISCs and especially for modern multimedia-oriented signal processors that have regfiles up to 128 locations.[1] For multimedia-oriented VLIW processors or recent super-scalar processors, regfiles with a very large access bandwidth, up to 17 ports, are provided (Jolly, 1991). Application-specific instruction-set processors (ASIPs) and custom processors make heavy use of regfiles for the same purpose. It should be noted that although it has the clear advantage of very fast access, the number of data words to be stored should be minimized as much as possible due to the power- and area-intensive structure of such register files (both due to the decoder and the cell overhead). Detailed circuit issues will not be discussed here (for review, see Weste and Eshraghian [1993]).

After this brief discussion of the local foreground memories, we will now proceed with on- and off-chip background memories of the random access type.

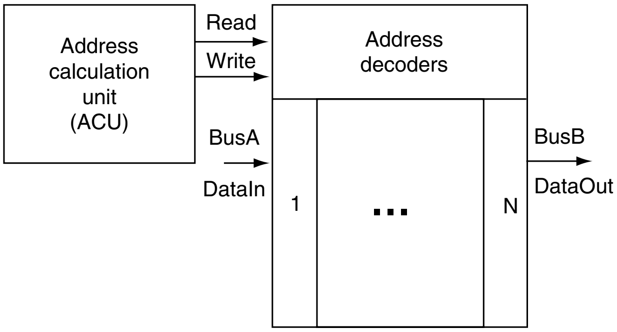

FIGURE 2.4 Regfile with Both R and W Addresses

[1] In this case, it becomes doubtful whether a register file is really a good option due to the very high area and power penalty.

2.2.3 RAM Organization

A large variety of possible types of RAMs for use as main memories has been proposed in the literature; research on RAM technology is still very active, as demonstrated by the results presented at International Solid-State Circuits (ISSCC) and Custom Integrated Circuit (CICC) conferences. Summary articles are available by Comerford and Watson (1992), Prince (1994), Oshima *et al.* (1997), and Lawton (1999). The general organization depends on the number of ports, but usually single-port structures are encountered in the large density memories. These structures will also be a restriction here. Most other distinguishing characteristics are related to the circuit design (and the technological issues) of the RAM cell, the decoder, and the auxiliary R/W devices. In this subsection, only the general principles are discussed.

For a B-bit organized RAM with a capacity of 2^k words, the floor plan in Figure 2.5 is the basis for everything. Notice the presence of read and write amplifiers that are necessary to drive or sense the (very) long bit-lines in the vertical direction. Notice also the presence of write-enable (WE) signal for controlling the R/W option and a chip select (CS) control signal that is mainly used to save power.

For large-capacity RAMs, the basic floor plan of Figure 2.5 leads to a very slow realization because of bit-lines that are too long. For this purpose, postdecoding is applied. This leads to the use of an X and a Y decoder (Figure 2.6), the flexibility of the floor plan shape is now used to end up with a near square (dimensions x by y), which makes use of the chip area in the most optimal way and reduces the access time and power (wire-length related). To achieve this, the following equations can be applied for a k-bit total address of $x + y = k$ and $x = y + \log 2B$, leading to $x = (\log 2B + k)/2$ and $y = k - x$ for maximal "squareness."

This breakup of a large memory plane into several subplanes is very important also for low-power memories. In that case, however, care should be taken to enable only the memory plane that contains data needed in a particular address cycle. If possible, the data used in successive cycles should also come from the same plane because activating a new plane takes up a significant amount of extra precharge power. An example floor plan in Figure 2.6 is drawn for $k = 8$ and $B = 4$. The memory matrix can be split up in two or more parts to reduce the length of the word lines also by a factor 2 or more. This results in a typically heavily partitioned floor plan (Itoh, 1997) as shown in a simplified form in Figure 2.7.

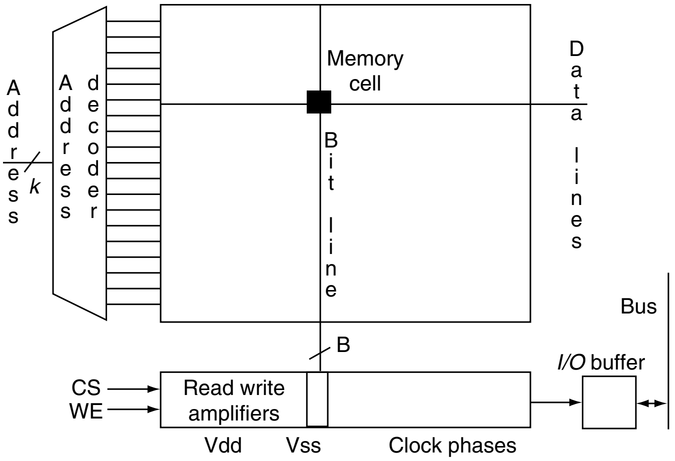

FIGURE 2.5 Basic Floor Plan for B-Bit RAM with 2^k Words

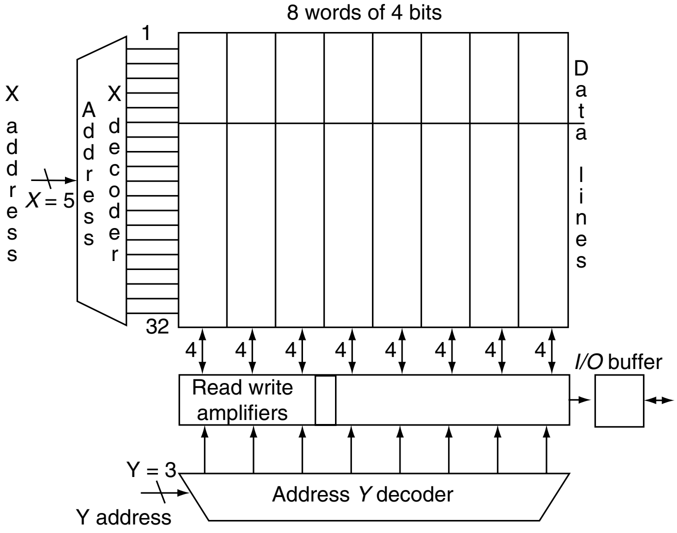

FIGURE 2.6 Example of Postdecoding

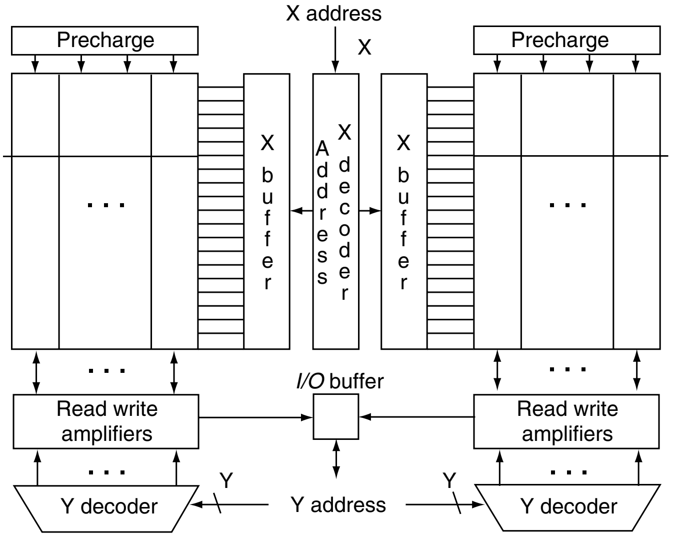

FIGURE 2.7 Partitioning of Memory Matrix Combined with Postdecoding

It should also be noted that the word length of data stored in the RAM is usually matched to the requirement of the application in the case of an on-chip RAM embedded in an ASIC. For RAM chips, this word organization normally has been

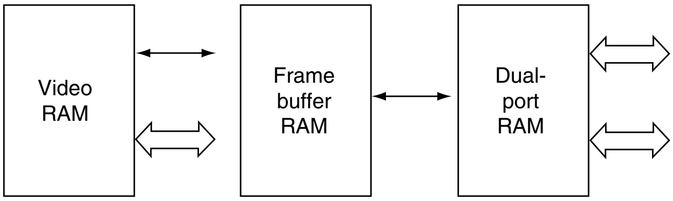

FIGURE 2.8 Specialized Storage Units. Thin arrows are serial ports; wide arrows represent parallel ports.

standardized to a few choices only. Most large RAMs are 1-bit RAMs. However, with the push for more application-specific hardware, 4-bit (nibble), 8-bit (byte), and 16-bit RAMs are now commonly produced. For the on-chip, clearly more options can be made available in a memory generator.

In addition to the mainstream evolution of these SRAMs, DRAMs, and SDRAMs, more customized large capacity high bandwidth memories are proposed that are intended for more specialized purposes. Examples are video RAMs, very wide DRAMs, and SRAMs with more than two ports (see the eight-port SRAM described by Takayanagi *et al.*, 1996, and review Prince, 1994). See also Figure 2.8.

2.3 Off-Chip and Global Hierarchical Memory Organization

Custom processors used in a data-dominated application context are driven from a customized memory organization. In programmable instruction-set processors, this organization is usually constructed according to a rigorous hierarchy that can be considered almost like a bidirectional pipeline from disk[2] over main memory and $L2/L1$ cache to the multiport register file. Still, the pipeline gets saturated and blocked more and more due to the large latencies that are introduced compared to the CPU clock cycles in current process technologies. This happens especially for the off-chip memories in the pipeline. In a custom processor context, more options are open to increase the on-chip bandwidth to the data, but off-chip similar restrictions apply for the off-chip. These issues are discussed in more detail in Subsection 2.3.1.

Next, a brief literature overview is presented of some interesting evolutions of current and future stand-alone RAM memory circuit organizations in different contexts. In particular, three different "directions" will be highlighted describing the apparent targets of memory vendors. They differ namely in terms of their mostly emphasized cost functions: power, speed, or density. Some of these directions can be combined, but several of them are noncompatible. One conclusion of this literature study is that the main emphasis in almost all directions is on the access structure and not on the way the actual storage takes place in the "cell." This access structure, which includes the "selection" part and the "input/output" part, dominates the overall cost in terms of power, speed, and throughput. When power-sensitive memories are constructed, the area contribution also becomes more balanced between the heavily distributed memory matrices and the access structures.

2.3.1 The External Data Access Bottleneck

Most older DRAMs are of the pipelined page-mode type. Pipelined memory implementations improve the throughput of a memory, but they don't improve the latency. For instance, in an extended data output (EDO) RAM, the address decoding and the actual access to the storage matrix (of the previous memory access) are done in parallel. In that case, the access sequence to the DRAM is also important. For example, the data sheet of an EDO memory chip specifies the sequence 10-2-2-23-2-2-2, where the numbers represent clock cycles. Each curly bracket indicates four bus cycles of 64-bit each—that is one cache line. The first sequence, 10-2-2-2, specifies the timing if the page is first opened and accessed four times. The second sequence, 3-2-2-2, specifies the timing if the page was already open and accessed four additional times—that means no other memory page was opened and accessed in between those times. The last sequence repeats as long as memory is accessed in the same page.

The data sheet in question relates to a memory bus running at 66 MHz. Taking another processing speed, say a 233-MHz processor, the timing becomes 35-7-7-711-7-7-7 in processor clocks (refer to Table 2.1).

Synchronous DRAMs (SDRAM) can have a larger pipeline that provides a huge theoretical bandwidth. Basically, the internal state machine enables to enlarge the pipeline. An SDRAM can sustain this high throughput rate by data access interleaving over several banks. However, the address needs to be known several cycles prior to when the data are actually needed. Otherwise the data path will stall, canceling the advantage of the pipelined memory. As already mentioned, modern stand-alone DRAM chips, which are often of this SDRAM type, also offer low-power solutions, but this comes at a price. Internally they contain banks and a small cache with a (very) wide width connected to the external high-speed bus

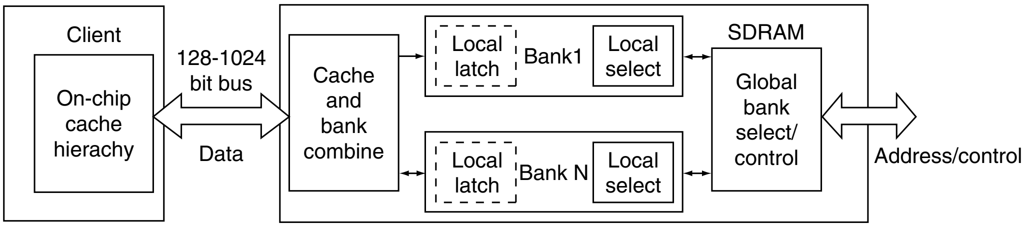

FIGURE 2.9 External Data Access Bottleneck Illustration with SDRAM

(see Figure 2.9) (Kim *et al.*, 1998; Kirihata *et al.*, 1998). So the low-power operation per bit is only feasible when the chips operate in burst mode with entire (parts of) memory column(s) transferred over the external bus. This is not directly compatible with the actual use of the data in the processor data paths, so without a buffer to the processors, most of the data words that are exchanged would be useless (and discarded). Obviously, the effective energy consumption per useful bit becomes very high in that case, and the effective bandwidth is low.

Therefore, a hierarchical and typically much more power-hungry intermediate memory organization is needed to match the central DRAM to the data ordering and bandwidth requirements of the processor data paths. The reduction of the power consumption in fast random-access memories is not as advanced as in DRAMs; moreover, this type of memory is saturating because many circuit and technology level tricks have already been applied also in SRAMs. As a result, fast SRAMs keep on consuming on the order of watts for high-speed operation around 500 MHz. So the memory-related system power bottleneck remains a very critical issue for data-dominated applications.

From the process technology point of view, this problem is not so surprising, especially for submicron technologies. The relative power cost of interconnections is increasing rapidly compared to the transistor (active circuit) related components. Clearly, local data paths, and controllers themselves contribute little to this overall interconnect compared to the major data/instruction busses and the internal connections in the large memories. Hence, if all other parameters remain constant, the energy consumption (and also the delay or area) in the storage and transfer organization will become even more dominant in the future, especially for deep submicron technologies. The remaining basic limitation lies in transporting the data and the control (like addresses and internal signals) over large on-chip distances and in storing them.

One last technological recourse to try to alleviate the energy-delay bottleneck is to embed the memories as much as possible on-chip. This has been the focus of several recent activities, such as in the Mitsubishi announcement of an SIMD processor with a large distributed DRAM in 1996 (Tsuruda *et al.*, 1996), followed by the offering of the "embedded DRAM" technology by several other vendors, and the IRAM initiative of Dave Patterson's group at U.C. Berkeley (Patterson *et al.*, 1997). The results show that the option of embedding logic on a DRAM process leads to a reduced power cost and an increased bandwidth between the central DRAM and the rest of the system. This is indeed true for applications where the increased processing cost is allowed (Wehn *et al.*, 1998). It is a one-time drop, however after which the widening energy-delay gap between the storage and the logic will keep on progressing due to the unavoidable evolution of the relative interconnect contributions (see previous discussion).

So on the longer term, the bottleneck should be broken also by other means. In sections 2.4 to 2.7 it is shown that this breakdown is feasible with quite spectacular effects at the level of the system-design methodology. The price paid will be increased design complexity that can however be offset with appropriate design methodology support tools.

2.3.2 Power Consumption Issues

In many cases, a processor requires one or more large external memories, mostly of the (S)DRAM type, to store long-term data. For data-dominated applications, the total system power cost in the past was for the most part attributed to the presence of these external memories on the board. Because of the heavy push toward lower power solutions to keep the package costs low, and also for mobile applications or due to reliability issues, the power consumption of such external DRAMs has been reduced significantly. This has also been a very active research topic.

The main concepts are a hierarchical organization with:

- Usually more than 32 divisions for RAM sizes above 16 Mb (Itoh *et al.*, 1995).
- Wide memory words to reduce the access speed (Amrutur and Horowitz, 1994).
- Multidivided arrays (both for word line and data line) with up to 1024 divisions in a single matrix (Sugibayashi *et al.*, 1993).
- Low on-chip Vdd up to 0.5 V (Yamagata *et al.*, 1995; Yamauchi *et al.*, 1996), with Vdd/2 precharge (Yamagata *et al.*, 1995).
- Negative word line drive (NWD) (Itoh *et al.*, 1995) or over-VCC grounded data storage (OVGS) (Yamauchi *et al.*, 1996) to reduce the leakage.[3]

[3] But both of these concepts requires several on-chip voltages to be fabricated, some of them negative.

- Level-controllable (Yamagata *et al.*, 1995) or boosted (Morimura and Shibata, 1996) word line for further reducing leakage,
- Multi-input selectively precharged NAND decoder (Morimura and Shibata, 1996),
- Driving level-controllable (Yamagata *et al.*, 1995) or boosted (Morimura and Shibata, 1996) word line instead of purely dynamic decoder of the past,
- Reduced bit/word line swing[4],
- Differential bus drivers,
- Charge recycling in the *I/O* buffers (Morimura and Shibata, 1996)

Because these principles distribute the power consumption from a few "hot spots" to all parts of the architecture (Itoh *et al.*, 1997), the end result is indeed a very optimized design for power where every piece consumes about an equal amount. An explicit power distribution is provided by Seki *et al.* (1993): 47% for everything to do with address selection and buffering (several subparts), 15% in the cells, 15% in the data line and sensing, and 23% in the output buffer.

The end result is a very low-power SRAM component (e.g., 5 mW for 1 M SRAM operating at 10 MHz for a 1-V 0.5-μm CMOS technology [Morimura and Shibata, 1996], and 10 mW for 1-M SRAM operating at 100 MHz for a longer term future 0.5-V 0.35-μm CMOS technology [Yamauchi *et al.*, 1996]. Combined with the advance in process technology, all this has also led to a remarkable reduction of the DRAM-related power: from several watts for the 16–32-Mb generation to about 100 mW for 100-MHz operation in a 256-Mb DRAM.

It is expected, however, that not much more can be gained because the "bag of tricks" now contains only the more complex solutions with a smaller return-on-investment. Note that the combination of all these approaches indicates a very advanced circuit technology, which still outperforms the current state-of-the-art in data path and logic circuits for low-power design (at least in industry). Hence, it can be expected that the relative power in the nonstorage parts can be more drastically reduced for the future (on condition that similar investments are done).

2.3.3 Synchronization and Access Times for High-Speed Off- and On-Chip RAMs

An important aspect of RAMs are the access times, both for read and write. In principle, these should be balanced as much as possible as the worst case determines the maximum clock rate from the point of view of the periphery. It should be noted that the RAM access itself can be either "asynchronous" or "clocked." Most individual RAM chips are of the asynchronous type. The evolution of putting more and more RAM on chip has led to a state defined by stand-alone memories that are nearly only DRAMs. In that category, the most important subclass is becoming the SDRAMs (see previous section). In that case, the bus protocol is fully synchronous, but the internal operation of the DRAM is still partly asynchronous. For the more conventional DRAMs that also have an asynchronous interface, the internal organization involves special flags, which signal the completion of a read or write and thus the "readiness" for a new data and/or address word. In this case, a distinction has to be made between the address access delay t_{AA} from the moment when the address changes and when the actual data are available at the output buffer and the chip (RAM) access delay t_{ACS} from the moment when the chip select (CS) goes up and the data are available. Ideally, $t_{ACS} = t_{AA}$, but in practice t ACS is the largest. So special "tricks" have to be applied to approach this ideal.

For on-chip (embedded) RAMs as used in ASICs, a clocked RAM is typically preferred as it is embedded in the rest of the (usually synchronous) architecture. These are nearly always SRAMs. Sometimes they are also used as stand-alone *L*2 cache, but the trend is to embed that cache level as well on the processor chip. A possible timing (clock) diagram for such a RAM is illustrated in Figure 2.10. The highest speeds can almost be achieved with embedded SRAMs. These memories are used in the so-called *L*1 cache of the modern microprocessors, where hundreds of megahertz are required to keep up with the speed of the CPU core. Representative examples of this category are a 2-ns (333-MHz) 256-kb (semi) set-associative cache (Covino *et al.*, 1996) that requires 8.7 W in a 2.5-V 0.5-μm CMOS technology and a 500-MHz 288-kb directly mapped cache (Furumochi *et al.*, 1996) requiring 1 W in a 2.5-V 0.25-μm CMOS technology.

2.3.4 High-Density Issues

The evolution at the process technology side has been the most prominent in the DRAM, leading to new device structures like the recessed-array stacked capacitor technology (Horiguchi *et al.*, 1995) resulting in a 1-Gb version in 0.16-μm TLM CMOS and the single-electron Coulomb cell (Yano *et al.*, 1996) for even larger sizes. Multilevel logic is also being

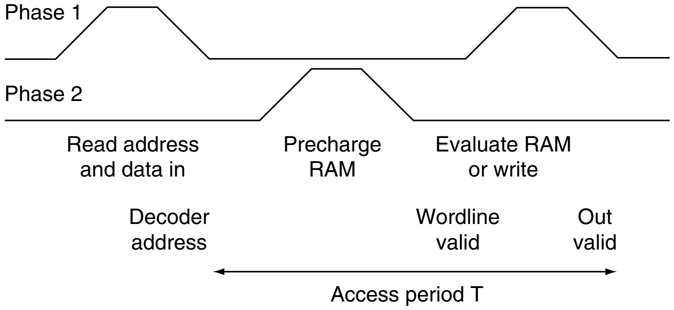

FIGURE 2.10 Timing Diagram for Synchronous Clocked RAM

[4] The reduction equals up to only 10% of the Vdd (Itoh *et al.*, 1995), which means less than 0.1 V for low voltage RAMs.

considered to put even more bits per square micrometer (Okuda and Murotani, 1997). This research direction is still mostly focused on the cell itself. SOI type devices are being investigated (Kuge *et al.*, 1996) to keep the power reasonable, but recognized is that low voltage CMOS does much to achieve this (Horiguchi *et al.*, 1995).

2.4 Code Rewriting Techniques to Improve Data Reuse and Access Locality

An efficiently used memory hierarchy is of primary importance in optimizing data transfer and storage. To exploit such a memory hierarchy, the code to be mapped should expose maximal data reuse possibilities. Code rewriting techniques, consisting of loop and data flow transformations, are essential to achieve this. The primitive loop transformations are also used in modern optimizing and parallelizing compilers to enhance the temporal and spatial locality for cache performance and to expose the inherent parallelism of the algorithm to the outer (for asynchronous parallelism) or inner (for synchronous parallelism) loops (Amarasinghe *et al.*, 1995; Wolf, 1992; Banerjee et al. 1993). Other application areas are communication-free data allocation techniques (Chen and Sheu, 1994) and optimizing communications in general (Gupta *et al.*, 1996).

It is thus no surprise that these code rewriting techniques are also at the heart of our data transfer and storage (DTSE) methodology (Catthoor *et al.*, 1998). As the first step (after the preprocessing and pruning) in the script, they are able to significantly reduce the required amount of storage and transfers. First, in the global data-flow transformation step, redundant accesses to large data types are removed. Moreover, the exploration space for the other steps is increased mainly by breaking/moving the critical data-flow bottlenecks and by exploiting algebraic laws. Next, global loop transformations are applied that significantly improve the overall regularity and access locality of the code. This enables the next step of the script, the data reuse step, to arrive at the desired reduction of storage and transfers. During this step, hierarchical data reuse copies are added to the code, exposing the different levels of reuse that are inherently present (but not directly visible) in the transformed code. A custom memory hierarchy can then be designed on which these copies can be mapped in an optimal way (see sections 2.5 and 2.6).

Crucial in our methodology is that the code transformations have to be applied globally (i.e., with the entire algorithm as scope). This is in contrast with most existing loop transformation research for which the scope is limited to one procedure or even one loop nest. This application can enhance the locality in that loop nest, but it does not solve the global data flow and associated buffer space needed between the loop nests or procedures. To allow these global transformations, a step has to be taken before the application is partitioned over different HW/SW components.

2.4.1 Methodology

Data-Flow and Loop Transformations

In a first step, the code has to be transformed to expose maximal locality and potential data reuse. This is done by globally applying data-flow and loop transformations. Loop transformations are well known and include loop interchange, merging, folding, and skewing. Data-flow transformations are less known and include, for example, algebraic law exploitation, recomputation (in terms of data transfer and storage, which can be beneficial to recompute certain data whenever they are needed instead of storing them in memory), and bottleneck removal (of which an illustration is shown in section 2.4.2). We will now give a simple example of applying loop transformations for data transfer and storage optimization.

The example is a three-level loop nest, in which a horizontal filter (with length L) is applied to a two-dimensional array. The initial description is the following (for simplicity, all filter coefficients are 1):

```
for (j = 0; j <= N−L; ++j)
  for (i = 0; i < N; ++i) {
    b [i] [j] = 0;                         (2.1)
    for (k = 0; k < L; ++k)
      b[i][j] + = a[i] [j + k];
  }
```

It is clear that code 2.1 has a bad locality because *L* new values of array *a*□□ have to be read from memory for each iteration of the *i*-loop. These values are reused only for each iteration of the outer *j*-loop. When this algorithm is implemented directly, it will result in high storage and bandwidth requirements (assuming that *N* is large): either the *a*□□ values are read from main memory each time they are needed, or a large buffer of $N \times L$ locations is implemented to avoid this.

By interchanging the *i*- and *j*-loop, we can achieve a much better locality. Indeed, for each iteration of *j*, $L - 1$ values of *a*□□ can be reused from the previous iteration, and only one new value has to be read from main memory. Only for each iteration of the outer *i*-loop, *L* new values of *a*□□ are needed. This will lead to significantly reduced storage and bandwidth requirements. The transformed code is as follows:

```
for (i = 0; i < N; ++i)
  for (j = 0; j < = N−L; ++j) {
    b [i] [j] = 0;                         (2.2)
    for (k = 0; k < L; ++k)
      b [i] [j] + = a [i] [j + k];
  }
```

Since exploring the search space for these transformations is tedious and error-prone, we are developing a systematic method for automating the global loop transformation step. Some information is available in (Catthoor *et al.*, 2000). This work, however, will still be in a research stage at the publication time of this book, and currently the step is applied manually.

Adding Hierarchical Data Reuse Copies

When the example transformed code 2.2 is executed on a processor with a small cache, it will perform much better than the initial code. To map it on a custom memory hierarchy, however, we have to know the optimal size of the different levels of this hierarchy. To this end, signal copies (buffers) are added to the code to make the data reuse explicit. For the example, this results in the following code (the initialization of *a_buf*□ has been left out for simplicity):

```
int a_buf [L];
int b_buf;
for (i = 0; i < N; ++i)
  {initialize a_buf}
  for (j = 0; j <= N−L; ++j) {
    b_buf = 0;                                   (2.3)
    a_buf [(j + L−1) % L] = a [i] [j + L−1];
    for (k = 0; k < L; ++k)
      b_buf + = a_buf[(j + k) % L];
    b [i] [j] = b_buf;
  }
```

In code 2.3, two data reuse buffers are present:

- *a_buf* □(*L* words) for the *a*□□ signals
- *b_buf* (1 word) for the *b*□□ signals

In the general case, more than one level of data reuse buffers is possible for each signal (see Section 2.4.2 for an example). We have developed a formal methodology (Wuytack *et al.*, 1998) for which all possible buffers are arranged in a tree. For each signal, such a tree is generated, and an optimal alternative is selected.

2.4.2 Illustration on Cavity Detection Application

The cavity detection algorithm, which will be used as an example throughout this section, is a medical image processing application that extracts contours from images to help physicians detect brain tumors. The initial algorithm consists of a number of functions, each of which has an image frame as input and one as output, as shown in Figure 2.11. In the first function, a horizontal and vertical **GaussBlur** step is performed, in which each pixel is replaced by a weighted average of itself and its neighbors. In the second function called **ComputeEdges**(), for each pixel, the difference with all eight neighbors is computed, and the pixel is replaced by the maximum of these differences. In the last function called **DetectRoots**(), the image is first reversed. To this end, the maximum value of the image is computed, and each pixel is replaced by the difference between this maximum value and itself. Next, for each pixel we look at whether a neighbor pixel is larger than itself. If this is the case, the output pixel is false; otherwise it is true. The complete cavity detection algorithm contains some more functions, but these have been left out here for simplicity:

```
void GaussBlur (unsigned char image_in [M] [N],
unsigned char gauss_xy [M] [N]) {
  // Perform horizontal horizontal and vertical
  GaussBlur step on each pixel
  unsigned char gauss_x [M] [N];
  for (y = 0; y < M; ++y)
    for (x = 0; x < N; ++x)
      gauss_x [y] [x] = . . . // Apply
      horizontal GaussBlur
  for (y = 0; y < M; ++y)
    for (x = 0; x < N; ++x)                                (2.4)
      gauss_xy [y] [x] = . . . // Apply
      vertical GaussBlur
}
void ComputeEdges (unsigned char gauss_xy [M] [N],

Transformed Cavity Detection Algorithm

We will now briefly describe how data-flow and loop transformations can introduce more locality and possibilities for data reuse into the code. These transformations are explained in more detail by Catthoor (2000).

First, a data-flow transformation is applied to remove the computation of the maximum of the whole image in the function Reverse(). Although this computation is negligible in terms of CPU time, it is very important in terms of data transfer and storage because the whole image has to read from memory and be stored again before the next function DetectRoots() can proceed.

Next, a global loop folding and merging transformation is applied to all the *y*-loops in the algorithm. As a result, the functions will not work on a whole image at once anymore but on a line-per-line pipelining base. This is shown in Figure 2.12.

Finally, a similar global loop folding and merging transformation is applied to the *x*-loops. The result is that the algorithm will now work on a fine-grain (pixel-per-pixel) pipelining base, as illustrated in Figure 2.13.

Adding Hierarchical Data Reuse Copies

From the above figures that illustrate the loop transformations, two levels of data reuse can be identified: line buffers and pixel buffers. As explained above, we will insert explicit buffers into the code to exploit the potential data reuse in an optimal way.

Line Buffers

For each of the functions, a buffer of three lines can be implemented, in which the line being processed is stored together with the previous and the next line:

- The horizontal GaussBlur is done on an incoming pixel, and the result is stored in the buffer gauss_*x*_lines □□.
- Next, the vertical GaussBlur is performed (on one pixel) in this buffer, and the result is stored in gauss_*xy*_lines □□.
- Then ComputeEdges() can be executed in that buffer, the result of which is stored in comp_edge_lines □□.
- Finally, DetectRoots () is executed in comp_edge_lines □□, and the resulting pixel is stored in the output image.

The resulting code is quite complex after inserting all necessary preambles and postambles or conditions; therefore, we give only the code for the heart of the loop nest here:

```
void cav_detect (unsigned char image_in [M] [N],
               unsigned char image_out [M] [N])
{
  unsigned char gauss_x_lines [3] [N] ;
  unsigned char gauss_xy_lines [3] [N] ;
  unsigned char comp_edge_lines [3] [N] ;
for (y=0; y<= M − 1 + 3; ++y) {

  for (x=0; x <= N − 1 + 2; + +x) {                (2.5)
    gauss_x_lines [y % 3] [x] = . . . // Apply hori-
    zontal GaussBlurr
    gauss_xy_lines [(y−1) % 3] [x] = . . . // Apply
    vertical GaussBlur
    comp_edge_lines  [(y−2)  % 3]  [x−1]  = . . . //
    Replace with max difference // with neighbors
    image_out [y−3] [x−2] = . . . // Is true if
    no neighbors are smaller than //
    comp_edge_lines [(y−3) % 3] [x−2] ;
```

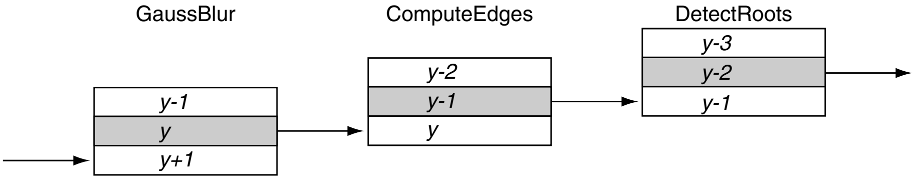

FIGURE 2.12 Cavity Detection Algorithm After *y*-Loop Transformation

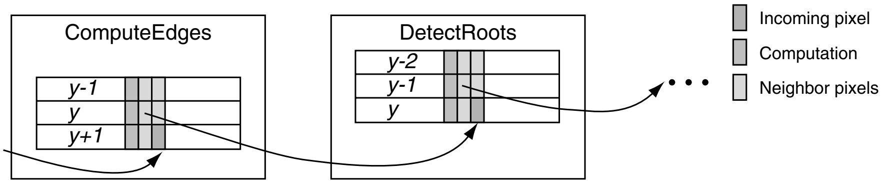

FIGURE 2.13 Cavity Detection Algorithm After *y*- and *x*-Loop Transformation

Pixel Buffers

In Figure 2.13, we can see that a second level of data reuse can be identified; that is, we can see the pixels in the neighborhood of the pixel being processed:

- For the horizontal GaussBlur, a buffer of three pixels in_pixels □ can be implemented, storing the last used values of the incoming image.
- For the vertical Gauss Blur, no such buffer is possible. However, the output of this step is stored into a three by three pixels buffer: gauss_xy_pixels□□.
- This buffer is used in ComputeEdges (), and the result of that step is again stored in a three by three buffer (i.e., comp_edge_pixels□□)
- Finally, DetectRoots () is performed on this buffer, and the result is stored in the output image.

The final code is (again without initializations and preambles and postambles) as follows:

```
void cav_detect (unsigned char image_in[M] [N],
               unsigned char image_out [M] [N])
{
  unsigned char gauss_x_lines [3] [N] ;
  unsigned char gauss_xy_lines [3] [N] ;
  unsigned char comp_edge_lines [3] [N] ;
  unsigned char in_pixels [3] ;
  unsigned char gauss_xy_pixels [3] [3] ;
  unsigned char comp_edge_pixels [3] [3] ;
  for (y=0; y<= M − 1 + 3; ++y) {
    for (x=0; x<= N − 1 + 3; ++x) {                (2.6)
      in_pixels[x % 3] = image_in[y] [x] ;
      gauss_x_lines [y % 3] [x−1] = . . . // Apply
      horizontal Gauss Blur
      gauss_xy_pixels [(y−1) % 3] [(x−1) % 3]
        = gauss_xy_lines [(y−1) % 3] [x−1] = . . .
                         // Apply vertical GaussBlur
      comp_edge_pixels [(y−2) % 3] [(x−2) % 3]
        = comp_edge_lines [(y−2) % 3] [x−2] = . . .
              // Replace with max difference with
              neighbors
      image_out[y−3] [x−3] = . . . // Is true if no
      neighbors are smaller than
                         // comp_edge_pixels [(y−3)
                         % 3] [(x−3) % 3] ;
    }
  }
}
```

Results

When processing the different versions presented above with our ATOMIUM access counting tool, we obtain the results presented in Table 2.2. This shows clearly that the final version is much better suited for mapping onto a custom memory hierarchy. The results in Section 2.6 will further substantiate this.

2.5 How to Meet Real-Time Bandwidth Constraints

In data transfer intensive applications, a costly and difficult issue to solve concerns getting the data to the processor quickly enough. A certain amount of parallelism in the data transfers is usually required to meet the application's real-time constraints. Parallel data transfers, however, can be very costly. Therefore, the trade-off between data transfer bandwidth and data transfer cost should be carefully explored. This section describes the potential trade-offs involved and also introduces a new way to systematically trade-off the data transfer cost with other components (illustrated for total system energy consumption).

In our application domain, an overall target storage cycle budget is typically imposed and corresponds to the overall throughput. In addition, other real-time constraints that restrict the ordering freedom can be present. In data transfer and storage intensive applications, the memory accesses are often the limiting factor to the execution speed, both in custom hardware and instruction-set processors (software). Data processing can easily be sped up through pipelining and other forms of parallelism. Increasing the memory bandwidth, on the other hand, is much more expensive and requires the introduction of different hierarchical layers, typically also involving multiport memories. These memories, however, cause a large penalty in area and energy. Because memory accesses are so important, it is even possible to make an initial system-level performance evaluation based solely on the memory accesses to complex data types (Catthoor *et al.*, 1998). Data processing is then temporarily ignored except for the fact that it introduces dependencies between memory accesses. This section focuses on the trade-off between cycle budget distribution over different system components and gains in the total system energy consumption. Before discussing this topic, a number of other issues need to be introduced.

Defining such a memory system based on a high-level specification is far from trivial when taking real-time constraints into account. High-level tools will have to support the definition of the memory system (see section 2.6). An accurate data-transfer scheduling is needed to derive a suitable memory architecture in the given (timing) constraints. This as such is an impossible task to do by hand, especially when taking sophisticated cost models into account.

The cost models can be based on area or power. Using both the models provides a clear trade-off in the power, area, and performance design space. In this section, we focus on the (cost) consideration and optimization freedom of all the three axes (Subsection 2.5.1). Moreover, the effective use of the trade-off is shown in Subsection 2.5.2. These trade-offs will be illustrated with real examples.

In Subsection 2.5.2, we will also use our tools to create Pareto curves visualizing the useful trade-off space between the cycle budget assigned to a given system submodule and its corresponding energy and/or area consumption (i.e., involving three search space axes). As far as we know, no other systematic (automatable) approach is available in literature to solve this important design problem. These curves can then be used to optimize the trade-offs between different system components at the global system level (see Subsection 2.5.3). These trade-offs are illustrated with real-life demonstrators. Prior to this, in Subsection 2.5.1, we will show how different cycle budgets assigned for the data transfer and storage requirements allow to (significantly) modify the required energy both in fully customizable processors and in predefined instruction-set processor contexts.

2.5.1 The Cost of Data Transfer Bandwidth

High performance applications do need a high bandwidth for their data. This high memory bandwidth requirement will typically involve a high system cost. A clear insight in these costs is necessary to optimize the memory subsystem. The cost will nearly always boil down to energy and area/size. These are the relevant costs for the end user and manufacturer. A high memory bandwidth can be obtained in several ways. Basically, two classes of solutions exist to obtain a high bandwidth: high access speed over a single port and high parallelism. Both come with large costs in energy and area.

Technology-wise, the basic access speed of memory planes increases slowly (less than 10% per year [Przybylski, 1997]). In contrast, the speed of the data path is doubling every 18 months (Moore's law). As a result, the performance gap between memory and data path increases rapidly. Advanced memory implementations are used to keep up with the path speed, but, in many cases, these can be quite energy consuming. Note that the maximal power consumption is not relevant in this context but that the actual energy consumed to execute a given application in a specific time period (cycle budget) is important. In many cases, from the application point of view, the external memory organization is used in an inefficient way. Sometimes data caches can overcome the problems partly at runtime, but these caches have a big area and energy overhead, especially when they are set-associative (Kamble and Ghose, 1997; Ko *et al.*, 1995; Su and Despain, 1995). Future memory organization solutions will have to provide more effective bandwidth at a reasonable actual energy consumption.

An alternative approach is to lower the application demand in terms of peak bandwidth. Lowering the peak bandwidth does not have to affect the overall application performance or functionality. Tool support is then needed to fully exploit this. Note also that the larger the available cycle budget, the more freedom exists to optimize the memory access ordering. Hence, the cycle budget (or performance) can be traded off for energy reduction.

Cost Model for High-Speed Memory Architectures

New memory architectures are developed to provide a higher basic access speed. To have a better understanding, we first briefly explain a model reflecting the virtual operation of a modern SDRAM[5] (see Figure 2.14). We abstract the physical implementation details that we cannot influence (e.g., the bitwidth, the circuits used, the floor-plan, and the memory plane organization). Some of these have already been mentioned in Subsection 2.3.1. The SDRAM consists of several banks that are accessed in an interleaved fashion to sustain a high throughput (pipelining principle). Every bank typically has several planes that can be activated separately. The **virtual plane** is defined as the total storage matrix entity that is activated (and consumes energy) when a particular memory access is performed. The planes contain a page that is copied to a local latch register for fast access.

It is also beneficial to have successive accesses located in a single page. Typically a factor 2 to 4 in energy can be saved this way. In an initial phase of a memory access, the row is selected. This row (= page) is sensed[6] and partly or entirely stored in a local register. Next, the proper column is transferred to the

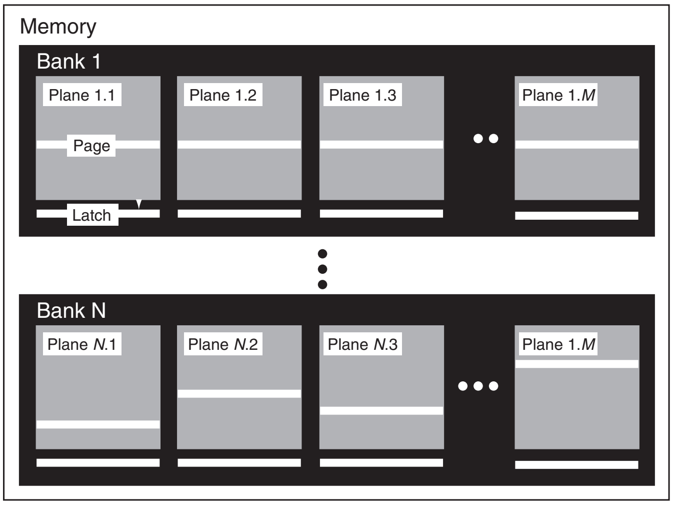

FIGURE 2.14 High-Level Synchronous DRAM Organization

[5] RAMBUS and other alternative architectures work with the same basic concept.

[6] Note that the sensing is an energy-consuming phase of an access.

output buffer. When the next access is in the same page, the row selection and sensing can be skipped. A high page hit rate is obtained when the next three conditions are fulfilled. First, the accesses need to be localized (local in every array). Second, the data layout should match the page mapping. Third, the memory access order in different arrays should access these page members together. Obviously, array access ordering and data layout freedom form the key factors.

Large memories consist of multiple planes that can be powered up separately. Multiple planes are used to avoid bit lines that are too long. By lowering switching between different planes, the energy is saved further. This should again be enabled by optimizing the access ordering and the data placement in the memories.

Costs in Highly Parallel Memory Architectures

The throughput can be enlarged by increasing the number of bits being transferred per access. Different signals can be transferred from different memories. Moreover, multiport memories can provide a higher memory bandwidth. The main problem here is creating the parallelism and efficient use of parallel data.

Increasing the number of memories has a positive influence on both bandwidth and memory energy consumption. But the interconnect complexity increases, causing higher costs. Obviously, there must be a trade-off. The definition of the memory architecture and assignment of signals to these memories has a large impact on the available bandwidth.

Multiported memories increase the bandwidth roughly linearly with the number of ports. A complete double wiring accomplishes the improvement. Unfortunately, this will also heavily increase the area of the memory matrix. Due to this increase, the average wire length increases as well. Therefore, the energy consumption and the cost in general will go up rapidly when using multiport memories. To this end, multiport memories have to be avoided as much as possible in energy-efficient solutions.

By packing different data elements together, a larger bandwidth can be obtained (Vandecappelle *et al.*, 1999). Consequently, the data bus widens and more data are transferred. These elements can belong to the same signal (packing), or they can belong to different signals (merging). In addition to the wider bus, such a coupling of two elements can cause many redundant transfers when only one of the elements is needed. Needless to say, this option should be considered very carefully.

Balance Memory Bandwidth

The previous two subsections focused on how to use the memories efficiently and on what can be done when we change the memory (architecture). In addition, much can be gained by balancing the bandwidth load over the application.

The required bandwidth is as large as the maximum bandwidth needed by the application (see Figure 2.15). When a very high demand is present in a certain part of the code (e.g., a certain loop nest), the entire application suffers. By flattening this peak, a reduced overall bandwidth requirement is obtained (see lower part of Figure 2.15).

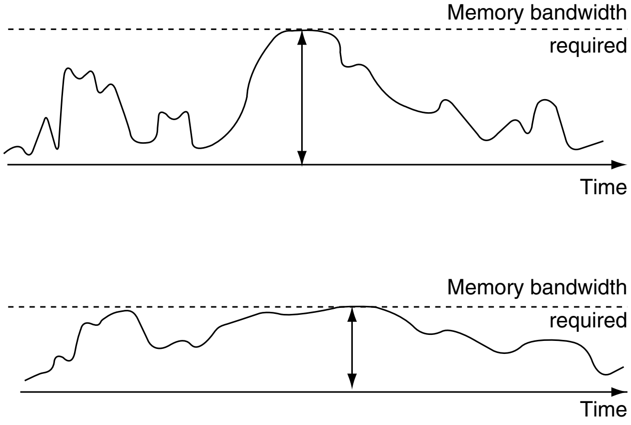

FIGURE 2.15 Balancing the Bandwidth and Lowering the Cost

The rebalancing of the bandwidth load is again performed by reordering the memory accesses (also across loop scopes). Moreover, the overall cycle distribution for the loops has a large impact on the peak bandwidth. Tool support is indispensable for this difficult task. An accurate memory access ordering is needed for defining the needed memory architecture.

2.5.2 Energy Cost Versus Cycle Budget Trade-Off

The previous subsection presented the most crucial factors influencing the data transfer and storage ("memory") related cost. Cost clearly increases when a higher memory bandwidth is needed. In most cases, designers of real-time systems assume that the time for executing a given (concurrently executed) task is predefined by "some" initial system decision step. Usually, this is only seemingly the case. When several communicating tasks or threads are co-operating concurrently, then trade-offs can be made between the cycle budget and timing constraints assigned to each of them, which makes the overall problem much more complex (see Subsection 2.5.3). Moreover, in data-dominated applications, the memory subsystem is not the only cost for the complete system. In particular, after our DTSE optimization steps, the data path is typically not negligible anymore, especially for instruction-set processor realization (see Subsection 2.5.3).

This subsection explains how to use the available trade-offs between cycle budget for a given task and the related memory cost. This leads to the use of **Pareto curves**. Moreover, several detailed real-life demonstrators are worked out. The data transfer and storage-related cycle budget ("memory cycle budget") is strongly coupled to the memory system cost (both energy and memory size/area are important here, as mentioned earlier). A Pareto curve is a powerful instrument for making the right trade-offs. The Pareto curve only represents the potentially

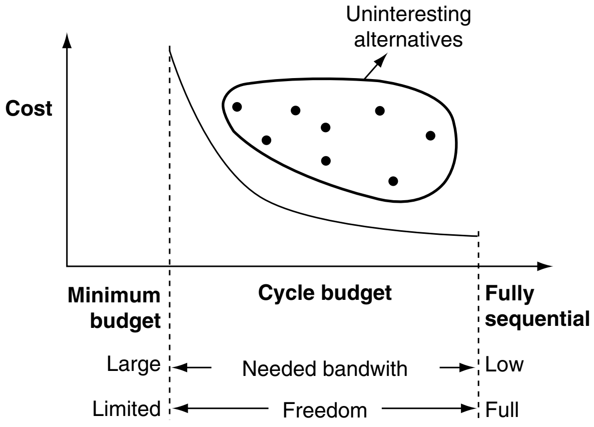

FIGURE 2.16 Pareto Curve for Trading of Memory Cycle Budget Versus Cost

interesting points in a search space with multiple axes and excludes all the solutions that have an equally good or worse solution for all the axes.

The memory cost increases when lowering the cycle budget (see Figure 2.16). When lowering the cycle budget, a more energy consuming and more complex (larger) memory architecture is needed to deliver the required bandwidth. Note that the lower cycle budget is not obtained by reducing the number of memory accesses, as in the case of the algorithmic changes and data-flow transformations (discussed in Section 2.4). These high-level code transformation related optimizations can be performed platform- and cycle-budget independent, prior to the trade-off that is the focus here. Therefore, during the currently discussed step in the system design trajectory, the amount of data transferred to the data-path remains equal over the complete cycle budget range. Nevertheless, some control flow transformations and data reuse optimizations can be beneficial for energy consumption and not for the cycle budget (or vice versa). These type of optimizations still have to be considered in the trade-off.

The interesting range of such a Pareto graph on the cycle budget axis should be defined from the critical path up to the fully sequential memory access path. In the fully sequential case, all the memory accesses can be transferred over a single port (lowest bandwidth). However, the number of memories is fully free, and the memory architecture can be freely defined. Therefore, the energy is the lowest. In the other extreme, the critical path, only a limited memory access ordering is valid. Many memory accesses are performed in parallel. Consequently, the constraints on the memory system are large, and a limited freedom is available. As a result, the energy consumption goes up. Because of a restricted cycle budget, the power itself increases even more of course, but the latter involves a more traditional trade-off that is not our focus here.

This energy-performance trade-off can be made on real-life applications thanks to the use of powerful novel tools that have been developed (IMEC, n.d.). Publications have focused on their use to generate a single near optimal solution in the entire search space. Their use in this new Pareto curve context is illustrated on a binary tree predictive coder (BTPC) used in offset image compression. Another demonstrator based on a digital audio broadcast (DAB) receiver is discussed by Brockmeyer *et al.* (1999) and Brockmeyer *et al.* (2000). Both demonstrators consist of several pages of *real* code containing multiple loops and arrays (in the range of 10 to 20) and a large number of memory access instructions (100 to 200).

BTPC is a lossless or lossy image compression algorithm based on multiresolution (Robinson, 1997). The image is successively split into a high-resolution image and a low-resolution quarter image, where the low-resolution image is split up further. The pixels in the high-resolution image are predicted based on patterns in the neighboring pixels. The remaining error is then expected to achieve high compression ratios with an adaptive Huffman coder.

Figure 2.17 shows the trade-off for the complete cycle budget range. The trade-off is obtained by letting the tool explore the cycle budget starting from the fully sequential mode and then progressing through the most interesting memory organizations (from a cost point of view) to reduce the cycle budget. Differently optimized code specifications are displayed and are derived by applying several system-level DTSE transformations prior to the individual Pareto curve generation. More information about these different versions of the code can be found in Brockmeyer (2000) and Vandecappelle (1999).

The code optimizations are performed in several steps defined by the upper part of our DTSE script (Catthoor, 1998). Platform-independent optimizations (as discussed in Section 2.4) reduce the number of memory accesses and improve the

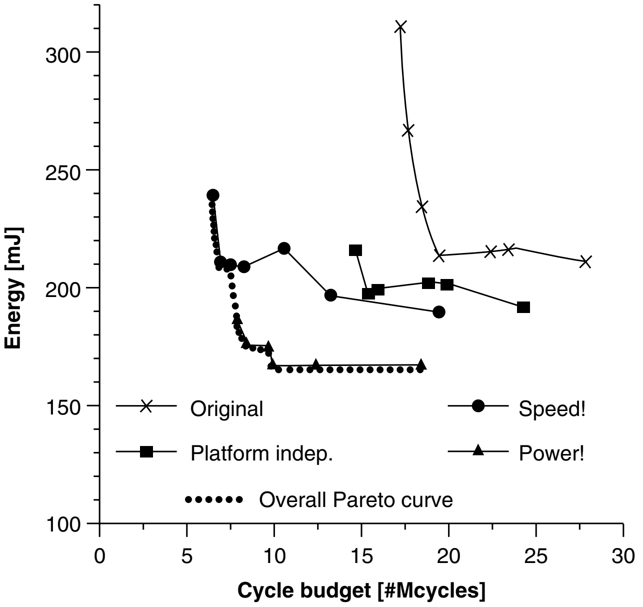

FIGURE 2.17 Pareto Curve for Binary Tree Predictive Coder

data locality (box curve). Next, two different optimization paths are followed: an energy-optimized one and a performance-optimized one. The main difference is the modified use of the available memory hierarchy: using the technique of Diguet *et al.* (1997), another intermediate signal is created and assigned differently for the speed-optimized implementation. As a consequence, an energy-intensive multiport memory is added in the memory hierarchy, delivering more bandwidth and improving the worst-case execution path of the application.

The overall Pareto curve obviously combines both differently optimized "sub-Pareto" results. For the high cycle budget and low performance situations, the low energy implementation is better. Only for a very high performance, the speed optimized implementation should be used. This kind of trade-off was first discussed by Brockmeyer *et al.* (2000). We will now also show how these curves can be effectively used to significantly improve the overall system design of data-dominated applications.

2.5.3 Exploiting the Use of the Pareto Curves

The previous subsections have shown which factors influence the memory cost. The memory cost increases when a higher memory bandwidth is needed (see Subsection 2.5.2). The memory subsystem, however, is not the only cost for the complete system. Data path is not always neglectable. Moreover, communicating tasks or threads make the problem more complex.

In this subsection, we will not go into detail on obtaining the information for the curve itself (see Section 2.4 and review IMEC [n.d.] and Brockmeyer [1999]), but we will show how to use them effectively in a low-power design context. Moreover, detailed real-life examples are worked out.

Trading off Cycles Between Memory Organization and Data Path

In case of a single thread and the memory subsystem being dominant in energy, the trade-off can be based solely on the memory organization Pareto curve. The given cycle budget defines the best memory architecture and its corresponding energy and area cost. Due to the use of latency hiding and a "system-level pipeline" between the computation and data communication, most of the cycles where memory access takes place are also useful for the data path. Still, to reduce the cost of the data path realization, it is important to leave some of the total cycle budget purely available for computation cycles (see further).

We will now illustrate how the assignment of spare cycles to the data path can have a significant impact on its energy consumption. Assigning too little indeed introduces an energy waste in the functional units when implemented in a low-power setup. For instance, several previous papers (see Chandrakasan *et al.* [1996] and its references) have motivated that functional units should operate at several voltages. The number of different Vdds has been restricted to a few specific values only because of practical reasons. Assume now that we either have a single unit that can operate part of the time at a higher Vdd and partly at a lower Vdd, or similarly assume two parallel units with different Vdds over which all the operations can be distributed (see Figure 2.18). This duplication will require some extra area, but on the entire chip this will involve a (very) small overhead, and for energy reasons this can be motivated. The high Vdd unit will clearly allow a higher speed. In the simple example of Figure 2.18, 110 million instructions need to be executed for the entire algorithm. Most instructions can be executed in the low energy functional unit in a very loose data path schedule (in total 1.0 s results in consuming 850 mJ). The same functionality, executed 25% faster, consumes twice as much energy due to the requirement to execute more on the high-speed functional unit (in total 0.75 s results in 1600 mJ). The assignment of cycles to memory accesses and to the data path is important for the overall energy consumption. Obviously, the contributions of both functions are summed. This motivates a trade-off between the memory system and the data path itself.

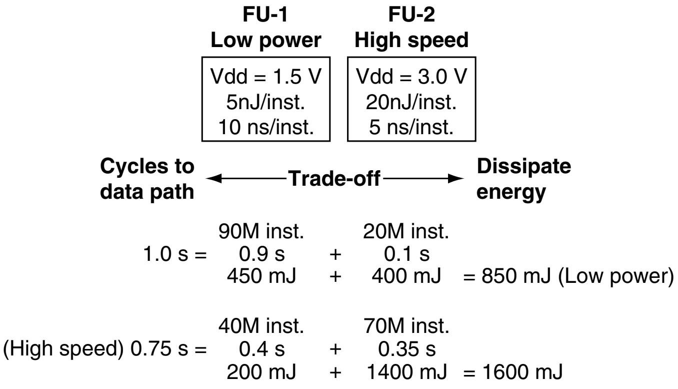

FIGURE 2.18 Data Path Example of a Performance Versus Energy Trade-Off

The reality, however, is still more complex. A certain percentage of the overall time can be spent to memory accesses, and the remaining part to computational issues, taking into account the system pipelining and the (large) overlap between memory accesses and computation (see Figure 2.19). The more time the overall budget is committed to the memory accesses, the more restrictions are imposed on the data path schedule that has less freedom for the ordering and the assignment to the functional units. As a result (see dotted curve), the Pareto curve for the data path usually exhibits a cost overhead that is small and constant for small to medium memory cycle budgets and that only starts to increase sharply when the memory cycle budget comes close to the globally available cycle budget (see Figure 3.19). Due to the fact that Pareto curve, are monotonous in their behavior, the sum of these two curves should exhibit a (unique) minimum.[7] This also advocates for an

[7] This sum usually will occur in the region where the two curves cross, but this is not necessarily the case.

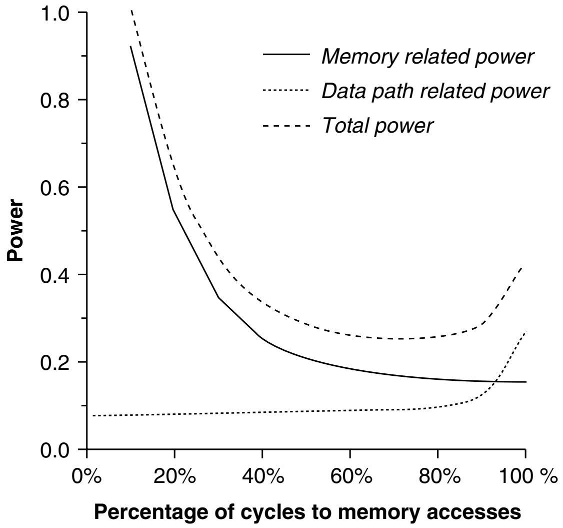

FIGURE 2.19 Trading Off Cycles for Memory Accesses Versus Cycles for Data Path Operations. Due to dependency and ordering, constraints cannot be executed in parallel with any data transfer.

accurate energy versus computation cycle budget modeling for the complex data path functions.

Energy Trade-Offs Between Concurrent Tasks

The performance–energy function can be used even better to trade off cycles assigned to different tasks in a complex system. Our Pareto curves should indeed be generated per concurrently executed task. It is then clearly visible that assigning too few cycles to a single task causes the cost of the entire system to increase. The Pareto curves also show the minimal (realistic) cycle budget per task. The cycle and energy estimates can clearly help the designer to assign concurrent tasks to processors and to distribute the cycles in the processors over the different tasks (see Figure 2.20). Minimizing the overall energy in a heterogeneous multiprocessor is then possible by applying Pareto function minimization on all the energy-cycle functions together. Even when multiple tasks have to be assigned to a single processor under control of an operating system, interesting trade-offs are feasible (a detailed example is given [Brockmeyer *et al.*, 2000]).

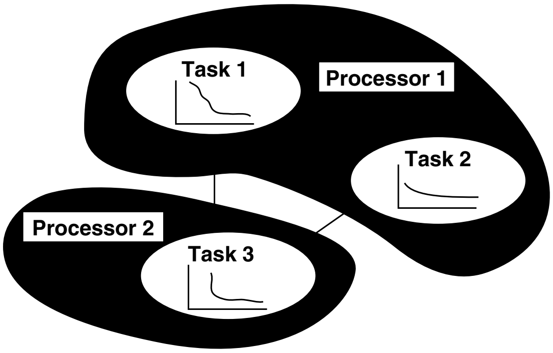

FIGURE 2.20 Trade-Off Cycles: Assigned Tasks

2.6 Custom Memory Organization Design

Many designs of VLSI systems assume a default organization of background memories. In contrast, with a customized memory organization, huge reductions are possible in the cost of the data storage. It is no trivial task, however, to achieve this cost reduction. This section first shows the cost reduction potential on the BTPC demonstrator. Then it explains the difficulties to achieve this reduction. Finally, a methodological approach to solve these problems is proposed.

2.6.1 Impact

In data-transfer intensive applications, a very high peak bandwidth to the background memories is needed. Spreading out the data transfers over time, as discussed in Subsection 2.5.1, helps to alleviate this problem, but the required bandwidth can still be high. The high-speed memory required to meet this bandwidth is a very important energy consumer and takes up much of the chip or board area (implying a higher manufacturing or assembly cost). In addition, purchasing a high-performance memory component is several times more expensive than a slower memory designed with older technology. The memory organization cost can be heavily reduced if it is possible to customize the memory architecture itself. Instead of having a single memory operating at high speed, it is better in terms of energy consumption, for example, to have two or more memories that can be accessed in parallel. Moreover, for embedded instruction-set processors, a partly customized memory architecture is possible: the processor core can be combined with one or more SRAMs or embedded DRAMs on the chip, and different configurations of the off-chip memories can also be explored. Although an instruction-set processor usually has only a single bus to connect with these memories, the clock frequency of the processor and the bus is often much higher than that of the memories, thus, the accesses to different memories can be interleaved over the bus.

An example of the impact of a custom memory organization is shown in Table 2.3 for the BTPC application introduced in

TABLE 2.3 Impact of a Custom Memory Organization for the BTPC Application

Memory architecture	On-chip area	On-chip energy	Off-chip energy
Default memory architecture One off-chip memory, One dual-port on-chip memory	200 mm^2	334 mJ	380 mJ
Custom memory architecture Three off-chip memories, Four single-port on-chip memories	111 mm^2	87 mJ	128 mJ

Subsection 2.5.2. The application's many memory accesses put a heavy load on the memory system. Therefore, the default memory configuration contains a high-speed off-chip DRAM as bulk memory and a dual-port SRAM for the arrays that are small enough to fit there. For this configuration, we have estimated the area of the on-chip SRAM and the energy consumption of both, based on the vendor's data-sheets and how many times each array is accessed. Then, we have also designed a custom memory organization for this application. In contrast to the default memory architecture, the custom memory organization can meet the real-time constraint with a much lower energy consumption and area cost. Slower, smaller, and more energy-efficient memories can be used. These results, however, are only attainable by careful systematic exploration of the alternatives, as the following subsection shows.

2.6.2 Difficulties

Although a custom memory organization has the potential to significantly reduce the system cost, achieving these cost reductions is far from trivial, especially manually. Figure 2.21 illustrates the problem of finding a custom memory architecture for an application. In this case, the application is specified using the C programming language. This specification contains arrays and accesses to them that have to be mapped into a background memory architecture. Designing such a custom memory architecture means deciding how many memories to use and which type. In addition, the memory accesses have to be ordered in time, so that the real-time constraints (the cycle budget) are met. Finally, each array must be assigned to a memory to enable arrays to be accessed in parallel as required to meet the real-time constraints.

For a given application, one can conceive numerous memory organizations: many memories or few memories, arrays stacked together into a memory or spread out over different memories, and memories with multiple ports to access the arrays in parallel, for example. Very few of these many alternative memory organizations, however, are acceptable. Most of them are actually very costly or dissipate a lot of energy. Many of them also fail to meet the real-time constraints: they don't provide the processor with the required data fast enough. Finally, some of them may be infeasible due to, for example, constraints on the size of the available memories.

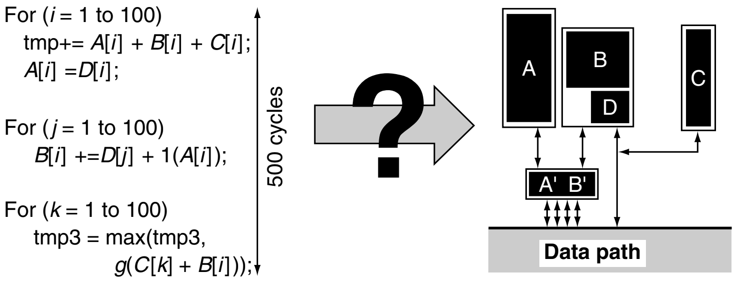
To tackle the complexity of finding a custom memory organization, a methodological approach is called for. Only few techniques for allocation and assignment of background memories have been proposed as opposed to the abundance of work on the scalar level (Stok, 1994; Pavlin and Knight, 1989; Verhaegh, 1995). As usual, when resources (memories) have to be used under timing constraints, there is a phase coupling problem between the scheduling of the resource and the allocation of it. Some techniques start from a given schedule (Lippens *et al.*, 1993). Others optimize the scheduling itself (Passos and Sha, 1995; Verhaegh, 1995), minimizing the parallelism of memory accesses. Still another technique bases the memory allocation on a bandwidth requirement estimation step (Balasa *et al.*, 1994).

In this discussion, we present an approach in two steps (Catthoor *et al.*, 1998; Slock *et al.*, 1997; Vandecappelle *et al.*, 1999). First, there is the **storage cycle budget distribution** (SCBD) step that does a partial ordering of the application's memory accesses. The ordering is driven by a cost function based on the nature of the conflicts that are created to leave as much freedom as possible for the next step. In the **memory allocation and assignment** (MAA) step, the memory architecture is defined by allocating memories and assigning arrays to them. To connect the two steps by propagating constraints from SCBD to MAA, we have developed the model of an **(extended) conflict graph**.

2.6.3 Storage Cycle Budget Distribution

The first step in custom memory organization design is to make sure the real-time constraints are met at minimal cost. All the memory accesses in the application have to be made within the given real-time constraint. A certain amount of memory bandwidth is needed to meet this constraint. The goal of the SCBD step is to order the memory accesses in the available time such that the resulting memory bandwidth is as cheap as possible.

To meet the real-time constraints, the data storage components of the system (i.e., the memory architecture) must be able to provide the required data to the data processing



```
For (i = 1 to 100)
   tmp+= A[i] + B[i] + C[i];
   A[i] =D[i];

For (j = 1 to 100)
   B[i] +=D[j] + 1(A[i]);

For (k = 1 to 100)
   tmp3 = max(tmp3,
              g(C[k] + B[i]));
```

FIGURE 2.21 Problem of Defining a Memory Architecture with Timing Constraints and Minimal Cost

components fast enough. In addition, the data processing components must work fast enough. However, the two can be cleanly separated. Most of the transfers can take place during the processing of other data; there may be a small amount of processing or a small amount of transfers that cannot be overlapped, but between these, there is a broad range of exploration, as indicated in Subsection 2.5.2.

It is important to explore the ordering freedom of the data transfers before scheduling the data processing itself, and not to do it the other way around. First of all, the cost of the data transfers is much higher than the cost of data processing, especially in data-transfer intensive applications. In addition, the constraints coming from first ordering the data transfers do not limit the scheduling freedom of the data processing too much, whereas the reverse is certainly not true.

To keep complexity reasonable, it is necessary at this stage to work at the level of arrays and not to expand them into scalars. In data-transfer intensive applications, the size of the arrays can go up to several millions of words, making scalar approaches completely infeasible. On the other hand, treating the arrays as a unit hardly limits the freedom; indeed, they will in any case be mapped into memories in a uniform way. The only disadvantage is that the analysis needs to be more advanced to be able to deal correctly with arrays (Balasa *et al.*, 1997; Catthoor *et al.*, 1998). This type of an analysis falls outside the scope of this book, however.

The ordering of the application's memory accesses in time determines how much memory bandwidth is needed. This memory bandwidth comes at a cost. Therefore, an estimation model of the memory bandwidth cost is required to steer the ordering of the memory accesses. Scheduling algorithms can then be used to optimize this cost; for example, the ones proposed by us (Wuytack *et al.*, 1996; Brockmeyer *et al.*, 2000; Omnès *et al.*, 2000), directly support the background memory cost in a global way. Manually exploring possible orderings and evaluating the resulting memory bandwidth is infeasible, so tool support is essential for this step.

The model for the memory bandwidth requirement is that of a conflict graph. It is derived from the ordering of the memory accesses, as shown in Figure 2.22. Its nodes represent the application's arrays, while its edges indicate that two arrays are accessed in parallel. It models the constraints on the memory architecture (see Subsection 2.6.4). An example is given in Figure 2.22, where array A cannot be stored in the same single-port memory as any of the other arrays: it is in conflict with them. However, there is no edge between B and D, so these two arrays can be stored in one memory. Note that to support multiport memories, this model must be extended with hyperedges (Catthoor *et al.*, 1998; Wuytack *et al.*, 1996).

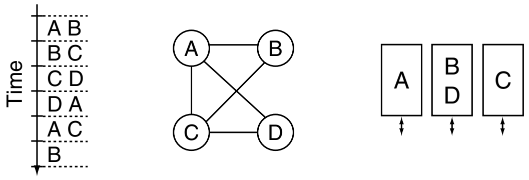


FIGURE 2.22 Conflict Graph Corresponding to Ordered Memory Accesses and a Possible Memory Organization Obeying the Constraints

From the conflict graph, it is possible to estimate the cost of the memory bandwidth required by the specified ordering of the memory accesses. Three main components contribute to the cost:

1. When two accesses to the same array occur in parallel, it means there is a **self-conflict**, a loop in the conflict graph. Such a self-conflict forces a two-ported memory in the memory architecture. Two-ported and multiported memories are much more costly; therefore self-conflicts carry a very heavy weight in the cost function.
2. In the absence of self-conflicts, the conflict graph's **chromatic number** indicates the minimal number of single-port memories required to provide the necessary bandwidth. For example, in Figure 2.22, the chromatic number of the graph is three: A, B, and C need three different colors to color the graph, for example. That means also a minimum of three single-port memories are required, even though three accesses never occur in parallel. More memories make the design (potentially) more costly; therefore, the conflict graph's chromatic number is the second component of the cost.
3. Finally, the more conflicts exist in the conflict graph, the more costly the graph is. Indeed, every conflict takes away some freedom for the assignment of arrays to memories (see also Subsection 2.6.4). In addition, not every conflict carries the same weight. For instance, a conflict between a very small, very heavily accessed array and a very large, lightly accessed array is not so costly because it is a good idea for energy efficiency to split these two up over different memories. A conflict between two arrays of similar size, however, is fairly costly because then the two cannot be stored in the same memory and potentially have to be combined with other arrays that do not match very well.

This abstract cost model makes it possible to evaluate and explore the ordering of memory accesses without going to a detailed memory architecture. Indeed, the latter is in itself a rather complex task, so combining the two is not feasible.

2.6.4 Memory Allocation and Assignment

In a custom memory architecture, the designer can choose how many memories to use, what their dimensions should be, and how many ports they have, for example. This decision, taking into account the constraints derived in the SCBD step, is the focus of the memory allocation and assignment step. The problem can be subdivided into two problems to be solved.

First, memories must be allocated: a number of memories is chosen from the available memory types and the different port configurations, different types are possibly mixed with each other, and some memories may be multiported. The dimensions of the memories are however only determined in the second stage. When arrays are assigned to memories, their sizes can be added up and the maximum bit width can be taken to determine the required size and bit width of the memory. With this decision, the memory organization is fully determined.

Allocating more or less memories has an effect on the chip area and the energy consumption of the memory architecture as shown in Figure 2.23 for single-port memories. With multiport memories, the number of possibilities becomes even much larger, but that will be left out of this discussion. Large memories consume more energy per access than small memories due to the longer word- and bit-lines. Therefore, the energy consumed by a single large memory containing all the data is much greater than the energy consumed when the data is distributed over several smaller memories. The area of the one-memory solution is also often higher when different arrays have different bit widths. For example, when a 6-bit and an 8-bit array are stored in the same memory, two bits are unused for every 6-bit word. By storing the arrays in different memories, one six-bits wide and the other eight bits wide, this overhead can be avoided. Note that the steepness of the curves heavily depends on the particular application and also on the memory library.

The other end of the spectrum is to store all the arrays in different memories. This leads to a relatively high energy consumption because then the external global interconnection lines connecting all these (small) memories with each other and with the data paths become an important contributor. Likewise, the area occupied by the memory system increases, due to the interconnections and the fixed address decoding and other overhead per memory.

Obviously, the interesting memory allocations lie somewhere between the two extremes. The area and the energy function reach a minimum somewhere but at a different point (the area typically at less memories than the energy). In between the two minima lies the useful exploration region to trade off the area with energy consumption.

The cost of the memory organization does not only depend on the allocation of memories, however, but also on the assignment of arrays to the memories (the previous discussion assumes an optimal assignment). When several memories are available, many ways exist to assign the arrays to them. The paragraph on the cost of conflicts in Subsection 2.6.3 demonstrates some of these issues. In addition, the optimal assignment of arrays to memories depends on the memories used. For example, the energy consumption of some memories is very sensitive to their size, while for others it is not. In the former case, it may be advantageous to accept some wasted bits to keep the heavily accessed memories very small, whereas in the latter case, the reverse may be true. To find a (near optimal signal-to-memory assignment, a huge number of possibilities have to be considered. Therefore, a tool to explore the memory organization possibilities based on a good memory library is indispensable for this step.

Both the memory allocation and the signal-to-memory assignment have to take into account the constraints generated by the SCBD tool to meet the real-time requirements. For the memory allocation, this means that a certain minimum number of memories is needed (again, for multiport memories, the situation is more complicated). This minimum is derived from the conflict graph's chromatic number and is also indicated in Figure 2.23. For the signal-to-memory assignment, conflicting arrays cannot be assigned to the same memory. When there is a conflict between two arrays that in the optimal assignment were stored in the same memory, a less efficient assignment must be accepted. Thus, more conflicts make the memory organization potentially more expensive.

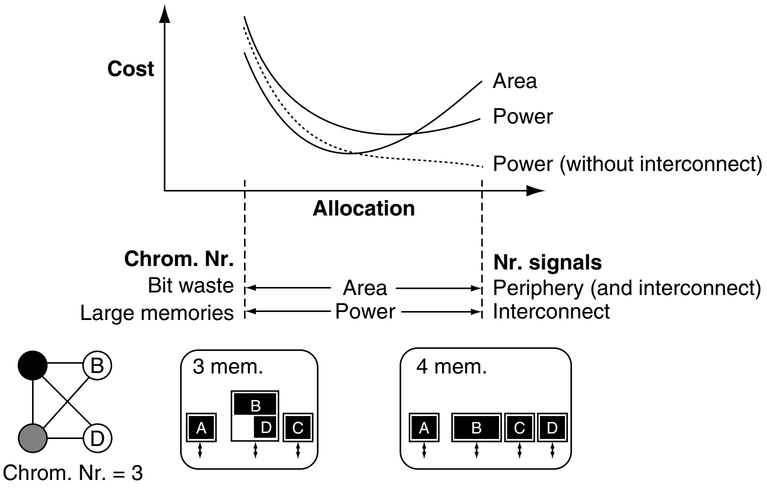

FIGURE 2.23 Exploration Space for the Number of Memories

2.6.5 Results

Manually exploring alternative custom memory organizations is infeasible, as discussed. Tool support is imperative for any application that is of realistic size. We have developed such tools such as the BTPC application and the cavity detector, and applied them to several realistic examples. The combination of the SCBD and MAA steps yields the Pareto curves for the BPTC demonstrator discussed in Section 2.5.

Figure 2.24 shows two results for the cavity detector application. The dashed curve is based on the code obtained after the DTSE optimizations introduced in Section 2.4. This assumes that all loops are executed one after the other.

Parallelizing some of the loops, which currently has to be done manually, allows to go to lower cycle budgets without increasing the (energy) cost. This is shown in the filled curve, where the four most important small loops are parallelized in a merge.

Figure 2.24 also shows the conflict graph and the optimal memory organization for three points on the cavity detector's Pareto curve. With lowering cycle budgets, more and more parallelism is required to meet the constraint. This is reflected by the additional conflicts in the conflict graph. The memory architecture needs more and more ports to provide the required parallelism and thus becomes more and more power-hungry. These results clearly substantiate the importance and the powerful exploration capability of the applied methodology and tools.

2.7 Data Layout Reorganization for Reduced Memory Size

In this section, we present some strategies that are capable of reducing the required memory sizes and the related power consumption of data-dominated multimedia applications. The main objective of these strategies is to reuse memory as much as possible by obtaining an optimal storage order for each of the arrays present in a program by means of data layout transformations that we have called "inplace data mapping." We assume that the arrays are already assigned to memories in the preceding MAA step of Section 2.6.

In the past, techniques for estimating memory reuse have been proposed (Cierniak and Li, 1995; Eisenbeis *et al.*, 1991; Wilde and Rajopadhye, 1996). These techniques however have provided only a memory reuse model and not a (complete) strategy for actually reusing memory space inside an array as well as between different arrays. This is due to the lack of exact mathematical model(s) of memory usage. In contrast, we have presented exact mathematical models for memory usage in examples presented by Catthoor *et al.* (1998), which allows us to perform more aggressive optimizations.

In this section, we first present an example illustration of the data layout reorganization strategy in Subsection 2.7.1. How this technique is actually realized is discussed in Subsection 2.7.2. Experimental results on a voice coder algorithm are given in Subsection 2.7.3. To conclude a summary is provided in Subsection 2.7.4.

2.7.1 Example Illustration

In this subsection, we illustrate how in-place mapping on arrays with partly nonoverlapping lifetimes allows the reduction of the required memory size for an algorithm. We use the autocorrelation part of a linear predictive coding vocoder algorithm introduced in Section 2.7.3.

1. **Initial Algorithm:** The initial algorithm is shown below in Figure 2.25. Note that we have two signals that are responsible for most of the memory accesses and that are dominant in size, namely ac_inter□ and

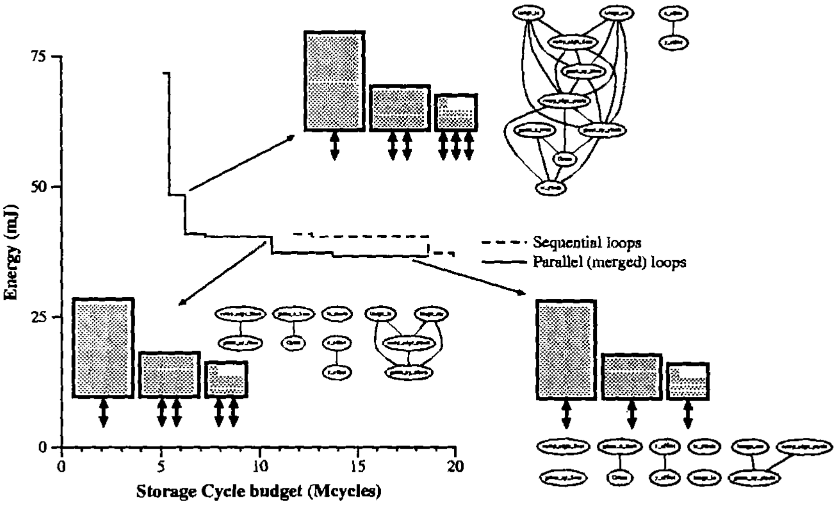

FIGURE 2.24 Pareto curve for Custom Memory Organization of the Cavity Detector (After DTSE Optimizations). This figure also shows the resulting memory organization for some of the Pareto points.

```
for(i6=0; i6 <11; i6 ++) {
  ac_inter [i6][i6] = Hamwind[0]*Hamwind [i6];
  ac_inter [i6] [i6+1] = Hamwind[1] * Hamwind
  [i6+1];
  for (i7 = (i6+2); i7<2400; i7++)
    ac_inter [i6] [i7] = ac_inter [i6] [i7-1] +
                         ac_inter [i6] [i7-2] +
               (Hamwind [i7-i6] * Hamwind [i7]);
  AutoCorr[i6] = ac_inter[i6] [2399] ;
}
for (i8=0; i8<10; i8++) {
  v[0] [i8] = AutoCorr [i8+1];
  u[0] [i8] = AutoCorr [i8];
}
```

FIGURE 2.25 Pseudocode for the Autocorrelation Function

Hamwind, with respective sizes of 26,400 and 2400 integer elements. Observe that the loop nest has nonrectangular access patterns dominated by accesses to the temporary variable ac_inter□. Thus to reduce power, we need to reduce the number of memory accesses to ac_inter□. This is possible only by first reducing the size of ac_inter□ and then placing this signal in a local memory.

2. **In-place data mapping:** Note that ac_inter□ has a dependency only on two of its earlier values; thus only three (earlier) integer values need to be stored for computing each of the autocorrelated values. Thus, by performing intrasignal in-place data mapping, as shown in Figure 2.26, we are able to drastically reduce the size of this signal from 26,400 to 33 integer elements. The signal AutoCorr□ is a temporary signal. By reusing the memory space of signal ac_inter□ for storing AutoCorr□, we can further reduce the total memory space required. This is achieved by intersignal in-place mapping of array AutoCorr□ on ac_inter□. Thus, initially ac_inter□ could not have been accommodated in the on-chip local memory due to the large size of this signal, but now we have removed this problem. This results both in reduced memory size and a reduction in the associated power consumption. Note that in Section 2.4, the data reuse step introduces additional buffers to exploit the reuse of data in a signal, whereas in-place mapping step exploits the reuse in as well as between signals to reduce the size of the existing signal.

```
for (i6=0; i6<11; i6++) {
  ac_inter [i6] [i6%3] = Hamwind [0] * Hamwind [i6];
  ac_inter [i6] [(i6+1)%3] = Hamwind [1] * Hamwind
  [i6+1];
  for (i7 = (i6+2); i7<2400; i7++)
    ac_inter [i6] [i7%3] = ac_inter [i6] [(i7-1)%3]+
                 ac_inter [i6] [(i7-2)%3] +
                 (Hamwind [i7-i6] * Hamwind [i7]);
}
for (i8=0; i8<10; i8++) {
  v[0] [i8] = ac_inter [i8+1] [2]; /* 2399 % 3 = 2 */
  u[0] [i8] = ac_inter [i8] [2];
}
```

2.7.2 Data Layout Reorganization Methodology

The data layout reorganization step comprises two phases, namely intrasignal in-place data mapping and intersignal in-place data mapping. These two phases are explained next.

Intrasignal In-Place Mapping

In a first phase, we optimize the internal organization of each array separately, resulting in a partially fixed storage order for each array. The intrasignal in-place mapping phase comprises calculation of the address reference window for-every array as shown in Figure 2.27 (A) and identification of an (optimal) intra-array storage order as shown in Figure 2.27 (D) (Greef *et al.*, 1997; Catthoor *et al.*, 1998). The address reference window represents the maximum distance between two addresses being occupied by the array at the same time.[8] This is calculated using the geometrical domains for each array referred to as **occupied address/time domains** (OATD's) as shown in Figure 2.27 (A) (Greef *et al.*, 1997).

The conventional (nonwindowed) memory allocation for arrays is shown in Figure 2.27 (B). We call this type of allocation **static allocation**. Figure 2.27 (D) shows the intrasignal in-place mapped arrays, also called **static windowed allocation** of memory space.

Thus, we observe that intrasignal in-place mapping helps reduce the memory size occupied by the individual array variable(s). In practice, we have observed that loop transformations such as loop fusion, loop tiling (Ciernak and Li, 1995; Lam *et al.*, 1991), and data reuse decisions (Diguet *et al.*, 1997) (see Section 2.4) help improve the temporal locality of data. Intrasignal in-place data mapping reduces the memory size of the data with good temporal locality. Thus, this technique is complementary to the loop transformations used for enhancing locality of data.

Intersignal In-place Mapping

The next step, intersignal in-place data mapping, optimizes the storage order between different arrays. We also refer to this step as **dynamic allocation**[9] and **dynamic windowed allocation** in Figure 2.27.

This step involves reusing the memory space between different arrays, both for arrays with disjoint and partially

[8] In our example illustration in Subsection 2.7.1, this distance was 3.

[9] Note that this step is performed at compile time, in contrast to traditional dynamic allocation provided by languages like *C*.

overlapped lifetimes (Greef *et al.*, 1997). The criterion that identifies (or checks) arrays with disjoint lifetimes is called **compatibility**, and the criterion that identifies arrays with partially overlapped life times that can be merged[10] is called **mergeability**. This step is illustrated in Figures 2.27(C) and 2.27(E). In Subsection 2.7.1, the arrays ac_inter□ and Auto-Corr□ had partially overlapped lifetimes and were mergeable. This resulted in the reuse of memory space occupied by array ac_inter□.

Figures 2.27(C) and 2.27(E) show that the combination of intra signal and intersignal in-place data mapping allows for an even larger reduction in the required memory size for the arrays as compared to intrasignal in-place mapping alone.

2.7.3 Voice Coder Algorithm and Experimental Results

Most of the communication applications like GSM require digital coding of voice for efficient, secure storage and transmission. We have used a linear predictive coding (LPC) vocoder, also called a voice coder, that provides an analysis–synthesis approach for speech signals (Rabiner and Schafer, 1988). In our algorithm, speech characteristics (energy, transfer function, and pitch) are extracted from a frame of 240 consecutive samples of speech. Consecutive frames share 60 overlapping samples. All information to reproduce the speech signal with an acceptable quality is coded in 54 bits. The general characteristics of the algorithm are presented in Figure 2.28. It is worth noting that the LPC analysis and pitch detection steps use autocorrelation to obtain the best matching predictor values and pitch (using a Hamming window). A part of this routine was used in Subsection 2.7.1 as an example illustration.

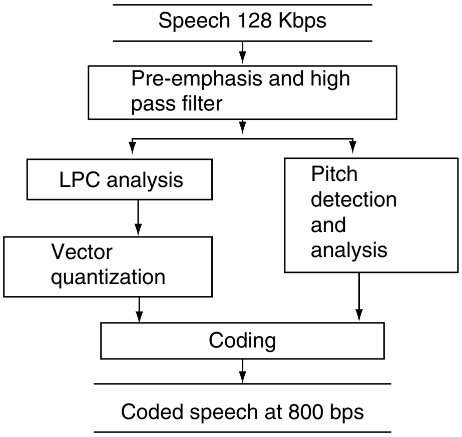

FIGURE 2.28 The Vocoder Algorithm and the Comprising Modules

Experimental Results

We now present the experimental results on the above described vocoder algorithm. Here, the initial algorithm represents the reference initial algorithm, the in-place mapped algorithm represents the initial algorithm with in-place data mapping, and the globally optimized algorithm comprises both in-place data mapping and loop transformations.

[10] Alternatively, memory space can be reused since all the R/W to particular addresses of one array are over just before the start of the second one for those addresses. If this is possible, we consider these arrays to be mergeable.

FIGURE 2.29 Experimental Results for the Vocoder Algorithm

Figure 2.29(A) shows the number of R/W to the on-chip local memory. Note that the number of accesses to the local memory is much larger for the globally optimized case, whereas it is much lower for the initial algorithm. Similarly, the in-place data mapped algorithm has a significantly larger number of accesses to the local memory. In Figure 2.29(B), we observe a similar phenomenon, but now the number of memory accesses is reduced for the optimized cases. We observe that for the initial algorithm, we have more accesses to the main memory than to the local memory. In contrast, for the globally optimized case, we access the main memory only a bit more than once per location. The rest of the accesses are to the local memory. This is due to the increased data locality that is brought about by the loop transformations and reduced working set sizes from data layout reorganization. Figure 2.29(C) gives the total power consumption in the memories for the different local memory sizes and optimization levels. We observe two issues here first, the globally optimized algorithm always performs better, and second the lowest power consumption for the globally optimized case is for a local memory size of 128 words and not for any higher size. This is because as we increase the local memory size, the number of memory accesses to this local memory does not increase proportionately and the number of accesses to the main memory remains the same. Hence, the total power consumption increases due to the increase in size of the local memory. Pure performance optimization does not lead to the best power solution.

Figure 2.29(D) shows the reduction in memory size for the two different steps of in-place data mapping obtained using a prototype tool. We observe that the initial algorithm requires 314K words, the intrasignal in-place mapped version needs 2387 words, and the intersignal in-place mapped version (after intrasignal in-place mapping) needs 1130 words. The benefits of these two steps are clearly evident. Figure 2.29(E) presents the comparison of the number of instructions and the code size for different cases. We observe that the overhead in code size and instructions are less than 15% for the most optimized case (64 words globally optimized), which is very acceptable for these application kernels because typically also a larger amount of additional purely control dominated code is present in the program memory. To conclude, we have executed the different algorithms on three different workstations to observe the performance gains. As shown in Figure 2.29(F), we observe an increase in performance by 20% on average, which is obtained apart from the large gains in power consumption.

2.7.4 Summary

The main conclusions from Section 2.7 are the following:

1. Aggressive data layout reorganization based on advanced array lifetime analysis allows designer(s) to reduce the required memory size of algorithms systematically.
2. Experimental results on a voice coder (vocoder) algorithm show that this technique is able to reduce the total memory size significantly and also reduce the associated power consumption. Automation of this technique has been demonstrated in a prototype tool that is being developed into a mature compiler program.

The Role of Hardware Description Languages in the Design Process of Multinature Systems

3.1 Introduction

In the past, information processing systems migrated from computing centers via desktops and laptops into embedded systems, which are a well-hidden part of not only transportation or production systems but even of devices for entertainment and leisure usage. These embedded systems derive their functionality from a cooperation of components that operate either **time-continuously** or **event-discretely**. In addition, embedded systems are products from different engineering disciplines, such as mechanical, electrical, and computer engineering. Examples of such systems are not only robots or automotive engine control units, for instance, and can be part of a scuba diver's equipment, as will be shown subsequently.

The engineering of such heterogeneous or multinature systems is not to be accomplished by well-known "identify and assign design tasks" approaches any more. A paradigm shift toward a holistic system view is mandatory due to the tight interaction of components that determines the overall performance of the system.

Specification, conceptualization, and assessment of design decisions are of utmost importance during the design process. In addition, these tasks have to be performed in a fast, reliable, and cost-efficient manner. Generation and application of models play an important role in the design process. Different models, abstraction levels, and accuracy requirements are to be considered and have to be handled efficiently regardless of the operation domains of all these models and engineering disciplines involved.

Starting with a real-world problem to be solved, a first conceptual model is derived that addresses the relevant properties of the problem. In general, this model is denoted in a mathematical way and has to be represented such that an execution becomes possible. At this point, the question of description languages gains interest. After some refinement steps at different abstraction and accuracy levels, the model is to be validated in the envisaged context, serving as a virtual prototype of the system to be produced.

This chapter addresses the refinement steps toward such a virtual prototype. It is organized as follows. Section 3.2 details the design process and the levels of abstraction to be covered in engineering multinature, mixed-mode embedded systems. Section 3.3 is a short introduction to the main features of the hardware description language VHDL–AMS (IEEE Standard 1076.1–1999) aimed to represent models for event-discrete and/or time-continuous operating heterogeneous systems. In Section 3.4, system modeling and simulation is demonstrated for an electronic depth gauge to be used by scuba divers. This application highlights the problems of combining multinature, mixed mode components into a virtual prototype. Finally, Section 3.5 concludes the chapter and recommends related literature for further reading.

3.2 Design Process and Levels of Abstraction

The design process for a technical product may, in general, be roughly subdivided into three main phases: conceptualization, concept refinement, and implementation. Inputs to the process are the design requirements, eventually resulting in the design results. A more detailed view to this "black box" model of the design process, as depicted in Figure 3.1, results in an identification of a process chain consisting of generating and analyzing activities to be performed iteratively in the outlined steps of conceptualization, refinement, and implementation.

The design requirements consist of a description of the envisaged functionality of the new product and sometimes of constraints referring to the final implementation, such as an exploitation of commercially available subsystems. This set of information is commonly known as the technical product specification, and it is still denoted in an informal way (i.e., written in a natural language and augmented by some tables and diagrams). Nontechnical specifications such as cost frames and design deadlines are important for the design process as well. They are, therefore, viewed as additional inputs to the design process as outlined in Figure 3.1.

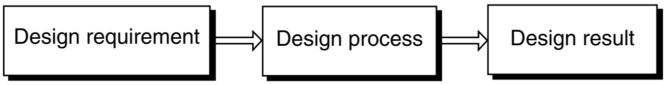

FIGURE 3.1 Black Box Model of a Design Process

The first and most important activities of the systems engineer during the conceptual phase are formalization of the specification, determination of solution strategies, and partitioning of the overall task into independent subtasks. These tasks are forwarded to design teams specializing in different areas, such as analog circuit design or real-time software engineering. Figure 3.2 depicts the design flow during conceptualization and refinement.

Modeling plays a central role in this design phase. Different model instantiations, abstraction levels, and accuracy requirements have to be dealt with during concept refinement. In addition, multinature systems in general operate time-continuously, but the information processing inherent to most such systems consists of digital hardware and software modules, which are best represented in a time- or even-discrete way. Levels of abstraction are well-defined in the digital domain. They are summarized in Table 3.1.

Views, abstraction levels, modeling concepts, structural primitives, and time models are related to the observable values produced by models of digital systems. These models may be denoted in a hardware description language such as Verilog or VHDL. We will focus on the latter in the following paragraphs for reasons given in the next section.

Abstraction levels for time-continuous systems are not yet that well agreed upon in terms of counterparts for digital circuits and systems. Table 3.2 introduces and discusses four levels of design concepts and observable signals beginning with the highest abstraction level.

	Gates	(Boolean) logic equations	Gates, flip-flop	Discrete (fine granularity)	Multivalued logic
Reactive	Switch	Discrete equations	Switch, discrete capacitors	Continuous (increase or decrease times)	Discrete (value, strength)
	Circuits	Differential equations	Transistors, *R*, *L*, *C*	Continuous (mathematical exact)	Continuous (voltage, current)

TABLE 3.2 Levels of Abstraction in Analog Systems

Level	Modeling concept	Observable signals
Functional	• Description of signal flow equivalent to data flow in digital circuits • Input/Output relations by means of mathematical functions	• Time- and value-continuous • Conservative laws *not* considered
Behavioral	• Equations that describe the relations between port variables of an entity	• Time- and value-continuous • Conservative laws considered
Macromodel	• Hierarchical composition using ideal functional blocks	• Same properties as at a behavioral level
Circuit	• Hierarchical composition based on discrete basic elements	• Same properties as at a behavioral level

These abstraction levels seem to be strongly related to analog circuit design only—especially levels three and four. However, an introduction of the abstraction levels one and two—functional and behavioral—is well suited for modeling purposes in other engineering domains as demonstrated in the last section of this chapter.

The interrelation between conceptual models according to Figure 3.3 and the executing simulator is highly complex. An appropriate support of model representations is thus mandatory. This is covered by highly expressive modeling languages such as VHDL–AMS, which originated recently from the well-known hardware description language VHDL aimed at denoting executable models of digital systems. Figure 3.4 highlights this relationship.

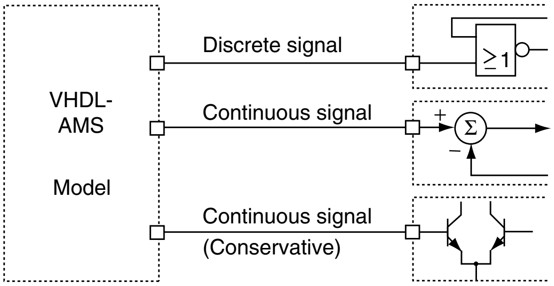

FIGURE 3.4 Combination of Signal Classes

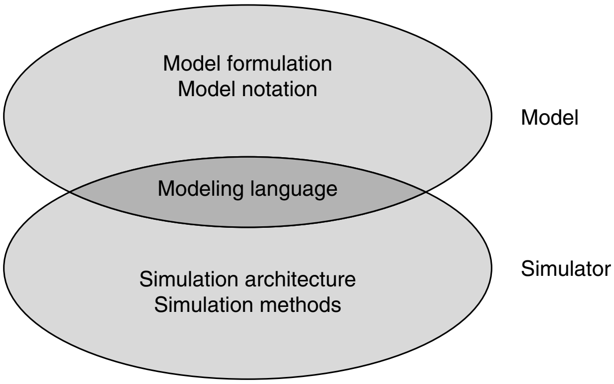

FIGURE 3.3 Interrelationship of Model and Simulator

3.3 Fundamentals of VHDL–AMS

The basic concepts of VHDL form the foundation for the extension of this hardware description language to the modeling domain of analog mixed signal (i.e., AMS), resulting in the new IEEE Standard 1076.1–1999. These concepts of VHDL are summarized here:

- Model composition of communicating, concurrently active "design entities"

- Strict separation of the unique interface description and the functional description(s) of an entity
- Execution of the model description based on the stimulus/answer paradigm (Events are only stimuli considered, resulting in an emphasis on digital circuits and systems.)
- Definition of the simulation process on top of an event-driven simulation cycle:

Simulation Process

```
  while transactions remain to be processed
  increase time until a transaction has to be processed
  update the state from the previous transactions
  determine events caused by updates
  resume processes sensitive to these events
end while
```

The description of a design entity consists of the entity declaration, one or more architectural bodies, and an optional configuration declaration. Syntactical details are as follows:

Entity Syntax

```
EntityDeclaration ::=
  entity Identifier is
    EntityHeader
    EntityDeclarativePart
  [begin
    Entity StatementPart]
  end [entity] [EntitySimpleName];
EntityHeader ::=
  [FormalGenericClause]
  [FormalPortClause]
GenericClause ::=
  generic (GenericList);
PortClause ::=
  port (PortList);
```

Architecture Syntax

```
ArchitectureBody ::=
  architecture Identifier of EntityName is
    ArchitectureDeclarativePart
  begin
    ArchitectureStatementPart
  end [architecture] [ArchitectureSimpleName];
ArchitectureStatement ::= ConcurrentStatement
```

The IEEE Standard 1076 of VHDL has been considerably extended to cope with modeling requirements in the time-continuous domain and especially with mixed-signal, multi-nature systems (i.e., event-discrete and time-continuous behaviors for heterogeneous models). This objective is depicted in Figure 3.4.

One problem arises when combining signal flow and physical models: the semantic of connections must be determined and implemented by appropriate methods as shown in Figure 3.5.

Obviously, the range of VHDL is by far not sufficient to suit all of these requirements. Therefore, extensions to design objects and declarations, to assignments, to attributes, and especially to the simulation cycle were necessary. These extensions to the original VHDL language are summarized in Figure 3.6.

Descriptions of value- and time-continuous variables and the enforcement of conservation in different physical domains, such as Kirchhoff's laws in the electrical domain, are possible when introducing the basic concepts of quantities and terminals.

The object class **quantity** has the following properties: representation of time-dependent functions, partial continuity with a finite number of discontinuities in one time interval, assignment of physical dimension, and existence of derivatives and integrals. Quantities may be defined as free, branch, or source quantities. Figure 3.7 shows their classification. Note that by means of this single basic concept, mixed descriptions in terms of domains, modes, and technologies are achievable.

FIGURE 3.8 Simple Example for Across and Through Quantities

The enforcement of conservative laws is of considerable interest when modeling physical systems, except for the functional level. Enforcement has been tackled in VHDL–AMS by means of a graph-based concept. Branch quantities with reference to terminals and natures are used for this purpose, as detailed in the following:

- Quantities between two **terminals** represent the unknown variables (branch quantities) in a conservative system of equations:
  a. **Across** quantity: Difference of potentials
  b. **Through** quantity: Quantity of flow in a branch
- Terminals are assigned to a physical domain, known as **nature**, which has to be defined appropriately.

Figure 3.8 shows how two branches between two terminals related to the nature electrical are defined.

Conservation laws have to be enforced independently of a user-defined partitioning of the entire model into design entities. This implies that the interface description of entities requires an enhancement. The connection pins of an entity, denoted as **ports** in VHDL terminology, may now carry waveforms of different qualities: digital signals and continuous quantities of some physical domain with or without conservation requirements as given in Table 3.3. The new interface description syntax of VHDL–AMS is given here; note that the compatability for VHDL 1076 is accomplished by a blank PortAttribute, which is interpreted as the **signal** attribute:

```
port (PortAttribute NameList: [Mode] Type)
PortAttribute : : =
  signal | quantity | terminal
```

TABLE 3.3 Values of Mode Subject to PortAttribute

PortAttribute	Mode	Remarks
Signal	**in, out, inout**	
Quantity	**in, out, inout**	
Terminal	—	No mode may be specified because a terminal is always bidirectional

The description of the functionality of a model is stated in the architectural body. In addition to the concurrent statements of VHDL used for digital circuits and systems (e.g., component instances, signal assignments, and process statements), simultaneous statements are available:

```
architectureStatement ::=
  concurrentStatement | simultaneousStatement

simultaneousStatement ::=
  simpleSimStatement | compoundSimStatement
```

Simultaneous statements can be either simple or compound. The latter form may consist of a **procedural**, a **case**, or an **if** statement. The simple statement as defined above unveils two interesting properties. First, it is a noncausal formulation of an equation. This means that the == symbol denotes equality in the mathematical sense and not an assignment such as the <= symbol in digital data flow descriptions. As a consequence, the modeler does not need to formulate explicit equations. The more general implicit differential algebraic equation (DAE) form may be used directly instead. Second, the other interesting property is related to the optional tolerance aspect of the statement. This is intended to specify the numerical accuracy of the equality, which is a very general way to deal with numerical problems. Usually, a modeler is interested only in accuracy aspects but not in selecting solution methods for (e.g., numerical) integration. The implementors of a VHDL–AMS simulation engine can provide the appropriate algorithms, whereas a modeler can specify accuracy levels only by means of tolerance aspects.

Statements in the architectural body of a design entity may consist of, as already detailed, both concurrent and simultaneous statements. This is of special interest to a modeler because it supports a consistent description of design objects operating in mixed-mode without an artificial separation into event-discrete and time-continuous parts. Mixing up event-oriented and time-continuous behavior in many cases results in dealing with model discontinuities. This problem is addressed by the "break" statement used for both initialization and for discontinuity handling. A simple example for a 1-bit D/A converter given in Figure 3.9 illustrates its usage.

```
entity DAC is
  generic (VHigh: Real := 5.0);
  port(signal S: in Bit;
    terminal A: Electrical)
end entity DAC;

architecture Simple of DAC is
  quantity V across I through A;

begin
  if S = '0' use
    V == 0.0;
  else
    V == VHigh
  end use;
  break on S;
end architecture Simple;
```

FIGURE 3.9 Model of a Simple D/A Converter

The mixed-mode property of the entity DAC is easily visible from the interface description. There is both a signal and a terminal definition at ports. Obviously, the model is aimed to the behavioral abstraction level. The branch quantities related to the terminal A linked to the **nature Electrical** are defined in the architectural body. There are two architecture statements in the executable part of the architectural body: a compound simultaneous statement (if...use...else...end use) and the break statement that is sensitive to an event on the signal *S*. The output voltage [V] of the D/A converter is recalculated each time the signal value of *S* changes. Note that no additional equations or definitions are required to enforce conservation laws at port A.

The modeling features of VDHL–AMS have been highlighted so far for electrical circuits only. A simple multinature modeling example will now demonstrate that all required concepts and syntax elements are already present for that purpose. First, we need to extend our set of **natures**. Figure 3.10 summarizes the definitions for two more physical domains. They are given as part of a package identified by the name **NaturePkg**:

A combined electrical and thermal model of a diode demonstrates how the effects of nonself-heating on its electrical characteristics may be modeled for a multinature application in an easy and consistent way. This model is outlined in Figures 3.11 and 3.12, respectively.

Passing of parameter values is accomplished by means of the "generic" mechanism of the entity declaration. There is one terminal port for the nature Thermal and two terminal ports for the nature Electrical. The associated branch quantities are defined in the architectural body. In addition, the two free quantities *Q* and *VT* are defined as well. The first three simultaneous equations denote the electrical behavior of the nonlinear diode. Note the differential equation relating the charge *Q* to the current *IC*. The thermal voltage is now determined by means of the constants Boltzmann and ElemCharge taken

The second one, Power, is calculated from the electrical branch quantities *V* and *ID* in the last equation. Note the noncausal notation of these equations. The diode current *ID* thus depends on the junction temperature via the thermal voltage *VT*.

3.4 Systems Modeling: A Multinature Example

The increasing complexity of information processing products and the pressure of design to market requirements are the main reasons for a change in the design process of these products, resulting in an emphasis of timely design validation of virtual prototypes instead of breadboarding. This reveals possible concept errors long before an implementation of real prototypes. On the other hand, such products are too complex to be modeled at lower (i.e., more accurate) abstraction levels. A need for a sensible mix of models on different abstraction levels thus arises and results in the necessity to represent and to execute models both in different domains and at several abstraction levels. The purpose of such a system model, known as virtual prototype, is to support an assessment of the conceptualization and the refinement according to the design flow outlined in Figure 3.1 in terms of meeting initial target specifications. The process of model definition, refinement, and assessment is demonstrated in the following by means of a depth gauge, a safety critical device for deep water divers.

The demonstrator was built with system simulation of multinature design objects in mind. It is a fairly complex but still easily comprehensive example on how to construct a simulation model in three physical domains featuring both time-continuous and event-discrete behavior. In addition, synthesizable models of digital signal processing units are incorporated at register and algorithmic levels as defined in Table 3.1.

All VHDL–AMS models are operational and were thoroughly tested by means of the ADVanceMS simulator from Mentor Graphics. Unfortunately, the complete set cannot be presented for space restriction reasons. All models of this depth gauge and additional information on other complex multinature modeling projects are available at the author's site. (www.vlsi.informatik.tu-darmstadt.de/vhdlams/)

3.4.1 Partitioning the System

The models are subdivided in two ways. The whole system is partitioned into smaller entities that are modeled as a unit; furthermore, there are several models (i.e., entities, which are each modeled as a unit; furthermore, there are several models (i.e., architectures) for each unit. These architectures differ in terms of abstraction levels and exactness or represent different implementation approaches. The architectures suited for system simulation are presented in the following.

The functional partitioning of the model of a depth gauge denoted Virtual Diving Computer (vdc) is based on

- functional classification
- entity reuse
- complexity
- testability.

The different architectures can be classified using the architecture name. Most of them are self-explanatory.

- The **simple** architecture is reduced to the fundamental features and it is modeled at the functional level. It yields low simulation cost and idealized results.
- The **digital_algorithmic** architecture is a high-level description using a synthesizable subset of VHDL. These models must be passed to a scheduling and resource allocation tool prior to mapping a target library. For the demonstrator, this is done with the Behavioral Compiler from Synopsys.
- The **digital_RTL** architecture is a register-transfer level description using again a synthesizable subset of VHDL. These models can be multiclock or even asynchronous designs and are easily mapped to target libraries. This is tested with the Design Compiler from Synopsys.
- The **beh** architecture is a behavioral model of analog or mixed-signal components. This model reproduces timing and signal waveforms of the entity, including major hazards and glitches.
- The **eldo** architecture is used to incorporate Spice (i.e., macro and circuit) level models.

3.4.2 Models of Functional Units

The Testbench

The entity denoted **testbench** is the top-level entity. It contains the environment and the device under test. The **testbench** is self-contained and used to define the interconnections between the single layers. Moreover, it selects the architectures to be used. The code is given in the following:

The Environmental Model

The environment is modeled to produce all the input data needed to test the depth gauge. In consequence, only observable effects for the device under test are reproduced.

The generic **timescale** can be used as a workaround for simulators that do not allow to change the resolution limit for the type **time**. Simulations based on femtoseconds reduce the guaranteed simulation time to 2.14 µs—typical application employments are several hours or even days. This requires range extensions beyond 2^{31} or changing the resolution limit to milliseconds. If both are not feasible, a **timescale** to shrink the simulation's duration may be used.

The port terminals **Pressure_sensor** and **Temp_sensor** are modeled as sources that guarantee pressure and temperature potentials without side effects. These potentials can be gained from the scuba diver's position. To simplify the model, only the resulting potentials are described in the following two architectures. The first is characteristic for lake diving, and the second is aimed at ocean diving.

The model for the lake dive outlined in the following reproduces the strong coherence between diving depth and water temperature. This temperature profile is typical for deep lakes during the summertime: the surface is heated by the sun, whereas wind and day/night changes form a several meter deep warm surface layer. Below this layer, the temperature drops rapidly below 10°C.

Temperature Sensor

The temperature sensor we used is a platinum resistor made in thin-layer technology on Al_2O_3 substrate. We use a 1-kΩ sensor with a temperature sensitivity (Tk) of $3.85 \cdot 10^3/°C$ (as specified in IEC 751). These sensors are quite popular in automotive applications. This results in low cost and good availability of subcomponents. The sensor is used in a voltage divider together with the constant resistor **Rfix**. The temperature information is represented in the output voltage **Uout**. The multinature property is thus obvious as shown in Figure 3.13.

The **simple** architecture is based on the Sensor Nite PT1000 from Heraeus. Thus, the modeling process is constrained to an exploitation of commercially available subsystems:

Digital Block

The depth is determined in the digital part from data obtained through pressure and temperature measurements and then represented as electrical quantities. In the first intermediate step, the actual temperature is calculated using the temperature data represented in 6-bit. This is followed by the calculation of the actual pressure from the pressure data given in 12-bit. The conversion of the specified pressure to a depth below the water surface is obtained by means of following equation:

$$\text{depth} = \frac{1\text{ m}}{0.1\text{ bar}} \cdot (\text{pressure} - 1\text{ bar}) \tag{3.1}$$

The model outlined in this section implements digital signal transformations aimed to compensate for the nonlinearities of the used sensors only. The depth is calculated with a guaranteed accuracy of 0.1 m.

The first plot visualizes the results of system simulation for a lake dive. Note the temperature profile of the lake (second trace).

In contrast, the second plot depicts the simulation results for an ocean dive. The system's model of the gauge is as before, but the environment has changed. The gauge model, therefore, acts as a virtual prototype being exercised in different contexts. The accuracy of the model is visible from the third trace in each plot. The absolute error (i.e., the difference between the actual and the measured depth) is in the range of the least significant bit of the discretized value.

3.5 Conclusion and Further Readings

The design of embedded systems is a highly complex task due to the tight interaction of their functional units, which, in general, originate from several engineering domains. Generation and assessment of models play an important role in the whole design process. When dealing with modeling issues, questions about concepts, representation, efficiency, and accuracy have to be addressed.

An introduction to modeling of multinature systems is best given by discussing the role of models and of associated abstraction levels in the design process as presented in the first section. The representation of abstract models should then allow for an execution and assessment of the captured specification. VHDL–AMS has been introduced as a highly expressive description language for the representation of mixed time-continuous and event-discrete operating embedded systems. The advantages for a design engineer, which result from the proposed modeling methodology, have been demonstrated for a practical multinature application example.

Plenty of good literature is available on digital hardware description languages, especially on VHDL, and on synthesis algorithms that exploit such languages as a means for specifying the functionality of digital components and systems. Continuous time modeling, however, and mixed-signal or multinature modeling are not yet covered sufficiently. In Cellier (1991), the reader will find a comprehensive discussion of this domain. An introduction to underlying numerical algorithms for solving differential-algebraic equations is given in (Brenan *et al.*, 1989). Modeling issues with an emphasis on analog circuits are covered in Mantooth and Fiegenbaum (1995) and Bergé *et al.* (1995). The language reference of VHDL–AMS is given by the IEEE Computer Society (1999). The Mentor Graphics (1999) user's manual is a good reference for a commercial simulator. Finally, in Vachoux *et al.* (1997), the modeling of multinature systems using VHDL–AMS is addressed by several authors, thus giving an in-depth insight into this evolving area.

Clock Skew Scheduling for Improved Reliability*

Ivan S. Kourtev

4.1 Introduction

Most high performance digital integrated circuits implement data processing algorithms based on the iterative execution of basic operations. Typically, these algorithms are highly parallelized and pipelined by inserting clocked registers at specific locations throughout the circuit. The synchronization strategy for these clocked registers in the vast majority of VLSI/ULSI-based digital systems is a fully synchronous approach. It is common for the computational process in these systems to be spread over hundreds of thousands of functional logic elements and tens of thousands of registers.

For such synchronous digital systems to function properly, the many thousands of switching events require a strict temporal ordering. This strict ordering is enforced by a global synchronization signal known as the **clock signal** that must be delivered to every register at a precise relative time. The delivery function is accomplished by a circuit and interconnect structure commonly known as a **clock distribution network** (Friedman, 1995, 1997).

Multiple factors affect the propagation delay of the data signals through the combinational logic gates and interconnect. Because the clock distribution network is composed of logic gates and interconnection wires, the signals in the clock distribution network are delayed. Moreover, the dependence of the correct operation of a system on the signal delay in the clock distribution network is far greater than on the delay of the logic gates. Recall that by delivering the clock signal to registers at precise times, the clock distribution network essentially quantizes the operational time of a synchronous system into clock periods, thereby permitting the simultaneous execution of operations.

The nature of the on-chip clock signal has become a primary factor limiting circuit performance, causing the clock distribu-

*This research was supported in part by the National Science Foundation under Grant No. MIP-9423886 and Grant No. MIP-9610108, a grant from the New York State Science and Technology Foundation to the Center for Advanced Technology-Electronic Imaging Systems, and by grants from the Xerox Corporation, IBM Corporation, and Intel Corporation.

tion network to become a performance bottleneck in high speed VLSI systems. The primary source of the load for the clock signals has shifted from the logic gates to the interconnect, thereby changing the physical nature of the load from a lumped capacitance (C) to a distributed resistive-capacitive (RC) load (Bakoglu, 1990; Bothra *et al.*, 1993). These interconnect impedances degrade the on-chip signal waveform shapes and increase the path delay. Furthermore, statistical variations of the parameters characterizing the circuit elements along the clock and data signal paths (caused by the imperfect control of the manufacturing process and the environment) introduce ambiguity into the signal timing that cannot be neglected. All of these changes have a profound impact on both the choice of synchronous design methodology and on the overall circuit performance. Among the most important consequences are increased power dissipated by the clock distribution network and increasingly challenging timing constraints that must be satisfied to avoid timing violations (Friedman, 1995; Gaddis and Lotz, 1996; Gronowski *et al.*, 1996; Vasseghi *et al.*, 1996; Bowhill *et al.*, 1995). Therefore, the majority of the approaches used to design a clock distribution network focus on simplifying the performance goals by targeting minimal or zero global clock skew (Neves and Friedman, 1993; Xi and Dai, 1996; Neves and Friedman, 1996), which can be achieved by different routing strategies (Jackson *et al.*, 1990; Tsay, 1993; Chou and Cheng, 1995; Ito *et al.*, 1995), buffered clock tree synthesis, symmetric n-ary trees (Gaddis and Lotz, 1996) (most notably H-trees), or a distributed series of buffers connected as a mesh (Friedman, 1995, 1997; Bowhill *et al.*, 1995).

4.2 Background

A **synchronous digital system** is a network of combinational logic and storage registers whose input and output terminals are interconnected by wires. An example of a synchronous system is shown in Figure 4.1. The sets of registers and logic gates of this specific system are outlined in Figure 4.1 and consist of the four registers, R_1 through R_4, and the four logic gates, G_1 through G_4, respectively. For clarity, the clock distribution network and clock signals to the registers are not shown, and the details of the registers and logic gates are also omitted.

A sequence of connected logic gates (no registers) is called a **signal path**. For example, in Figure 4.1, one signal path begins at the register R_1 and propagates through the logic gates G_1 and G_2 before reaching the register R_3. Other signal paths can also be identified in the system shown in Figure 4.1. Every signal path in a synchronous system is delimited by a pair of registers—one register each for the start and the end of the path. Such a pair of registers is called a **sequentially adjacent pair** and is defined next:

Definition 4.1 Sequentially adjacent pair of registers: *For an arbitrary* ordered *pair of registers* $\langle R_i, R_f \rangle$ *in a synchronous circuit, one of the following two situations can be observed. Either there exists at least one signal path that connects some output of* R_i *to some input of* R_f, *or inputs of* R_f *cannot be reached from outputs of* R_i through a signal path.[1] *In the former case—denoted by* $R_i \rightsquigarrow R_f$*—the pair of registers* $\langle R_i, R_f \rangle$ *is called a sequentially adjacent pair of registers, and switching events at the output of* R_i *can possibly affect the input of* R_f *during the same clock period. A sequentially adjacent pair of registers is also referred to as a local data path* (Friedman, 1995).

4.2.1 Permissible Range of Clock Skew

The clock signal is delivered to both the initial, R_i, and final, R_f, registers of any sequentially adjacent pair of registers $R_i \rightsquigarrow R_f$ in a circuit. The delays of the clock signal to these two registers, R_i and R_f, may be different. This difference in clock signal delay is accounted for by the concept of **clock skew** defined next:

Definition 4.2 Clock skew: *In a given digital synchronous circuit, the clock skew* $T_{Skew}(i, j)$ *between the registers* R_i *and* R_j *is defined as the algebraic difference*:

$$T_{Skew}(i, j) = t^i_{cd} - t^j_{cd}, \tag{4.1}$$

where C_i and C_j are the clock signals driving the registers R_i and R_j, respectively, and t^i_{cd} and t^j_{cd} are the delays of the clock signals C_i, and C_j, respectively.

In definition 4.2, the clock delays, t^i_{cd} and t^j_{cd}, are with respect to an arbitrary—but necessarily the same—reference point. A commonly used reference point is the source of the clock distribution network on the integrated circuit. Note that the clock skew $T_{Skew}(i, j)$ as defined in definition 4.2 obeys the antisymmetric property:

$$T_{Skew}(i, j) = -T_{Skew}(j, i). \tag{4.2}$$

Technically, the clock skew $T_{Skew}(i, j)$ can be calculated for any ordered pair of registers $\langle R_i, R_j \rangle$. However, the clock skew between a nonsequential pair of registers has little practical value. The clock skew $T_{Skew}(i, j)$ between sequentially adjacent pairs of registers $R_i \rightsquigarrow R_j$ (that is, a local data path) is of primary practical importance since $T_{Skew}(i, j)$ is part of the timing constraints of these paths (Friedman, 1995, 1990; Afghani and Svensson, 1990; Unger and Tan, 1986; Kourtev, 1999; Kourtev and Friedman, 1996).

For notational convenience, clock skews in a circuit are frequently denoted throughout this work with the small letter s with a single subscript. In such cases, the clock skew s_k corresponds to a uniquely identified local data path k in the circuit, where the local data paths have been numbered 1 through a certain number p. In other words, the skew s_1 corresponds to the local data path one, the skew s_2 corresponds to the local data path two, and so on.

Previous research (Neves and Friedman, 1996a, 1996b) has indicated that tight control over the clock skews rather than the clock delays is necessary for the circuit to operate reliably. The timing constraints of sequentially adjacent pairs of registers are used to determine a **permissible range** of allowable clock skew for each signal path (Friedman, 1995; Neves and Friedman, 1996a, 1996b; Afghani and Svensson, 1990; Kourtev, 1999). The concept of a permissible range for the clock skew s_k of a data path $R_i \rightsquigarrow R_f$ is illustrated in Figure 4.2.

Each signal data path has a unique permissible range associated with it.[2] The permissible range is a continuous interval of valid skews for a specific path. As illustrated in Figure 4.2, every permissible range is delimited by a lower and upper bound of the clock skew. These bounds—denoted by l_k and u_k, respectively—are determined based on the timing parameters and timing constraints of the individual local data paths. Note that the bounds l_k and u_k also depend on the operational clock period for the specific circuit. When $s_k \in [l_k, u_k]$—as shown in Figure 4.2—the timing constraints of this specific k-th local data path are satisfied. The clock skew s_k is not permitted to be in either the interval $(-\infty, l_k)$ because a race condition will be created or the interval $(u_k, +\infty)$ because the minimum clock period will be limited.

Furthermore, note that the reliability of a circuit is related to the probability of a timing violation occurring for any local data path $R_i \rightsquigarrow R_f$. This observation suggests that the reliability of any local data path $R_i \rightsquigarrow R_f$ of a circuit (and therefore of the entire circuit) is increased in two ways:

1. By choosing the clock skew s_k for the kth local data path as far as possible from the borders of the interval $[l_k, u_k]$; that is, by (ideally) positioning the clock skew s_k in the middle of the permissible range: $s_k = \frac{1}{2}(l_k + u_k)$
2. By increasing the width $(u_k - l_k)$ of the permissible range of the local data path $R_i \rightsquigarrow R_f$

Even if the clock signals can be delivered to the registers in a given circuit with arbitrary delays, it is generally not possible to have all clock skews in the middle of the permissible range as suggested above. The reason behind this characteristic is that inherent structural limitations of the circuit create linear dependencies among the clock skews in the circuit. These linear dependencies and the effect of these dependencies on a number of circuit optimization techniques are examined in detail in Section 4.3.

4.2.2 Graphical Model of a Synchronous System

Many different fully synchronous digital systems exist. It is virtually impossible to describe the variety of all past, current, or future such systems depending on the circuit manufacturing technology, design style, performance requirements, and multiple other factors. A system **model** of these fully synchronous digital systems is required so that the system properties can be fully understood and analyzed from the perspective of clock skew scheduling and clock tree synthesis while permitting unnecessary details to be abstracted.[3]

[2] Section 4.2 later shows that it is more appropriate to refer to the permissible range of a sequentially adjacent pair of registers. There may be more than one local data path between the same pair of registers, but circuit performance is ultimately determined by the permissible ranges of the clock skew between pairs of registers.

[3] As a matter of fact, the graph model described here is quite universal and can be successfully applied to a variety of circuit analysis and optimization purposes.

In this section, a graphical model used to represent fully synchronous digital systems is introduced. The purpose of this model is twofold. First, the model provides a common abstract framework for the automated analysis of circuits by computers, and second, it permits a significant reduction of the size of the data that needs to be stored in the computer memory when performing analysis and optimization procedures on a circuit. This graph-based model can be arrived at in a natural way by observing what constitutes relevant system information (in terms of the clock skew scheduling problem). For example, it is sufficient to know that a pair of registers $\langle R_i, R_j \rangle$ are sequentially adjacent, whereas knowing the specific functional information characterizing the individual logic gates along the signal paths between R_i and R_j is not necessary.

Consider, for instance, the system shown in Figure 4.1. This system is completely described (for the purpose of clock skew scheduling) by the timing information describing the four registers, four logic gates, ten wires (nets), and the connectivity of these wires to the registers and logic gates. Consider next the abstract representation of this system shown in Figure 4.3. Note that the registers R_1 through R_4 are represented by the vertices of the graph shown in Figure 4.3. However, the logic gates and wires have been replaced in Figure 4.3 by arrows, or arcs, representing the signal paths among the registers. The four logic gates and ten nets in the original system have been reduced to only six local data paths represented by the arcs. For clarity, each arc, or edge, is labeled with the logic gates[4] along the signal path represented by this specific arc.

The type of data structure shown in Figure 4.3 is known as a multigraph (West, 1996) since there may be more than one edge between a pair of vertices in the graph. To simplify data storage and the relevant analysis and optimization procedures, this multigraph is reduced to a simple graph (West, 1996) model by imposing the following restrictions:[5]

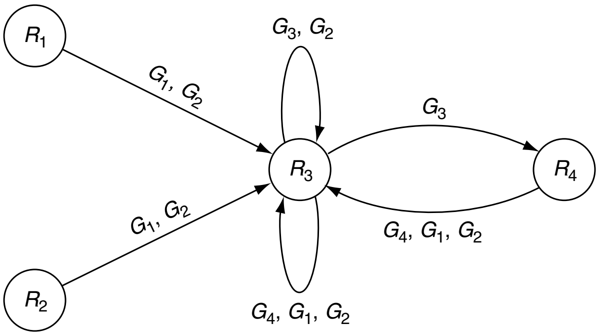

FIGURE 4.3 A Directed Multigraph Representation of the Synchronous System Shown in Figure 4.1. The graph vertices correspond to the registers R_1, R_2, R_3, and R_4, respectively.

- Either one or zero edges can exist between any two different vertices of the graph;
- There cannot be self-loops or edges that start and end at the same vertex of the graph;
- Additional labelings (or markings) of the edges are introduced to represent the timing constraints of the circuit.

With the above restrictions, a formal definition of the circuit graph model is as follows:

Definition 4.3 Circuit graph: *A fully synchronous digital circuit C is represented as the connected undirected simple graph G_C. The graph G_C is the ordered sixtuple $G_C = \langle V^{(C)}, E^{(C)}, \boldsymbol{A}^{(C)}, h_l^{(C)}, h_u^{(C)}, h_d^{(C)} \rangle$, where:*

- $V^{(C)} = \{v_1, \ldots v_r\}$ *is the set of vertices of the graph* G_C;
- $E^{(C)} = \{e_1, \ldots e_p\}$ *is the set of edges of the graph* G_C;
- $\boldsymbol{A}^{(C)} = [a_{ij}^{(C)}]_{r \times r}$ *is the symmetric adjacency matrix of* G_C.

Each vertex from $V^{(C)}$ represents a register of the circuit C. There is exactly one edge in $E^{(C)}$ for every sequentially adjacent pair of registers in C. The mappings $h_l^{(C)}$: $E^{(C)} \mapsto \mathbb{R}$ and $h_u^{(C)}$: $E^{(C)} \mapsto \mathbb{R}$ to the set of real numbers $\mathbb{R}$ assign the lower and upper permissible range bounds, $l_k, u_k \in \mathbb{R}$, respectively, for the sequentially adjacent pair of registers indicated by the edge $e_k \in E$. The edge labeling $h_d^{(C)}$ defines a direction of signal propagation for each edge v_x, e_z, v_y.

Note that in a fully synchronous digital circuit, there are no purely combinational signal cycles; that is, it is impossible to reach the input of any logic gate G_k by only starting at the output of G_k and going through a sequence of combinational logic gates (Friedman, 1995; Kourtev, 1999).

Naturally, all registers from the circuit C are preserved when constructing the circuit graph G_C as described in definition 4.3—these registers are enumerated 1 through r, and a vertex v_i is created in the graph for each register R_i. Alternatively, an edge between two vertices is added in the graph if there is one or more local data paths between these two vertices. The self-loops are discarded because the clock skew of these local data paths is always zero and cannot be manipulated in any way.

The graph G_C for any circuit C can be determined by either direct inspection of C, or by first building the circuit multigraph and then modifying the multigraph to satisfy definition 4.3. Consider, for example, the circuit multigraph shown in Figure 4.3—the corresponding circuit graph is illustrated in Figure 4.4. Observe the labelings of the graph edges in Figure 4.4. Each edge is labeled with the corresponding permissible range of the clock skew for the given pair of registers. An arrow is drawn next to each edge to indicate the order of the registers in this specific sequentially adjacent pair—recall that the clock skew as defined in definition 4.2 is an algebraic difference. As shown in the rest of this section, either direction of an edge can be selected as long as the proper choices of lower and upper clock skew bounds are made.

In most practical cases, a unique signal path (a local data path) exists between a given sequentially adjacent pair of regis-

[4] The arcs are labeled in the order in which the traveling signals pass through the gates.

[5] The restrictions refer to the model itself and *not* to the ability of the model to represent features of the circuits.

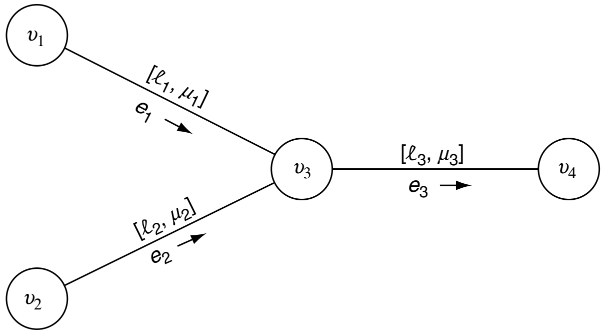

FIGURE 4.4 A Graph Representation of the Synchronous System Shown in Figure 4.1 According to Definition 4.3. The graph vertices v_1, v_2, v_3, and v_4 correspond to the registers R_1, R_2, R_3, and R_4, respectively.

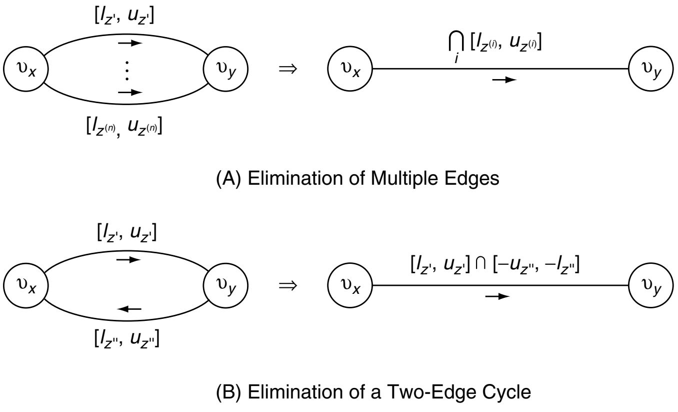
ters $\langle R_i, R_j \rangle$. In these cases, the labeling of the corresponding edge is straightforward. The permissible range bounds l_k and u_k are computed as shown in (Friedman, 1995; Neves and Friedman, 1996a, 1996b; Afghani and Svensson, 1990; Kourtev, 1999), and the direction of the arrow is chosen so as to coincide with the direction of the signal propagation from R_i to R_j. With these choices, the clock skew is computed as $s = t_{cd}^i - t_{cd}^j$. In Figure 4.4 for example, the direction labelings of both e_1 and e_2 can be chosen from v_1 to v_3 and from v_2 to v_3, respectively.

Multiple signal paths between a pair of registers, R_x and R_y, require a more complicated treatment. As specified before, there can be only one edge between the vertices v_x and v_y in the circuit graph. Therefore, a methodology is presented for choosing the correct permissible range bounds and direction labeling for this single edge. This methodology is illustrated in Figure 4.5 and is a two-step process. First, multiple signal paths in the same direction from the register R_x to the register R_y are replaced by a single edge in the circuit graph according to the transformation illustrated in Figure 4.5(A). Next, two-edge cycles between R_x and R_y are replaced by a single edge in the circuit graph according to the transformation illustrated in Figure 4.5(B).



(A) Elimination of Multiple Edges

(B) Elimination of a Two-Edge Cycle

FIGURE 4.5 Transformation Rules for the Circuit Graph

In the former case, Figure 4.5(A), the edge direction labeling is preserved while the permissible range for the new single edge is chosen such that the permissible ranges of the multiple paths from R_x to R_y are simultaneously satisfied. As shown in Figure 4.5(A), the new permissible range $[l_z, u_z]$ is the intersection of the multiple permissible ranges $[l_{z'}, u_{z'}]$ through $[l_{z^{(n)}}, u_{z^{(n)}}]$ between R_x and R_y. In other words, the new lower bound is $l_z = \max_i \{l_{z^{(i)}}\}$ and the new upper bound is $u_z = \min_i \{u_{z^{(i)}}\}$.

In the latter case, Figure 4.5(B), an arbitrary choice for the edge direction can be made—the convention adopted here is to choose the direction toward the vertex with the higher index. For the vertex v_y, the new permissible range has a lower bound $l_z = \min(l_{z'}, -u_{z''})$ and an upper bound $u_z = \max(u_{z'}, -l_{z''})$. It is straightforward to verify that any clock skew $s \in [l_z, u_z]$ satisfies both permissible ranges $[l_{z'}, u_{z'}]$ and $[l_{z''}, u_{z''}]$ as shown in Figure 4.5(B). The process for computing the permissible ranges of a circuit graph (Friedman, 1995; Neves and Friedman, 1996a, 1996b; Afghani and Svensson, 1990; Kourtev, 1999), and the transformations illustrated in Figure 4.5 have linear complexity in the number of signal paths because each signal path is examined only once.

Note that the terms, *circuit* and *graph*, are used throughout the rest of this chapter interchangeably to denote the same fully synchronous digital circuit. In addition, note that for brevity, the superscript C, when referring to the circuit graph G_C of a circuit C, is omitted unless a circuit is explicitly indicated. The terms, *register* and *vertex*, are also used interchangeably as are *edge, local data path, arc*, and *a sequentially adjacent pair of registers*. On a final note, it is assumed that the graph of any circuit considered here is connected. If this is not the case, each of the disjoint connected portions of the graph (circuit) can be individually analyzed.

4.2.3 Clock Scheduling

The process of nonzero clock skew scheduling is discussed in this section. The following substitutions are introduced for notational convenience:

Definition 4.4 *Let C be a fully synchronous digital circuit, and let R_i and R_f be a sequentially adjacent pair of registers* (i.e., $R_i \rightsquigarrow R_f$). *The long path delay $\hat{D}_{PM}^{i,f}$ of a local data path $R_i \rightsquigarrow R_f$ is defined as:*

$$\hat{D}_{PM}^{i,f} = \begin{cases} (D_{CQM}^{Fi} + D_{PM}^{i,f} + \delta_S^{F,f} + 2\Delta_L), \text{ if } R_i, R_f \text{ are flip-flops.} \\ (D_{CQM}^{Li} + D_{PM}^{i,f} + \delta_S^{Lf} + \Delta_L + \Delta_T), \text{ if } R_i, R_f \text{ are latches.} \end{cases} \tag{4.3}$$

The D_{CQM}^{Fi} and D_{CQM}^{Li} are the maximum clock-to-output delay propagation times of the flip-flop and latch i, respectively; $D_{PM}^{i,f}$ is the maximum logic propagation delay from R_i to R_f, δ_S^{Ff} and δ_S^{Lf} are the setup times of the flip-flop and latch f, respectively; and Δ_L and Δ_T are the maximum deviations of the leading and trailing edges of the clock signal, respectively. Similarly, the short delay $\hat{D}_{Pm}^{i,f}$ of a local data path *$R_i \rightsquigarrow R_f$ is defined as:*

$$\hat{D}_{Pm}^{i,f} = \begin{cases} (D_{Pm}^{i,f} + D_{CQ}^{Fi} - \delta_H^{Ff} - 2\Delta_L), \text{ if } R_i \text{ and } R_f \text{ are flip-flops.} \\ (+D_{CQm}^{Li} + D_{Pm}^{i,f} - \delta_H^{Lf} - \Delta_L - \Delta_T), \text{ if } R_i \text{ and } R_f \text{ are latches.} \end{cases} \quad (4.4)$$

The D_{CQ}^{Fi} and D_{CQ}^{Li} are the minimum clock-to-output delay propagation times of the flip-flop and latch i, respectively; $D_{Pm}^{i,f}$ is the minimum logic propagation delay from R_i to R_f; and δ_H^{Ff} and δ_H^{Lf} are the hold times of the flip-flop and latch f, respectively.

For example, using the notations described in definition 4.4, the timing constraints of a local data path $R_i \rightsquigarrow R_f$ with flip-flops are (Friedman, 1995; Kourtev, 1999) as follows:

$$T_{Skew}(i, f) \leq T_{CP} - \hat{D}_{PM}^{i,f}. \quad (4.5)$$

$$-\hat{D}_{Pm}^{i,f} \leq T_{Skew}(i, f). \quad (4.6)$$

For a local data path $R_i \rightsquigarrow R_f$ consisting of the flip-flops R_i and R_f, the setup and hold-time violations are avoided if equations 4.5 and 4.6, respectively, are satisfied.

The clock skew $T_{Skew}(i, f)$ of a local data path $R_i \rightsquigarrow R_f$ can be either positive or negative. Note that negative clock skew may be used to effectively speed up a local data path $R_i \rightsquigarrow R_f$ by allowing an additional $T_{Skew}(i, f)$ amount of time for the signal to propagate from the register R_i to the register R_f. However, excessive negative skew may create a hold-time violation, thereby creating a lower bound on $T_{Skew}(i, f)$ as described by equation 4.6 and illustrated by l in Figure 4.2. A hold-time violation is a clock hazard or a race condition, also known as **double clocking** (Friedman, 1995; Fishburn, 1990). Similarly, positive clock skew effectively decreases the clock period T_{CP} by $T_{Skew}(i, f)$, thereby limiting the maximum clock frequency and imposing an upper bound on the clock skew as illustrated by u in Figure 4.2.[6] In this case, a clocking hazard known as **zero clocking** may be created (Friedman, 1995; Fishburn, 1990).

Examination of the constraints, 4.5 and 4.6, reveals a procedure for preventing clock hazards. Assuming equation 4.5 is not satisfied, a suitably large value of T_{CP} can be chosen to satisfy constraint 4.5 and prevent zero clocking. Also note that unlike equation 4.5, equation 4.6 is independent of the clock period T_{CP} (or the clock frequency). Therefore, T_{CP} cannot be changed to correct a double clocking hazard. Rather, a redesign of the entire clock distribution network may be required (Neves and Friedman, 1996a).

Both double and zero clocking hazards can be eliminated if two simple choices characterizing a fully synchronous digital circuit are made. Specifically, if equal values are chosen for all clock delays, then the clock skew $T_{Skew}(i, f) = 0$ for each local data path $R_i \rightsquigarrow R_f$ becomes zero:

$$\forall \langle R_i, R_f \rangle : t_{cd}^i = t_{cd}^f \Rightarrow T_{Skew}(i, f) = 0. \quad (4.7)$$

Therefore, equations 4.5 and 4.6 become:

$$T_{Skew}(i, f) = t_{cd}^i - t_{cd}^f = 0 \leq T_{CP} - \hat{D}_{PM}^{i,f} \quad (4.8)$$

$$-\hat{D}_{Pm}^{i,f} \leq 0 = T_{Skew}(i, f) = t_{cd}^i - t_{cd}^f. \quad (4.9)$$

Note that equation 4.8 can be satisfied for each local data path $R_i \rightsquigarrow R_f$ in a circuit if a sufficiently large value—larger than the greatest value $\hat{D}_{PM}^{i,f}$ in a circuit—is chosen for T_{CP}. Furthermore, equation 4.9 can be satisfied across an entire circuit if it can be ensured that $\hat{D}_{Pm}^{i,f} \geq 0$ for each local data path $R_i \rightsquigarrow R_f$ in the circuit. The timing constraints of these equations can be satisfied because choosing a sufficiently large clock period T_{CP} is always possible and $\hat{D}_{Pm}^{i,f}$ is positive for a properly designed local data path $R_i \rightsquigarrow R_f$. The application of this zero clock skew methodology of equations 4.7 through 4.9 has been central to the design of fully synchronous digital circuits for decades (Friedman, 1995, 1997; Lee and Kong, 1997). By requiring the clock signal to arrive at each register R_j with approximately the same delay t_{cd}^j, these design methods have become known as **zero clock skew methods**.[7]

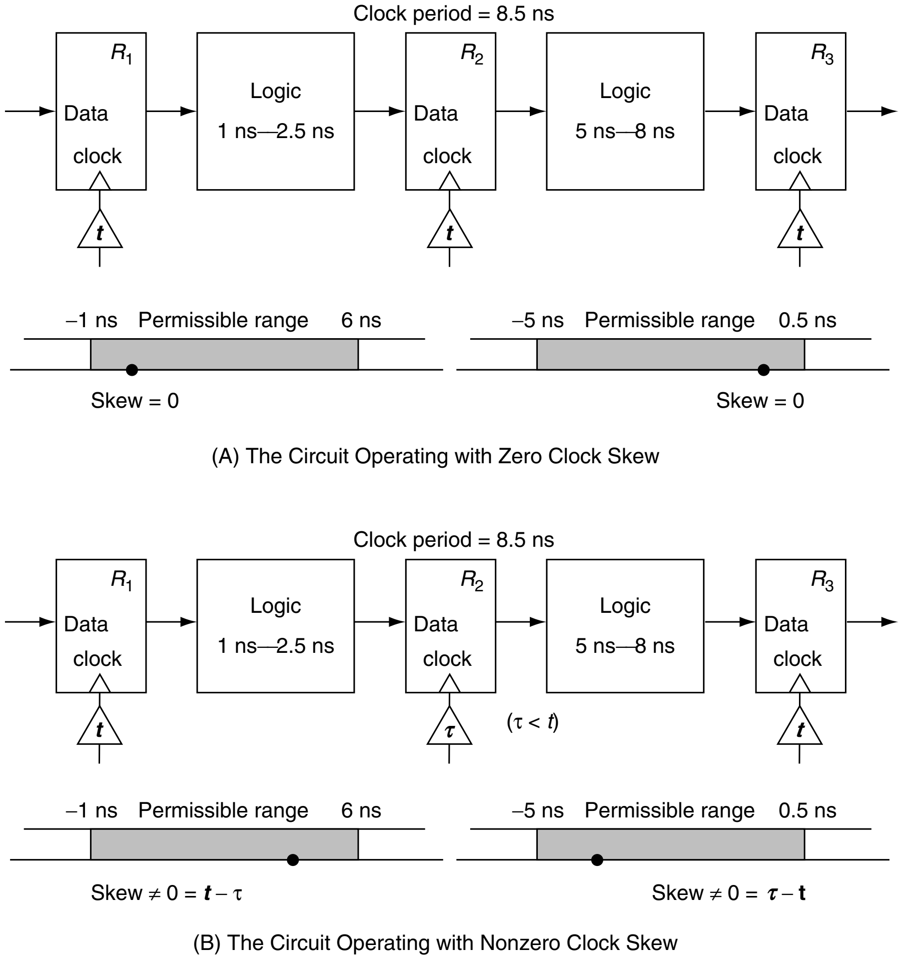
As shown by previous research (Friedman, 1995, 1992; Neves and Friedman, 1993, 1996a, 1996b; Xi and Dai, 1996; Kourtev and Friedman, 1999b), both double and zero clocking hazards may be removed from a synchronous digital circuit even when the clock skew is not zero [$T_{Skew}(i, f) \neq 0$ for some or all local data paths $R_i \rightsquigarrow R_f$]. As long as equations 4.5 and 4.6 are satisfied, a synchronous digital system can operate reliably with nonzero clock skews, permitting the system to operate at higher clock frequencies while removing all race conditions.

The vector column of clock delays $T_{CD} = [t_{cd}^1, t_{cd}^2, \ldots]^T$ is called a **clock schedule** (Friedman, 1995; Fishburn, 1990). If T_{CD} is chosen such that equations 4.5 and 4.6 are satisfied for every local data path $R_i \rightsquigarrow R_f$, T_{CD} is called a **consistent clock schedule**. A clock schedule that satisfies equation 4.7 is called a **trivial clock schedule**. Note that a trivial clock schedule T_{CD} implies global zero clock skew since for any i and f, $t_{cd}^i = t_{cd}^f$; thus, $T_{Skew}(i, f) = 0$.

An intuitive example of nonzero clock skew being used to improve the performance and reliability of a fully synchronous digital circuit is shown in Figure 4.6. Two pairs of sequentially adjacent flip-flops, $R_1 \rightsquigarrow R_2$ and $R_2 \rightsquigarrow R_3$, are shown in Figure 4.6, where both zero skew and nonzero skew situations are illustrated in Figures 4.6(A) and 4.6(B), respectively. Note that the local data paths made up of the registers R_1 and R_2 and of R_2 and R_3, respectively, are connected in series (R_2 being common to both $R_1 \rightsquigarrow R_2$ and $R_2 \rightsquigarrow R_3$). In each of the Fig-

[6] Positive clock skew may also be thought of as increasing the path delay. In either case, positive clock skew ($T_{Skew} > 0$) increases the difficulty of satisfying equation 4.5.

[7] Equivalently, it is required that the clock signal arrive at each register at approximately the same time.



(A) The Circuit Operating with Zero Clock Skew

(B) The Circuit Operating with Nonzero Clock Skew

FIGURE 4.6 Application of Nonzero Clock Skew to Improve Circuit Performance (a Lower Clock Period) or Circuit Reliability (Increased Safety Margins in the Permissible Range)

ures 4.6(A) and 4.6(B), the permissible ranges of the clock skew for both local data paths, $R_1 \rightsquigarrow R_2$ and $R_2 \rightsquigarrow R_3$, are lightly shaded under each circuit diagram. As shown in Figure 4.6, the target clock period for this circuit is $T_{CP} = 8.5$ ns.

The zero clock skew points (skew = 0) are indicated in Figure 4.6(A)—zero skew is achieved by delivering the clock signal to each of the registers R_1, R_2 and R_3 with the same delay t (symbolically illustrated by the buffers connected to the clock terminals of the registers). Observe that while the zero clock skew points fall within the respective permissible ranges, these zero clock skew points are dangerously close to the lower and upper bounds of the permissible range for $R_1 \rightsquigarrow R_2$ and $R_2 \rightsquigarrow R_3$, respectively. A situation could be foreseen in which, for example, the local data path $R_2 \rightsquigarrow R_3$ has a longer than expected delay (longer than 8 ns), thereby causing the upper bound of the permissible range for $R_2 \rightsquigarrow R_3$ to decrease below the zero clock skew point. In this scenario, a setup violation will occur on the local data path $R_2 \rightsquigarrow R_3$.

Consider next the same circuit with nonzero clock skew applied to the data paths $R_1 \rightsquigarrow R_2$ and $R_2 \rightsquigarrow R_3$, as shown in Figure 4.6(B). Nonzero skew is achieved by delivering the clock signal to the register R_2 with a delay $\tau < t$, where t is the delay of the clock signal to both R_1 and R_3. By applying this delay of $\tau < t$, positive $(t - \tau > 0)$ and negative $(\tau - t < 0)$ clock skews are applied to $R_1 \rightsquigarrow R_2$ and $R_2 \rightsquigarrow R_3$, respectively. The corresponding clock skew points are illustrated in the respective permissible ranges in Figure 4.6(B). Comparing Figure 4.6(A) to Figure 4.6(B), observe that a timing violation is less likely to occur in the latter case. For the previously described setup timing violation to occur in Figure 4.6(B), the deviations in the delay parameters of $R_2 \rightsquigarrow R_3$ would have to be much greater in the nonzero clock skew case than in the zero clock skew case. If the precise target value of the nonzero clock skew $\tau - t < 0$ is not met during the circuit design process, the safety margin from the skew point to the upper bound of the permissible range would be much greater.

Therefore, there are two identifiable benefits of applying a nonzero clock skew. First, the safety margins of the clock skew (that is the distances between the clock skew point and the bounds of the permissible range) in the permissible ranges of a data path can be improved. The likelihood of correct circuit operation in the presence of process parameter variations and operational conditions is improved with these increased margins. In other words, the circuit reliability is improved. Second, without changing the logical and circuit structure, the performance of the circuit can be increased by permitting a higher maximum clock frequency (or lower minimum clock period).

Friedman (1989) first presented the concept of negative nonzero clock skew as a technique to increase the clock frequency and circuit performance across sequentially adjacent pairs of registers. Soon afterward, Fishburn (1990) first suggested an algorithm for computing a consistent clock schedule that is nontrivial. It is shown in both Friedman's and Fishburn's studies that by exploiting negative and positive clock skew in a local data path $R_i \rightsquigarrow R_f$, a circuit can operate with a clock period T_{CP} smaller than the clock period achievable by a zero clock skew schedule while satisfying the conditions specified by equations 4.5 and 4.6. In fact, Fishburn (1990) determined an optimal clock schedule by applying linear programming techniques to solve for T_{CD} to satisfy these equations while minimizing the objective function $F_{\text{objective}} = T_{CP}$.

The process of determining a consistent clock schedule T_{CD} can be considered as the mathematical problem of minimizing the clock period T_{CP} under the constraints of equations 4.5 and 4.6. However, there are important practical issues to consider before a clock schedule can be properly implemented. A clock distribution network must be synthesized such that the clock signal is delivered to each register with the proper delay to satisfy the clock skew schedule T_{CD}. Furthermore, this clock distribution network must be constructed to minimize the deleterious effects of interconnect impedances and process parameter variations on the implemented clock schedule. Synthesizing the clock distribution network typically consists of determining a topology for the network, together with the circuit design and physical layout of the buffers and interconnect that make up a clock distribution network (Friedman, 1995, 1997).

4.3 Clock Scheduling for Improved Reliability

The problem of determining an optimal clock skew schedule for a fully synchronous VLSI system is considered in this section from the perspective of improving system reliability. An original formulation of the clock skew scheduling problem by the authors is introduced as a constrained quadratic programming (QP) problem (Kourtev and Friedman, 1999a, 1999b).

The operation of a fully synchronous digital system was discussed in Section 4.1. Briefly, for such systems to function properly, a strict temporal ordering of the many thousands of switching events in the circuit is required. This strict ordering is enforced by a global synchronizing clock signal delivered to every register in a circuit by a clock distribution network. Algorithms for determining a nonzero clock skew schedule that satisfy the tighter timing constraints of high-speed VLSI complexity systems can be found in (Friedman, 1995; Neves and Friedman 1996a, 1996b; Afghani and Svensson, 1990; Kourtev, 1999; Fishburn, 1990).

In this section, a different class of clock skew scheduling algorithms is introduced. In these algorithms, the primary objective is to improve circuit reliability by maximizing the tolerance to process parameter variations. Improvements are achieved by first choosing an objective clock skew value for each local data path. A consistent clock schedule is found by applying the proposed optimization algorithm. Unlike a performance optimization approach, the algorithm presented in this section minimizes the *least square* error between the computed and objective clock skew schedules.[8] A secondary objective of the clock skew scheduling algorithm developed in this chapter is to increase the system-wide clock frequency.

This section begins with an alternative formulation of the clock skew scheduling problem as a quadratic programming problem discussed in detail in Section 4.3.1. The mathematical procedures used to determine the clock skew schedule are developed and analyzed in Section 4.4.

4.3.1 Problem Formulation

Existing algorithms for clock skew scheduling are reviewed in this section.[9] The classical linear programming approach for minimizing only the clock period T_{CP} of a circuit is first described in the subsection entitled Clock Scheduling for Maximum Performance. A new quantitative measure to compare different clock schedules is introduced in Further Improvement. This section is concluded by sketching the clock skew scheduling problem as an efficiently solvable problem in Clock Scheduling as a Quadratic Programming Problem.

Recall the short delay $\hat{D}_{Pm}^{i,j}$ and long delay $\hat{D}_{PM}^{i,j}$ of a local data path $R_i \rightsquigarrow R_j$ introduced in definition 4.4. Using the substitutions, equations 4.3 and 4.4, the timing constraints of a local data path $R_i \rightsquigarrow R_f$ are rewritten in equations 4.5 and 4.6. A pair of constraints such as in these latter equations must be satisfied for each local data path in a circuit for this circuit to operate correctly. Furthermore, the local data path timing constraints lead to the concept of a permissible range introduced in

[8] In a performance optimization strategy, the starting point is the set of timing constraints and the objective of the clock.

[9] Scheduling algorithms is to determine a feasible clock schedule and clock distribution network given these constraints (Friedman, 1995; Neves and Friedman 1996a, 1996b; Afghani and Svensson, 1990; Kourtev, 1999; Fishburn, 1990).

Section 4.2.1 and illustrated in Figure 4.2. Formally, the lower and upper bounds of the permissible range of a local data path $R_i \rightsquigarrow R_j$ are the following:

$$l_{i,j} = -\hat{D}^{i,j}_{Pm}. \tag{4.10}$$

$$u_{i,j} = T_{CP} - \hat{D}^{i,j}_{PM}. \tag{4.11}$$

Also defined here for notational convenience are the width $w_{i,j}$ and middle $m_{i,j}$ of the permissible range. Specifically, these are the equations:

$$w_{i,j} = u_{i,j} - l_{i,j} = T_{CP} - \left(\hat{D}^{i,j}_{PM} - \hat{D}^{i,j}_{Pm}\right). \tag{4.12}$$

$$m_{i,j} = \frac{1}{2}(l_{i,j} + u_{i,j}) = \frac{1}{2}\left(T_{CP} - \hat{D}^{i,j}_{PM} - \hat{D}^{i,j}_{Pm}\right). \tag{4.13}$$

Recall from Section 4.2.3 that it is frequently possible to make two simple choices (concerning equation 4.7) characterizing the clock skews and delays in a circuit, such that both zero and double clocking violations are avoided. Specifically, if equal values are chosen for all clock delays and a sufficiently large value—larger than the longest delay $\hat{D}^{i,f}_{PM}$—is chosen for T_{CP}, neither of these two clocking hazards will occur. Formally,

$$\forall \langle R_i,\, R_f \rangle \colon t^i_{cd} = t^f_{cd} = \text{Const} \tag{4.14}$$

and

$$R_i \rightsquigarrow R_f \Rightarrow T_{CP} > \hat{D}^{i,f}_{PM}, \tag{4.15}$$

and with equations 4.14 and 4.15, the timing constraints 4.5 and 4.6 for a hazard-free local data path $R_i \rightsquigarrow R_f$ become:

$$\hat{D}^{i,f}_{PM} < T_{CP}. \tag{4.16}$$

$$\hat{D}^{i,f}_{Pm} > 0. \tag{4.17}$$

Next, recall that each clock skew $T_{Skew}(i, f)$ is the difference of the delays of the clock signals t^i_{cd} and t^f_{cd}. These delays are the tangible physical quantities that are implemented by the clock distribution network. The set of all clock delays in a circuit can be denoted as the vector column:

$$\boldsymbol{t_{cd}} = \begin{bmatrix} t^1_{cd} \\ t^2_{cd} \\ \vdots \end{bmatrix},$$

which is called a clock skew schedule or simply a clock schedule (Friedman, 1995; Fishburn, 1990; Kourtev and Friedman, 1997b). If $\boldsymbol{t_{cd}}$ is chosen such that equations 4.5 and 4.6 are satisfied for every local data path $R_i \rightsquigarrow R_j$, $\boldsymbol{t_{cd}}$ is called a *feasible* clock schedule. A clock schedule that satisfies equation 4.7 (respectively, equations 4.14 and 4.15) is called a trivial clock schedule. Again, a trivial $\boldsymbol{t_{cd}}$ implies global zero clock skew since for any i and f, $t^i_{cd} = t^f_{cd}$; thus, $T_{Skew}(i, f) = 0$. Also, observe that if $[t^1_{cd}\ t^2_{cd}\ \ldots]^t$ is a feasible clock schedule (trivial or not), $[c + t^1_{cd}\ c + t^2_{cd}\ \ldots]^t$ is also a feasible clock schedule where $c \in \mathbb{R}^1$ is any real constant.

An alternative way to refer to a clock skew schedule is to specify the vector of all clock skews in a circuit corresponding to a set of clock delays $\boldsymbol{t_{cd}}$ as specified above. Denoted by $\boldsymbol{s}$, the vector column of clock skews is $\boldsymbol{s} = [s_1\ s_2\ \ldots]^t$ where the skews $s_1, s_2, \ldots s_n$ of all local data paths in the circuit are enumerated. Typically, the dimension of $\boldsymbol{s}$ is different from the dimension of $\boldsymbol{t_{cd}}$ for the same circuit. If a circuit consists of r registers and p local data paths, for example, then $\boldsymbol{s} = \left[s_1 \ldots s_p\right]^t$ and $\boldsymbol{t_{cd}} = \left[t^1_{cd} \ldots t^r_{cd}\right]^t$ for this circuit. Therefore, the clock skew schedule refers to either $\boldsymbol{t_{cd}}$ or $\boldsymbol{s}$, where the precise reference is usually apparent from the context.

Note that $\boldsymbol{t_{cd}}$ must be known to determine each clock skew within $\boldsymbol{s}$. The inverse situation, however, is *not* true; that is, the set of all clock skews in a circuit need not be known to determine the corresponding clock schedule $\boldsymbol{t_{cd}}$. As is shown in Sections 4.3.1 and 4.4, a small subset of clock skews (compared to the total number of local data paths or clock skews) uniquely determines all the skews in a circuit as well as the different feasible clock schedules $\boldsymbol{t_{cd}}$. Finally, note that a given feasible clock schedule $\boldsymbol{s}$ allows for many possible implementations $\boldsymbol{t_{cd}} = \left[c + t^1_{cd}\ c + t^2_{cd}\ \ldots\right]^t$ where any specific constant c implies a different $\boldsymbol{t_{cd}}$ but the same $\boldsymbol{s}$. Thus, the term clock schedule is used to refer to $\boldsymbol{t_{cd}}$ where the choice of the real constant $c \in \mathbb{R}^1$ is arbitrary.

Clock Scheduling for Maximum Performance

The linear programming (LP) problem of computing a feasible clock skew schedule while minimizing the clock period T_{CP} of a circuit can be found in (Friedman, 1995; Neves and Friedman 1996a, 1996b; Afghani and Svensson, 1990; Kourtev, 1999; Fishburn, 1990). With T_{CP} as the value of the objective function being minimized, this problem is formally defined as problem LCSS:

Problem LCSS__________ (LP Clock skew scheduling)

$$\begin{aligned} &\min\ T_{CP} \\ \text{subject to: } & t^i_{cd} - t^j_{cd} \le T_{CP} - \hat{D}^{i,j}_{PM} \\ & t^i_{cd} - t^j_{cd} \ge -\hat{D}^{i,j}_{Pm}. \end{aligned} \tag{4.18}$$

To develop additional insight into problem LCSS, consider a circuit C_1 consisting of four registers, R_1, R_2, R_3, and R_4, and five local data paths, $R_1 \rightsquigarrow R_2$, $R_1 \rightsquigarrow R_3$, $R_3 \rightsquigarrow R_2$, $R_3 \rightsquigarrow R_4$, and $R_4 \rightsquigarrow R_2$. Let the long and short delays for this circuit be[10] $\hat{D}^{1,2}_{Pm} = 1$, $\hat{D}^{1,2}_{PM} = 3$, $\hat{D}^{1,3}_{Pm} = 2$, $\hat{D}^{1,3}_{PM} = 4$, $\hat{D}^{3,2}_{Pm} = 5$, $\hat{D}^{3,2}_{PM} = 7$,

[10] The times used in this section are all assumed to be in the same time unit. The actual time unit—e.g., picoseconds, nanoseconds, microseconds, milliseconds, seconds—is irrelevant and is therefore omitted.

TABLE 4.1 Clock Schedule t^1_{cd}: Clock Skews and Permissible Ranges for the Example Circuit C_1 (for the Minimum Clock Period $T_{CP} = 5$)

Local data path	Permissible range	Clock skew
$R_1 \rightsquigarrow R_3$	$[-2, 1]$	$t^1_{cd} - t^3_{cd} = 1 - 0 = 1$
$R_3 \rightsquigarrow R_4$	$[-2.5, 0]$	$t^3_{cd} - t^4_{cd} = 0 - 2.5 = -2.5$
$R_1 \rightsquigarrow R_2$	$[-1, 2]$	$t^1_{cd} - t^2_{cd} = 1 - 2 = -1$
$R_3 \rightsquigarrow R_2$	$[-5, -2]$	$t^3_{cd} - t^2_{cd} = 0 - 2 = -2$
$R_4 \rightsquigarrow R_2$	$[-2, 1]$	$t^4_{cd} - t^2_{cd} = 2.5 - 2 = 0.5$

$\hat{D}^{3,4}_{Pm} = 2.5$, $\hat{D}^{3,4}_{PM} = 5$, $\hat{D}^{4,2}_{Pm} = 2$, and $\hat{D}^{4,2}_{PM} = 4$. Solving problem LCSS (4.18) yields a feasible clock schedule t^1_{cd} for the minimum achievable clock period $T_{CP} = 5$:

$$\min T_{CP} = 5 \to t^1_{cd} = \begin{bmatrix} t^1_{cd} \\ t^2_{cd} \\ t^3_{cd} \\ t^4_{cd} \end{bmatrix} = \begin{bmatrix} 1 \\ 2 \\ 0 \\ 2.5 \end{bmatrix}.$$

These results are summarized in Table 4.1 along with the actual permissible range for each local data path for the minimum value of the clock period $T_{CP} = 5$ (recall that the permissible range depends on the value of the clock period T_{CP}).

Note that most of the clock skews (specifically, the first four) listed in Table 1 are at one end of the corresponding permissible range. This positioning is due to the inherent feature of linear programming that seeks the objective function extremum at a vertex of the solution space. In practice, however, this situation can be dangerous since correct circuit operation is strongly dependent on the accurate implementation of a large number of clock delays—effectively, the clock skews—across the circuit. It is quite possible that the actual values of some of these clock delays may fluctuate from the target values—due to manufacturing tolerances as well as variations in temperature and supply voltage—thereby causing a catastrophic timing failure of the circuit. Observe that while zero clocking failures can be corrected by operating the circuit at a slower speed (higher clock period T_{CP}), double clocking violations are race conditions that are catastrophic and render the circuit nonfunctional.

Maximizing Safety

Frequently in practice, a target clock period T_{CP} is established for a specific circuit implementation. Making the target clock period smaller may not be a primary design objective. If this is the case, alternative optimization strategies may be sought such that the resulting circuit is more tolerant to inaccuracies in the timing parameters. Two different classes of timing parameters are considered—the local data path delays and the clock delays (respectively, the clock skews). Note first that the clock skew scheduling process depends on accurate knowledge of the short and long path delays ($\hat{D}^{i,j}_{Pm}$ and $\hat{D}^{i,j}_{PM}$) for every local data path $R_i \rightsquigarrow R_j$. Second, provided the path delay information is predictable, correct circuit operation is contingent upon the accurate implementation of the computed clock schedule t_{cd}. Both of these factors must be considered if reliable circuit operation under various operating conditions is to be attained.

One way to achieve the specified goal of higher circuit reliability is to artificially shrink the permissible range of each local data path by an equal amount from either side of the interval and determine a feasible clock skew schedule based on these new timing constraints. This idea has been addressed by Fishburn (1990) as the problem of maximizing the minimum *slack* (over all inequalities of equations 4.5 and 4.6) or the amount by which an inequality exceeds the limit. Formally, the problem can be expressed as the linear programming problem LCSS–SAFE:

Problem LCSS–SAFE ___________ (LP Clock skew scheduling for safety)

$$\begin{aligned} & \max M \\ & \text{subject to: } t^i_{cd} - t^j_{cd} + M \leq T_{CP} - \hat{D}^{i,j}_{PM} \\ & \qquad t^i_{cd} - t^j_{cd} - M \geq -\hat{D}^{i,j}_{Pm} \\ & \qquad M \geq 0 \end{aligned} \tag{4.19}$$

To gain additional insight into problem LCSS–SAFE, consider again the circuit example used in Table 4.1. Two solutions of problem LCSS–SAFE are listed in Table 4.2 for two different values of the clock period, $T_{CP} = 6.5$ and $T_{CP} = 6$, respectively. These results are shown—denoted by t^2_{cd} and t^3_{cd}, respectively—in columns 2 through 5 and 6 through 9 for $T_{CP} = 6.5$ (clock schedule t^2_{cd}) and $T_{CP} = 6$ (clock schedule t^3_{cd}), respectively. For the specific value of T_{CP}, the permissible range is listed in columns 2 and 6, respectively, and the clock skew solution is listed in columns 3 and 7, respectively.

Note that there are two additional columns of data for either value of T_{CP} in Table 4.2. First, an "ideal" objective value of the clock skew is specified for each local data path in columns 4 and 8, respectively. This objective value of the clock skew is chosen in this example to be the value corresponding to the middle $m_{i,j}$ (note equation 4.13) of the permissible range of a local data path $R_i \rightsquigarrow R_j$ in a circuit with a clock period T_{CP}. The middle point of the permissible range is equally distant from either end of the permissible range, thereby providing the maximum tolerance to process parameter variations. Second, the absolute value of the distance $|T_{Skew}(i, j) - m_{i,j}|$ between the ideal and actual values of the clock skew for a local data path is listed in columns 5 and 9, respectively. This distance is a measure of the difference between the ideal clock skew and the scheduled clock skew. Note that in the general case, it is virtually impossible to compute a clock schedule t_{cd} such that the clock skew T_{Skew} (i, j) for each local data path $R_i \rightsquigarrow R_j$ is exactly equal to the middle $m_{i,j}$ of the permissible range of this path. The reasons for this characteristic are due to structural limitations of the circuits as highlighted in Section 4.4.

Further Improvement

Problem LCSS–SAFE (see equation 4.19) provides a solution to the clock skew scheduling problem for a case in which circuit reliability is of primary importance and clock period minimization is not the focus of the optimization process. As shown in the previous subsection, a certain degree of safety may be achieved by computing a feasible clock schedule subject to artificially smaller permissible ranges (as defined in equation 4.19). Problem LCSS–SAFE, however, is a brute force approach since it requires that the same absolute margins of safety are observed for each permissible range regardless of the range width. Therefore, this approach does not consider the individual characteristics of a permissible range and does not differentiate among local data paths with wider and narrower permissible ranges.

It is possible to provide an alternative approach to clock skew scheduling that considers all permissible ranges and also provides a natural quantitative measure of the quality of a particular clock schedule. Consider, for instance, a circuit with a target clock period T_{CP}. Furthermore, denote an *objective* clock skew value for a local data path $R_i \rightsquigarrow R_j$ by $g_{i,j}$, where it is required that $l_{i,j} \leq g_{i,j} \leq u_{i,j}$ (recall the lower equation 4.10 and upper equation 4.11 bounds of the permissible range). For most practical circuits, it is unlikely that a feasible clock schedule can be computed that is exactly equal to the objective clock schedule for each local data path. Multiple linear dependencies among clock skews in each circuit exist—those linear dependencies define a solution space such that the clock schedule $s = \begin{bmatrix} g_{i_1,j_1} & g_{i_2,j_2} & \cdots \end{bmatrix}^t$ most likely is *not* within this solution space (unless the circuit is constructed of only nonrecursive feed-forward paths). If t_{cd} is a feasible clock schedule, however, it is possible to evaluate how close a realizable clock schedule is to the objective clock schedule by computing the sum:

$$\varepsilon = \sum_{R_i \rightsquigarrow R_j} \left[T_{Skew}(i, j) - g_{i,j} \right]^2, \tag{4.20}$$

over all local data paths in the circuit.

Note that ε, as defined in equation 4.20 is the total least squares error of the actual clock skew as compared to the objective clock skew. This error permits any two different clock skew schedules to be compared. Moreover, the clock skew scheduling problem can be considered as a problem of minimizing ε of a clock schedule t_{cd} given the clock period T_{CP} and an "ideal" clock schedule $\begin{bmatrix} g_{i_1,j_1} & g_{i_2,j_2} & \cdots \end{bmatrix}^t$ subject to any specific circuit design criteria. The flexibility permitted by such a formulation is far greater since the ideal schedule $\begin{bmatrix} g_{i_1,j_1} & g_{i_2,j_2} & \cdots \end{bmatrix}^t$ can be any clock schedule that satisfies a specific target circuit.

Consider, for instance, the solution of LCSS–SAFE listed in Table 4.2 for $T_{CP} = 6.5$ and $T_{CP} = 6$. Computing the total error (as defined by equation 4.20) for both solutions gives $\varepsilon_{6.5} = 6.25$ and $\varepsilon_6 = \frac{1049}{144} = 7.2847$. Next, consider an alternative clock schedule $t_{cd}^{2'}$ for $T_{CP} = 6.5$ as follows:

$$T_{CP} = 6.5 \rightarrow t_{cd}^{2'} = \begin{bmatrix} t_{cd}^1 \\ t_{cd}^2 \\ t_{cd}^3 \\ t_{cd}^4 \end{bmatrix} = \begin{bmatrix} 43/32 \\ 38/32 \\ 0 \\ 31/32 \end{bmatrix}. \tag{4.21}$$

It can be verified that with $t_{cd}^{2'}$ as specified, $\varepsilon_{6.5}$ improves to $\frac{675}{128} = 5.2734$ from 6.25 for t_{cd}^2 (columns two equations 4.2 through 4.5 in Table 4.2). Similarly, an alternative clock schedule t_{cd}^3 for the clock period $T_{CP} = 6$ is

$$T_{CP} = 6.5 \rightarrow t_{cd}^{3'} = \begin{bmatrix} t_{cd}^1 \\ t_{cd}^2 \\ t_{cd}^3 \\ t_{cd}^4 \end{bmatrix} = \begin{bmatrix} 35/32 \\ 54/32 \\ 0 \\ 39/32 \end{bmatrix}. \tag{4.22}$$

Again, using $t_{cd}^{3'}$ leads to an improvement of ε_6 to 6.1484 as compared to 7.2847 for the solution of LCSS–SAFE t_{cd}^3 (see Table 4.2, columns 6 through 9).

Clock Scheduling as a Quadratic Programming Problem

As discussed in the previous three subsections, a common design objective is ensuring reliable system operation under a target clock period. It is possible to redefine the problem of clock skew scheduling for this case. The input data for this redefined problem consists of:

- The clock period of the circuit T_{CP};
- The circuit connectivity and delay information (i.e., all local data paths $R_i \rightsquigarrow R_j$ and the short and long delays $\hat{D}_{Pm}^{i,j}$ and $\hat{D}_{PM}^{i,j}$, respectively); and
- An objective clock schedule $g = \begin{bmatrix} g_{i_1,j_1} \\ g_{i_2,j_2} \\ \vdots \end{bmatrix}$.

Given this information, the optimization goal is to compute a feasible clock schedule s^* (respectively t_{cd}^*) so as to minimize the least square error between the computed clock schedule $\boldsymbol{s}^*$ and the objective clock schedule g. Recall that the least square error ε_τ (described by equation 4.20) is defined as the sum of the squares of the distances (algebraic differences) between the actual and objective clock skews over all local data paths in the circuit. This problem is described in a formal framework in the following section. Also in the following section, the mathematical algorithm to solve this revised problem is explained in greater detail.

4.4 Derivation of the QP Algorithm

The formulation of clock skew scheduling as a quadratic programming problem is described in detail in this section. First, the graph model introduced in Section 4.2.2 is further analyzed in Section 4.4.1. The linear dependencies among the clock skews and the fundamental set of cycles are introduced and analyzed in Section 4.4.2. Finally, the quadratic programming problem is formulated and solved in Section 4.4.3.

4.4.1 The Circuit Graph

As discussed in Section 4.2.2, a synchronous circuit C can be represented as the simple undirected graph $g_C = \{V^{(C)}, E^{(C)}, A^{(C)}, h_l^{(C)}, h_u^{(C)}, h_d^{(C)}\}$, where $V_C = \{v_1, \ldots, v_r\}$ is the set of vertices of the graph, $E_C = \{e_1, \ldots, e_p\}$ is the set of edges of the graph, and the symmetric $r \times r$ matrix A_C—called the adjacency matrix—contains the graph connectivity (West, 1996). Vertices from g_C correspond to the registers of the circuit C, and the edges reflect the fact that pairs of registers are sequentially adjacent. Note the cardinalities $|V_C| = r$ and $|E_C| = p$—the circuit C has r registers and p local data paths. The adjacency matrix $A_C = [a_{ij}]_{r \times r}$ is a square matrix of order $r \times r$ where both the rows and columns of A correspond to the vertices of g_C. As previously mentioned, for notational convenience s_j denotes the clock skew corresponding to the edge $e_j \in E_C$. Specifically, if the vertices v_{i_1} and v_{i_2} correspond to the sequentially adjacent pair of registers $R_{i_1} \rightsquigarrow R_{i_2}$ connected by the j-th edge e_j, then:

$$s_j \overset{\text{def}}{=} T_{Skew}(i_1, i_2).$$

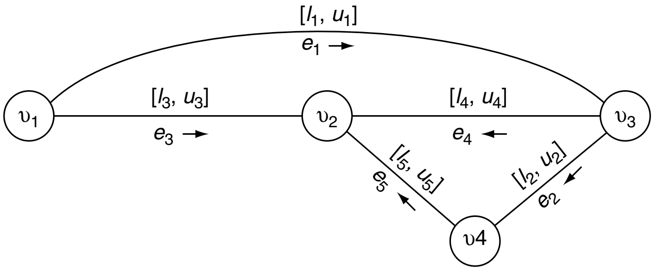

FIGURE 4.7 Circuit Graph of the Simple Example Circuit C_1

To illustrate these concepts, the graph g_{C_1} of the small circuit example C_1 introduced previously is illustrated in Figure 4.7 (note the enumeration and labeling of the edges as specified in definition 4.3). For this example, $r = 4$, $p = 5$, and the adjacency matrix is the following:

$$A_{C_1} = \begin{array}{c|cccc} & v_1 & v_2 & v_3 & v_4 \\ \hline v_1 & 0 & 1 & 1 & 0 \\ v_2 & 1 & 0 & 1 & 1 \\ v_3 & 1 & 1 & 0 & 1 \\ v_4 & 0 & 1 & 1 & 0 \end{array}.$$

Observe that in general, the elements of A_C are defined as:

$$a_{ij}^u = \begin{cases} 1 & \textit{if there is an edge } e_k \textit{ connecting the vertices } v_i \textit{ and } v_j. \\ 0 & \textit{otherwise.} \end{cases} \tag{4.23}$$

In addition, note that the adjacency matrix as defined in equation 4.23 is always symmetric. The edges of g_C have no direction, so each edge between vertices v_i and v_j is shown in both of the rows corresponding to i and j. In addition, all diagonal elements of the adjacency matrix are zeros since self-loop edges are excluded by the required circuit graph properties described in Section 4.2.2. As a final reminder and without any loss of generality, it is assumed that a circuit has a connected graph (West, 1996). In other words, a circuit does not have isolated groups of registers. If a specific circuit has a disconnected graph, then each connected subgraph (subcircuit) can be considered separately.

4.4.2 Linear Dependence of Clock Skews

Consider the circuit graph of C_1 illustrated in Figure 4.7. The clock skews for the local data paths $R_3 \rightsquigarrow R_2$, $R_3 \rightsquigarrow R_4$, and $R_4 \rightsquigarrow R_2$ are $s_4 = T_{Skew}(3, 2) = t_{cd}^3 - t_{cd}^2$, $s_2 = T_{Skew}(3, 4) = t_{cd}^3 - t_{cd}^4$, and $s_5 = T_{Skew}(4, 2) = t_{cd}^4 - t_{cd}^2$, respectively. Note that $s_4 = s_2 + s_5$ (that is the clock skews s_2, s_4, and s_5 are **linearly dependent**). In addition, note that other sets of linearly dependent clock skews can be identified within C_1, such as s_1, s_3, and s_4.

Generally, large circuits contain many feedback and feed-forward signal paths. Thus, many possible linear dependencies among clock skews—such as those described in the previous paragraph—are typically present in such circuits. A natural question arises as to whether there exists a minimal set[11] of linearly independent clock skews that uniquely determines all clock skews in a circuit. (The existence of any such set could lead to substantial improvements in the run time of the clock scheduling algorithms as well as permit significant savings in storage requirements when implementing these algorithms on a digital computer.) It is generally possible to identify multiple minimal sets in any circuit. Consider C_1, for example—it can be verified that $\{s_3, s_4, s_5\}$, $\{s_1, s_3, s_5\}$, and $\{s_1, s_4, s_5\}$ each are sets with the property that (a) the clock skews in the set are linearly independent and (b) C_1 can be expressed as a linear combination of the clock skews that exist in the set.

Let C be a circuit with graph g_C and let v_{i_0}, e_{j_0}, $v_{i_1}, \ldots,$ $e_{j_{z-1}}$, $v_{i_z} \equiv v_{i_0}$ be an arbitrary sequence of vertices and edges. Formally, the condition for linear dependence of the clock skews, $s_{j_0}, s_{j_1}, \ldots, s_{j_{z-1}}$, is as written here:

$$\left.\begin{aligned} \prod_{k=0}^{z-1} a_{i_k j_k} \neq 0 \\ (i_z = i_0) \neq i_1 \neq \ldots \neq i_{z-1} \end{aligned}\right\} \Rightarrow \sum_{k=0}^{z-1} \pm T_{Skew}(i_k, j_k) = 0, \tag{4.24}$$

where the proof of equation 4.24 is trivial by substitution. The product on the left side of this equation requires that there exists an edge between every pair of vertices v_{i_k} and $v_{i_{k+1}} (k = 0, \ldots, z-1)$. The sum can be interpreted[12] as traversing the vertices of the cycle $C = v_{i_0}$, e_{j_0}, $v_{i_1}, \ldots, e_{j_z - 1}$, $v_{i_z} \equiv v_{i_0}$ in the order of appearance in C and adding the skews along C with a positive or negative sign, depending on whether the direction labeled on the edge coincides with the direction of traversal.

Typically, multiple cycles can be identified in a circuit graph and an equation—such as equation 4.24—can be written for each of these cycles. Referring to Figure 4.7, three such cycles are as follows:

$$\begin{aligned} C_1 &= v_1,\ e_1,\ v_3,\ e_2,\ v_4,\ e_5,\ v_2,\ e_3,\ v_1 \\ C_2 &= v_2,\ e_4,\ v_3,\ e_2,\ v_4,\ e_5,\ v_2 \\ C_3 &= v_1,\ e_1,\ v_3,\ e_4,\ v_2,\ e_3,\ v_1. \end{aligned}$$

These cycles can be identified and the corresponding linear dependencies written as:

$$\text{cycle } C_1 \rightarrow s_1 + s_2 - s_3 \quad + s_5 = 0 \tag{4.25}$$

$$\text{cycle } C_2 \rightarrow \quad s_2 \quad - s_4 + s_5 = 0 \tag{4.26}$$

$$\text{cycle } C_3 \rightarrow s_1 \quad - s_3 + s_4 \quad = 0. \tag{4.27}$$

Note that the order of the summations in equations 4.25 through 4.27 has been intentionally modified from the order of cycle traversal to highlight an important characteristic. Specifically, observe that equation 4.25 is the sum of equations 4.26 and 4.27 that is, there exists a linear dependence not only among the skews in the circuit C but also among the cycles (or sets of linearly dependent skews).

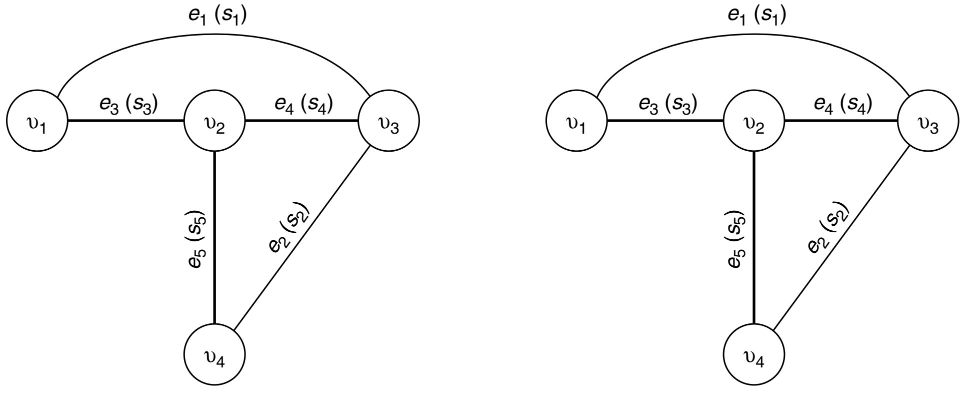
Note that any minimal set of linearly independent clock skews must not contain a cycle (as defined by equation 4.24), for if the set contains a cycle, the skews in the set would not be linearly independent. Furthermore, any such set must span all vertices (registers) of the circuit, or it is not possible to express the clock skews of any paths in and out of the vertices not spanned by the set. Given a circuit C with r registers and p local data paths, these conclusions are formally summarized in the following two results from graph theory (West, 1996; Reingold *et al.*, 1997):

1. *Minimal set of linearly independent clock skews*: A minimal set of clock skews can be identified such that (a) the skews in the set are linearly independent and (b) every skew in C is a linear combination of the skews from the set. Such a minimal set is any **spanning tree** of g_C and consists of exactly $r - 1$ elements (recall that a spanning tree is a subset of edges such that all vertices are spanned by the edges in the set). These $r - 1$ skews (respectively, edges) in the spanning tree are referred to as the **skew basis** while the remaining $p - (r - 1) = p - r + 1$ skews (edges) of the circuit are referred to as **chords**. Note that there is a unique path between any two vertices such that all edges of the path belong to the spanning tree.
2. *Minimal set of independent cycles*: A minimal set of cycles (where a cycle is as defined by equation 4.24) can be identified such that (a) the cycles are linearly independent and (b) every cycle in C is a linear combination of the cycles from the set. Each choice of a spanning tree of g_C determines a unique minimal set of cycles, where each cycle consists of exactly one chord $\{v_{i_1}, e_j, v_{i_2}\}$ plus the unique path that exists in the spanning tree between the vertices v_{i_1} and v_{i_2}. Since there are $p - (r - 1) = p - r + 1$ chords, a minimal set of independent cycles consists of $p - r + 1$ cycles. The minimal set of independent cycles of a graph is also called a fundamental set of cycles (West, 1996; Chan *et al.*, 1972; Reingold *et al.*, 1997).

To illustrate the aforementioned properties, observe the two different spanning trees of the example in circuit C_1 outlined with the thicker edges in Figure 4.8 (the permissible ranges and direction labelings have been omitted from Figure 4.8 for simplicity). The first tree is shown in Figure 4.8(A) and consists of the edges $\{e_3, e_4, e_5\}$ and the independent cycles C_2 (equation 4.26) and C_3 (equation 4.27). As previously explained, both C_2 and C_3 contain precisely one of the skews

[11] Such that the removal of any element from the set destroys the property.

[12] Note the similarity with Kirchhoff's voltage law (KVL or loop equations) for an electrical network (Chan *et al.*, 1972).



(A) Spanning Tree {e_3, e_4, e_5}

(B) Spanning Tree {e_1, e_3, e_5}

FIGURE 4.8 Two Spanning Trees. These trees show the corresponding minimal sets of linearly independent clock skews and linearly independent cycles for the circuit example C_1. Edges from the spanning tree are indicated with thicker lines

not included in the spanning tree—s_2 for C_2 and s_1 for C_3. Similarly, the second spanning tree {e_1, e_3, e_5} is illustrated in Figure 4.8(B). The independent cycles for the second tree are C_1 (equation 4.25) and C_3 (equation 4.27)—generated by s_2 and s_4, respectively.

Let a circuit C with r registers and p local data paths be described by a graph g, and let a skew basis (spanning tree) for this circuit (graph) be identified. For the remainder of this work, it is assumed that the skews have been enumerated such that those skews from the skew basis have the highest indices.[13] Introducing the notation s^b for the basis and s^c for the chords, the clock schedule s can be expressed as:

$$\mathrm{s} = \begin{bmatrix} \mathrm{s}^c \\ \mathrm{s}^b \end{bmatrix} = [\underbrace{\overbrace{s_1 \cdots s_{p-r+1}}^{p-r+1}}_{\text{Chords}} \underbrace{\overbrace{s_{p-r+2} \cdots s_p}^{r-1}}_{\text{Basis}}]^t, \tag{4.28}$$

where

$$s^c = \begin{bmatrix} s_1 \\ \vdots \\ s_{p-r+1} \end{bmatrix} \text{ and } s^b = \begin{bmatrix} s_{p-r+2} \\ \vdots \\ s_p \end{bmatrix}. \tag{4.29}$$

Note that the case illustrated in Figure 4.8(A) is precisely the type of enumeration just described by equations 4.28 and 4.29—e_1, e_2 (s_1, s_2) are the chords and e_3, e_4, e_5 (s_3, s_4, s_5) are the basis.

With the notation and enumeration as specified above, let $n_b = r - 1$ be the number of skews (edges) in the basis, and let $n_c = p - r + 1 = p - n_b$ be the number of chords (equal to the number of cycles). The set of linearly independent cycles is $C_1, \ldots, C_{n_c}$ and the clock skew dependencies for these cycles are these:

$$\begin{aligned} &\text{cycle } C_1 = v_{i_0^1},\ e_{j_0^1},\ v_{i_1^1}, \ldots,\ e_{j_{z-1}^1},\ v_{i_0^1} \quad \rightarrow 0 = \sum_{k=i_0^1}^{i_{z-1}^1} \pm s_{j_k^1}. \\ &\qquad\qquad\qquad\qquad\vdots \\ &\text{cycle } C_{n_c} = v_{i_0^{nc}},\ e_{j_0^{nc}},\ v_{i_1^{nc}}, \ldots,\ e_{j_{z-1}^{nc}},\ v_{i_0^{nc}} \rightarrow 0 = \sum_{k=i_0^{nc}}^{i_{z-1}^{nc}} \pm s_{j_k^{nc}}. \end{aligned} \tag{4.30}$$

Note that the sums in equation 4.30 can be written in matrix form:

$$Bs = 0, \tag{4.31}$$

where $B = [b_{ij}]_{n_c \times p}$ is a matrix of order $n_c \times p$. The matrix B will be called the **circuit connectivity matrix**, and each row of B corresponds to a cycle of the circuit graph and contains elements from the incidence matrix A combined with zeros depending on whether a skew (an edge) belongs to the cycle. Note that since each cycle contains exactly one chord, the cycles can always be permuted such that the cycles appear in the order of the chords i.e. C_1 corresponds to e_1, C_2 corresponds to e_2, and so on). If this correspondence is applied, the matrix B can be represented as:

$$B = [I_{n_c} C_{n_c \times n_b}], \tag{4.32}$$

where the submatrix I_{n_c} is an identity[14] matrix of dimension $n_c \times n_c$, thereby permitting equation 4.31 to be rewritten as:

[13] Such enumeration is always possible since the choice of indices for any enumeration (including this example) is arbitrary.

[14] Recall that an identity matrix I_n is a square $n \times n$ matrix such that the only nonzero elements are on the main diagonal and are all equal to one.

$$Bs = [I\ \ C]\begin{bmatrix} s^c \\ s^b \end{bmatrix} = s^c + Cs^b = 0. \tag{4.33}$$

Consider, for instance, the choice of spanning tree illustrated in Figure 4.8(A). There are two independent cycles denoted by C_1 (corresponding to C_2 in equation 4.26) and C_2 (corresponding to C_3 in equation 4.27). The matrix relationship of equation 4.31 for this case is the following:

$$s_1 - s_3 + s_4 = 0 \leftarrow \text{cycle } C_1 = v_1,\ e_1,\ v_3,\ e_4,\ v_2,\ e_3,\ v_1.$$
$$+\, s_2 - s_4 + s_5 = 0 \leftarrow \text{cycle } C_2 = v_3,\ e_2,\ v_4,\ e_5,\ v_2,\ e_4,\ v_3.$$

The matrices B and C, respectively, are

$$\begin{aligned} B = [I_2\ \ C_{2\times 3}] &= \begin{bmatrix} 1 & 0 & -1 & 1 & 0 \\ 0 & 1 & 0 & -1 & 1 \end{bmatrix}, \\ C &= \begin{bmatrix} -1 & 1 & 0 \\ 0 & -1 & 1 \end{bmatrix}. \end{aligned} \tag{4.34}$$

From an algebraic standpoint (Bretscher, 1996), equation 4.31 requires that any clock schedule s must necessarily be in the kernel $\ker(B)$ of the linear transformation B: $\mathbb{R}^p \rightarrow \mathbb{R}^{n_c}$ (that is $s \in \ker B$). The inverse situation, however, is not true; that is, an arbitrary element of the kernel is *not* necessarily a feasible clock schedule. Furthermore, note that B is already in reduced row echelon form (Bretscher, 1996) so the rank of B is $\text{rank}(B) = n_c$. Thus, the dimension of ker (B) is [33] as follows:

$$\begin{aligned} \dim(\ker(B)) &= \text{columns of } B - \text{rank}(B) \\ &= p - \text{rank}(B) \\ &= p - n_c = n_b. \end{aligned} \tag{4.35}$$

Therefore, equation 4.31 is referred to here as the circuit kernel equation.

This last result expressed by equation 4.35 demonstrates that there are $n_b = r - 1$ linearly independent skews in a circuit. Furthermore, considering that the matrix C is:

$$C = \begin{bmatrix} | & & | \\ c_1 & \cdots & c_{n_b} \\ | & & | \end{bmatrix},$$

one possible basis for $\ker(B)$ can be written from inspection:

$$\text{basis for } \ker(B) = \underbrace{\begin{bmatrix} -c_1 \\ 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix}\begin{bmatrix} -c_2 \\ 0 \\ 1 \\ \vdots \\ 0 \end{bmatrix}\cdots\begin{bmatrix} -c_{n_b} \\ 0 \\ 0 \\ \vdots \\ 1 \end{bmatrix}}_{n_b\text{vectors}}. \tag{4.36}$$

Any feasible clock schedule $s \in \ker(B)$ can be expressed as a linear combination of the vectors from the basis of the kernel:

$$s = \begin{bmatrix} s^c \\ s^b \end{bmatrix} = s_1^b \begin{bmatrix} -c_1 \\ 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix} + s_2^b \begin{bmatrix} -c_2 \\ 0 \\ 1 \\ \vdots \\ 0 \end{bmatrix} + \ldots + s_{n_b}^b \begin{bmatrix} -c_{n_b} \\ 0 \\ 0 \\ \vdots \\ 1 \end{bmatrix} = \begin{bmatrix} -Cs^b \\ s^b \end{bmatrix}, \tag{4.37}$$

where the scalars, $s_1^b, s_2^b, \ldots, s_{r'}^b$, in equation 4.37 are the elements of the vector s^b as defined by equation 4.28:

$$s^b = \begin{bmatrix} s_1^b \\ s_2^b \\ \vdots \\ s_{n_b}^b \end{bmatrix} = \begin{bmatrix} s_{n_c+1} \\ s_{n_c+2} \\ \vdots \\ s_p \end{bmatrix}. \tag{4.38}$$

Observe that either knowing or deliberately choosing s^b not only provides sufficient information to determine the corresponding s^c (respectively, the entire s) but also permits computation of the clock delays t_{cd} to implement the desired clock schedule s. Specifically, the dependencies among the clock skews in the branches (the local data paths) and the clock delays to the vertices (the registers) can be described in matrix form as follows:

$$s^b = T_{n_b \times r} t_{cd} \tag{4.39}$$

Note that each skew is the difference of two clock delays so that each row of the matrix T in equation 4.39 contains exactly two nonzero elements. These two nonzero elements are 1 and -1, respectively, depending on which two clock delays determine the clock skew corresponding to this equation (or row in the matrix). Also note that equation 4.39 is a consistent linear system (the rows correspond to linearly independent skews in the circuit) with fewer equations than the r unknown clock delays t_{cd}. Therefore, equation 4.39 has an infinite number of solutions all corresponding to the same clock schedule s.

Finding a solution t_{cd} of equation 4.39 is now a straightforward matter. For example, setting $t_{cd}^r = 0$ and rewriting this equation to account for this substitution:

$$t_{cd}^r = 0 \Rightarrow s^b = T^*_{n_b \times n_b} t_{cd} = T^*_{n_b \times n_b}, \tag{4.40}$$

yields a consistent linear system with the same number of variables as equations where the matrix $T^*_{n_b \times n_b}$ is the matrix $T_{n_b \times r}$ with the rightmost column deleted. The most efficient way to solve the system characterized by equation 4.40 with the highest accuracy is by back substitution (only addition/subtraction operations are necessary). In the software implementation of this algorithm discussed in this work, t_{cd} is computed in an efficient way by traversing the edges of the spanning tree.

This section concludes by illustrating the concepts discussed with a small circuit example C_1; the circuit graph $\mathcal{g}C_1$ is shown in Figure 4.7, and the respective spanning tree is shown in Figure 4.8(A). For this circuit, $r = 4$, the number of local data paths is $p = 5$, and $n_b = 4 - 1 = 3$. The clock schedule is as follows:

$$\mathrm{s} = \begin{bmatrix} \mathrm{s}^c \\ \mathrm{s}^b \end{bmatrix}, \text{ where } \mathrm{s}^c = \begin{bmatrix} s_1 \\ s_2 \end{bmatrix}, \mathrm{s}^b = \begin{bmatrix} s_3 \\ s_4 \\ s_5 \end{bmatrix}. \tag{4.41}$$

The independent cycles are C_2 (from equation 4.26) and C_3 (from equation 4.27) and the matrices B and C are as defined in equation 4.34. A basis for the kernel of B has a dimension $n_b = 3$ and consists of the vectors:

$$\begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} -1 \\ 1 \\ 0 \\ 1 \\ 0 \end{bmatrix}, \text{ and } \begin{bmatrix} 0 \\ -1 \\ 0 \\ 0 \\ 1 \end{bmatrix}. \tag{4.42}$$

Any clock schedule is in ker(B) and can be expressed as a linear combination of the vectors from the kernel basis:

$$s = s_3^b \begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \\ 0 \end{bmatrix} + s_4^b \begin{bmatrix} -1 \\ 1 \\ 0 \\ 1 \\ 0 \end{bmatrix} + s_5^b \begin{bmatrix} 0 \\ -1 \\ 0 \\ 0 \\ 1 \end{bmatrix}. \tag{4.43}$$

Consider, for instance, the clock skew schedule for $T_{CP} = 6.5$ shown in Table 4.2. Substituting $s_3 = 0$, $s_4 = -1.5$, and $s_5 = -1$ into equation 4.43 yields the clock schedule:

$$s = 0 \begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \\ 0 \end{bmatrix} - 1.5 \begin{bmatrix} -1 \\ 1 \\ 0 \\ 1 \\ 0 \end{bmatrix} - 1 \begin{bmatrix} 0 \\ -1 \\ 0 \\ 0 \\ 1 \end{bmatrix} = \begin{bmatrix} 1.5 \\ -0.5 \\ 0 \\ -1.5 \\ -1 \end{bmatrix}. \tag{4.44}$$

Finally, the clock delays t_{cd} are derived from the underdetermined linear system (as described by equation 4.39):

$$s^b = \begin{bmatrix} 0 \\ -1.5 \\ -1 \end{bmatrix} = \begin{bmatrix} 1 & -1 & 0 & 0 \\ 0 & -1 & 1 & 0 \\ 0 & -1 & 0 & 1 \end{bmatrix} \begin{bmatrix} t_{cd}^1 \\ t_{cd}^2 \\ t_{cd}^3 \\ t_{cd}^4 \end{bmatrix}, \tag{4.45}$$

where setting $t_{cd}^4 = 0$ yields:

$$s^b = \begin{bmatrix} 0 \\ -1.5 \\ -1 \end{bmatrix} = \begin{bmatrix} 1 & -1 & 0 \\ 0 & -1 & 1 \\ 0 & -1 & 0 \end{bmatrix} \begin{bmatrix} t_{cd}^1 \\ t_{cd}^2 \\ t_{cd}^3 \end{bmatrix} \Rightarrow \begin{matrix} t_{cd}^1 = 1 \\ t_{cd}^2 = 1 \\ t_{cd}^3 = -0.5. \end{matrix} \tag{4.46}$$

Interestingly, the clock schedule $\begin{bmatrix} 1 & 1 & -1/2 & 0 \end{bmatrix}^t$ differs from the solution shown in Table 4.2 by only a constant of $c = -1/2$, namely,

$$\begin{bmatrix} 1 & 1 & -\frac{1}{2} & 0 \end{bmatrix}^t = \begin{bmatrix} c + \frac{3}{2} & c + \frac{3}{2} & c + 0 & c + \frac{1}{2} \end{bmatrix}^t. \tag{4.47}$$

4.4.3 Optimization Problem and Solution

Recall the intuitive definition of clock skew scheduling as a quadratic programming (QP) problem first introduced in Section 4.3. In this section, the QP formulation is formalized, and the solution of the problem is explained in detail.

Problem QP-1__________(QP Clock Skew Scheduling)

Let C be a circuit with r registers, p local data paths, and a target clock period T_{CP}, and let the local data paths be enumerated as:

$$p \text{ local data paths} \begin{cases} \text{path}_1 & \rightarrow & R_{i_j} \rightsquigarrow R_{j_1} \\ & \vdots & \\ \text{path}_p & \rightarrow & R_{i_p} \rightsquigarrow R_{j_p}. \end{cases} \tag{4.48}$$

For each local data path path$_k(R_{i_k} \rightsquigarrow R_{j_k})$ in C, let the lower bound l_{i_k, j_k}, upper bound u_{i_k, j_k}, width w_{i_k, j_k}, and middle m_{i_k, j_k} of the permissible range of this path, respectively, be defined as in equations 4.10, 4.11, 4.12 and 4.13, respectively. For simplicity, these parameters of the permissible range are denoted with a single subscript corresponding to the number of the respective local data path; that is, for the path$_k \equiv R_{i_k} \rightsquigarrow R_{j_k}$, $l_{i_k, j_k} = l_k$, $u_{i_k, j_k} = u_k$, $w_{i_k, j_k} = w_k$, and $m_{i_k, j_k} = m_k$. Furthermore, let the circuit graph of C be $\mathcal{G}C$, let the skew basis s^b and chords s^c be identified in $\mathcal{G}C$ (according to equation 4.28), and let the corresponding independent set of cycles be described by the matrix $B = \begin{bmatrix} I & C \end{bmatrix}$ as defined in equation 4.32. Let an objective clock schedule be $g = \begin{bmatrix} g_1 & \dots & g_p \end{bmatrix}^t = \begin{bmatrix} m_1 & \dots & m_p \end{bmatrix}^t$, and let $l = \begin{bmatrix} l_1 & \dots & l_p \end{bmatrix}^t$ and $u = \begin{bmatrix} u_1 & \dots & u_p \end{bmatrix}^t$ be the vectors of the lower and upper bounds, respectively, of the permissible ranges. Find a feasible clock schedule s that minimizes the least square error ε between s and g. Formally, it is shown that:

$$\begin{aligned} \min \ \varepsilon &= \sum_{k=1}^{p} (s_k - g_k)^2, \\ \text{subject to: } Bs &= 0 \\ l &\leq s \\ s &\leq u, \end{aligned} \tag{4.49}$$

where the inequalities in equation 4.49 are treated in terms of each component (that is, $l_1 \leq s_1 \leq u_1$, $l_2 \leq s_2 \leq u_2$, and so on).

Problem QP-1 is a constrained QP problem with bounded variables—methods such as **active constraints** exist for solving such problems (Ciarlet and Lions, 1990; Farebrother, 1988; Osborne, 1985; Fletcher, 1987; Björck, 1996). These methods are both analytically and numerically challenging, so a two-phase solution process is suggested here such that a constrained version of problem QP-1 is solved initially. If the result is not feasible, a rapidly converging iterative refinement of the objective g is performed until the feasibility of s is satisfied. This two-phase process is defined formally as:

$$\begin{aligned}&\text{Phase 1} \rightarrow \min \varepsilon = \sum_{k=1}^{p} (s_k - g_k)^2,\\ &\qquad\qquad \text{subject to } Bs = 0.\\ &\text{Phase 2} \rightarrow \text{Iterative refinement of } s,\end{aligned} \tag{4.50}$$

where Phase 1 is an equality-constrained quadratic optimization problem expressed as the following problem QP-2:
Problem QP-2 __________ (QP Clock skew scheduling)

$$\begin{aligned}&\min\ \varepsilon = (s-g)^2 = \sum_{k=1}^{p} (s_k - g_k^{\tau})^2\\ &\text{subject to: } Bs = 0.\end{aligned} \tag{4.51}$$

Problem QP-2 is representative of a broader class of optimization problems where the function that is minimized is a distance in the Euclidean space $\mathbb{R}^n$. One typical problem that arises in a variety of situations, for instance, is the linear least squares problem. The objective of the linear least squares problem is to find $x^* \in \mathbb{R}^n$ such that the Euclidean distance between $Dx^* \in \mathbb{R}^m$ and $b \in \mathbb{R}^m$ is as small as possible. The matrix D is an $m \times n$ matrix, and the system $Dx = b$ is typically inconsistent. The function being minimized in the linear least squares problem is the following:

$$\sum_{i=1}^{m} (d_i^t x - b_i)^2, \text{ where } D^t = \begin{bmatrix} | & & | \\ d_1 & \ldots & d_m \\ | & & | \end{bmatrix}.$$

It is well known (Bretscher, 1996; Björck, 1996) that if the kernel of D is $\ker(D) = \{0\}$, then x^* is the solution of the consistent system $D^t Dx = D^t b$.

The quadratic programming problem QP-2 is solved by applying the classical method of **Lagrange multipliers** for constrained optimization (Fletcher, 1987; Björck, 1996; Lawson and Hanson, 1974). To start, note that minimizing the objective function ε in equation 4.51 is equivalent to minimizing the function:

$$\varepsilon^* = s^t s - 2g^t s.$$

For a quick proof of this equivalence, consider expanding the value of ε:

$$\begin{aligned}\varepsilon &= (s-g)^2\\ &= (s)^2 - 2g^t s + (g)^2\\ &= s^t s - 2g^t s + g^t g,\end{aligned} \tag{4.52}$$

where the inner product $g^t g$ in equation 4.52 is a numeric constant. Therefore, if a value $s = s^*$ exists that minimizes ε^* in equation 4.52, s^* also minimizes ε. Note that since $\varepsilon^* = \varepsilon - g^t g$, the two minimums are related by:

$$\min(\varepsilon^*) = \min(\varepsilon) - g^t g. \tag{4.53}$$

Thus, problem QP-2 is transformed into the following problem QP-3:
Problem QP-3 __________ (QP Clock skew scheduling)

$$\begin{aligned}&\min\ \varepsilon^* = s^t s - 2g^t s,\\ &\text{subject to: } Bs = 0.\end{aligned} \tag{4.54}$$

To apply the method of Lagrange multipliers to problem QP-3, the vector $\lambda = [\lambda_1 \ldots \lambda_{n_c}]^t$ is introduced, where each multiplier λ_i in λ corresponds to the i-th equality constraint from $Bs = 0$. The Lagrangian function $\mathcal{L}(s, \lambda)$ is introduced next:

$$\begin{aligned}L(s, \lambda) &= \varepsilon^* + \lambda^t Bs\\ &= s^t s - 2g^t s + \lambda^t Bs,\end{aligned} \tag{4.55}$$

where the term $\lambda^t Bs$ in equation 4.55 is the sum of all equality constraints for the product of the ith constraint times the multiplier λ_i.

Any extremum of ε^* must be a stationary point of the Lagrangian $\mathcal{L}(s, \lambda)$ (Bretscher, 1996); that is, the first derivatives of $\mathcal{L}(s, \lambda)$ with respect to $s_i\ i \in \{1, \ldots, p\}$ and $\lambda_j\ j \in \{1, \ldots, n_c\}$, must be zero. Formally, if the differential operator is denoted as ∇, then any stationary point (s^*, λ^*) of $\mathcal{L}(s, \lambda)$ is a solution of the system of equations:

$$\nabla \mathcal{L}(s, \lambda) = 0 \ \Rightarrow \left| \begin{array}{l} \nabla_s \mathcal{L}(s, \lambda) = 0 \\ \nabla_\lambda \mathcal{L}(s, \lambda) = 0. \end{array}\right. \tag{4.56}$$

In the general case of a QP problem with any type of constraints, systems such as equation 4.56 can be nonlinear and difficult to solve. In the case of linear constraints, however, a solution can be derived in a straightforward manner. To this end, consider the derivatives $\nabla_s \mathcal{L}(s, \lambda)$ and $\nabla_\lambda \mathcal{L}(s, \lambda)$ of the Lagrangian:

$$\begin{aligned}\nabla_s \mathcal{L}(s, \lambda) &= \nabla_s (s^t s - 2g^t s + \lambda^t Bs)\\ &= 2s - 2g + (\lambda^t B)^t\\ &= 2s - 2g + B^t \lambda,\end{aligned} \tag{4.57}$$

$$\text{and } \nabla_\lambda \mathcal{L}(s, \lambda) = \nabla_\lambda (s^t s - 2gs + \lambda^t Bs) = Bs. \tag{4.58}$$

Note that equations 4.57 and 4.58 contain p and n_c equations, respectively (recall that s and λ have p and n_c variables, respectively). Therefore, the solution of equation 4.56 requires finding exactly $p + n_c = 2p - n_b = 2p - r + 1$ variables.

Substituting equations 4.57 and 4.58 back into 4.56 yields the linear system:

$$\left|\begin{array}{r} 2s + B^t\lambda = 2g \\ Bs = 0, \end{array}\right. \tag{4.59}$$

which can be conveniently written in matrix form:

$$\begin{bmatrix} 2I_p & B^t \\ B & 0 \end{bmatrix} \begin{bmatrix} s \\ \lambda \end{bmatrix} = 2\begin{bmatrix} g \\ 0 \end{bmatrix}. \tag{4.60}$$

Solving equation 4.60 by Gauss-Jordan elimination is straightforward by premultiplying with $1/2B$ the first row of the system described by equation 4.60 and subtracting the result from the second row, thereby yielding:

$$\begin{bmatrix} 2I_p & B^t \\ B & 0 \end{bmatrix} \begin{bmatrix} s \\ \lambda \end{bmatrix} = 2\begin{bmatrix} g \\ 0 \end{bmatrix} \Rightarrow \begin{bmatrix} 2I_p & B^t \\ 0 & BB^t \end{bmatrix} \begin{bmatrix} s \\ \lambda \end{bmatrix} = 2\begin{bmatrix} g \\ Bg \end{bmatrix}. \tag{4.61}$$

A natural way to solve the linear system described by equation 4.61 is by back substitution,[15] such that λ is initially computed, followed by the computation of s. The Lagrange multipliers λ are determined from the equation $(BB^t)\lambda = 2Bg$ in the second row of equation 4.61, where the right-hand side $2Bg$ is a nonzero vector; that is, $Bg \neq \{0\}$. The opposite situation, $Bg = \{0\}$, is highly unlikely to occur since $Bg = \{0\}$ means that $g \in \ker(B)$, which in turn means (recall equation 4.35 through 4.38) that the objective clock schedule g is feasible and no optimization needs to be performed.[16]

Therefore, the equation $(BB^t)\lambda = 2Bg$ in equation 4.61 can have either no solutions or exactly one solution depending on whether the matrix BB^t is singular or not. In other words, the nonsingularity of BB^t is a *necessary* and *sufficient* condition for the existence of a unique solution $\left[\hat{s}^t \;\; \hat{\lambda}^t\right]^t$ of equation 4.60. If the product BB^t is denoted by M, note that the symmetric $n_c \times n_c$ matrix:

$$M = BB^t = [I \quad C]\begin{bmatrix} I \\ C^t \end{bmatrix} = I + CC^t \tag{4.62}$$

is strictly positive-definite and thus nonsingular. Therefore, the system 4.60 is guaranteed to have a unique solution of:

$$\hat{\lambda} = 2M^{-1}Bg \tag{4.63}$$

and

$$\hat{s} = -\frac{1}{2}B^t\lambda + g = -(B^tM^{-1}B)g + g, \tag{4.64}$$

where the matrix M is as introduced in equation 4.62.

To gain further insight into the solution described by equations 4.60 through 4.64, consider substituting equation 4.32 for B into equation 4.60 and representing the vector column g of the objective clock skew schedule as:

$$g = \begin{bmatrix} g^c \\ g^b \end{bmatrix}, \tag{4.65}$$

where g^c and g^b correspond to s^c and s^b; that is, g_1 is the objective value of the clock skew s_1, g_2 is the objective value of the clock skew s_2, and so on. With these substitutions, the system represented by equation 4.60 can be written as:

$$\begin{bmatrix} 2I_{n_c} & 0 & I_{n_c} \\ 0 & 2I_{n_b} & C^t \\ I_{n_c} & C & 0 \end{bmatrix} \begin{bmatrix} s^c \\ s^b \\ \lambda \end{bmatrix} = K\begin{bmatrix} s^c \\ s^b \\ \lambda \end{bmatrix} = 2\begin{bmatrix} g^c \\ g^b \\ 0 \end{bmatrix}, \tag{4.66}$$

where the coefficient matrix K on the left is symmetric. In equation 4.66, the Gaussian elimination step described by equation 4.61 is equivalent to multiplying by 1/2 the first row of K, premultiplying by 1/2 C the second row of K, and subtracting both of these rows from the third row:

$$\begin{gathered} \begin{bmatrix} 2I & 0 & I \\ 0 & 2I & C^t \\ I & C & 0 \end{bmatrix} \begin{bmatrix} s^c \\ s^b \\ \lambda \end{bmatrix} = 2\begin{bmatrix} g^c \\ g^b \\ 0 \end{bmatrix} \Rightarrow \\ \begin{bmatrix} 2I & 0 & I \\ 0 & 2I & C^t \\ 0 & 0 & I + CC^t \end{bmatrix} \begin{bmatrix} s^c \\ s^b \\ \lambda \end{bmatrix} = 2\begin{bmatrix} g^c \\ g^b \\ g^c + Cg^b \end{bmatrix}. \end{gathered} \tag{4.67}$$

Observe that the linear system of equation 4.67 is simply a more detailed technique for rendering the linear system described by equation 4.61, where the first row has been expanded into the first two rows of equation 4.67:

$$BB^t = [I \quad C]\begin{bmatrix} I \\ C^t \end{bmatrix} = I + CC^t \tag{4.68}$$

$$Bg = [I \quad C]\begin{bmatrix} g^c \\ g^b \end{bmatrix} = g^c + Cg^b. \tag{4.69}$$

With the matrix M as defined in equation 4.62, the solution of equation 4.67 is the following:

[15] This is true because the coefficient matrix is an upper triangular matrix.

[16] The chances of g being feasible for a large real circuit are infinitesimally small.

$$\hat{\lambda} = 2M^{-1}Bg, \tag{4.70}$$

$$\hat{s}^b = -\frac{1}{2}C^t\hat{\lambda} + g^b, \tag{4.71}$$

$$\hat{s}^c = -\frac{1}{2}\hat{\lambda} + g^c. \tag{4.72}$$

As a final note, observe that the solution described by equations 4.63 and 4.64 is not only a stationary point of the Lagrangian function $\mathcal{L}(s, \lambda)$ (i.e., a potential local minimizer), but the solution is also a *global* minimizer of ε^* in equation 4.54 (Björck, 1996). As a matter of fact, problem QP-3 belongs to a broader class of optimization problems for which the function being minimized is of the form $f(x) = x^tZx + y^tx$ (note that in the case of problem QP-3, the matrix Z is the positive-definite identity matrix I_p). A proof can be found in (Björck, 1996): if Z is positive-definite, a solution process similar to the process represented by equations 4.55 through 4.64 can be applied to obtain a unique global minimizer of $f(x) = x^tZx + y^tx$. Björck (1996) provides a most thorough treatment of this subject as well as proofs of the existence and uniqueness of the solution.

4.5 Practical Considerations

A new formulation of clock skew scheduling as a QP problem was introduced in Sections 4.3 and 4.4. Recall that in this formulation, a feasible and consistent clock schedule is found that is close[17] to a previously chosen "ideal" objective clock schedule.

In this section, a computer methodology is presented for the solution of the QP clock scheduling problem introduced in Section 4.3. Different computer implementations are analyzed and compared in detail in Subsection 4.5.1. It is shown that the QP problem can be efficiently solved, and three computer algorithmic procedures for this solution are discussed. These three algorithms are demonstrated to have $O(r^3)$ run time complexity and $O(r^2)$ storage complexity, where r is the number of registers in the circuit. The numerical constants of the leading terms in these complexity expressions are derived as a function of the ratio of the number of local data paths to the number of registers in the circuit, thereby permitting a suitable algorithm to be chosen for a specific circuit. Furthermore, the methodology presented in Section 4.3 is extended here to account for two important details of practical interest. The circuit graph model is revisited in Section 4.5.3, where it is shown that certain clock skews from the basis are unconstrained[18], and this information is integrated into the mathematical framework described in Section 4.3. Section 4.5.4, demonstrates how to efficiently handle the timing constraints of the *I/O* registers of a circuit and reviews the necessary modifications to the mathematical optimization procedure.

4.5.1 Computational Analysis

The solution to problem QP-3 was described in Section 4.4.3 in purely mathematical terms and without consideration of any computational aspects. Naturally, the solution described by equations 4.63 and 4.64 is determined from a program running on a digital computer. In this section, the time and memory requirements of three different computer implementations are analyzed in greater detail. The run time complexity N of these algorithms is considered to be dependent on the number of multiplicative (multiple and divide) floating point operations. Similarly, the memory complexity M is considered to be the largest number of floating point storage units that must be stored in memory at any time during the execution of the specific algorithm.[19]

It is shown here that the run time complexity of all three algorithms described in this section is $O(r^3)$, where r is the number of registers in the circuit. Furthermore, it is shown that the numerical constant of the leading r^3 term in these complexity expressions is a function of the ratio:

$$k = \frac{p}{r}. \tag{4.73}$$

The ratio in 4.73 refers to the number of local data paths p to the number of registers r in a circuit. Similarly, the memory complexity of all three algorithms is $O(r^2)$ where the numerical constant of the r^2 term is a function of k introduced in equation 4.73. This relationship is exploited to determine the most efficient algorithm for a specific circuit.

Note that formally, the Lagrange multipliers λ are *not* required for the solution of problem QP-3 because the objective of the procedures described here is to determine a feasible clock schedule s. Since the existence and uniqueness of a clock schedule $\hat{s}$ satisfying problem QP-3 have been established in Section 4.4.3, this clock schedule can be directly computed by evaluating the rightmost expression in equation 4.64:

$$\hat{s} = -(B^tM^{-1}B)g + g. \tag{4.74}$$

As an alternative, a sequential approach can be adopted such that the Lagrange multipliers $\hat{\lambda}$ are computed first, followed by computing $\hat{s}$ (consisting of $\hat{s}^b$ and $\hat{s}^c$) using $\hat{\lambda}$.

In the former case (a straightforward computation of $\hat{s}$), the complexity of evaluating the expression described by equation 4.74 determines the complexity of the overall solution. In the

[17] The clock schedule is close in a Euclidean sense.

[18] These skews are independent from other skews in the circuit. Nevertheless, these skews must satisfy the permissible range requirement.

[19] Memory transfers between main and secondary storage are, of course, always an option. For the quickest execution, however, all data must reside in the main storage.

latter case (computing $\hat{\lambda}$ first), both $\hat{s}^b$ and $\hat{s}^c$ can be computed quickly because these computations involve only the addition and subtraction operations (recall that all nonzero elements of the matrix C are either 1 or -1). Therefore, in the case of computing $\hat{\lambda}$ and $\hat{s}$ in this order, the complexity of the overall solution of problem QP-3 is dominated by the computation of the Lagrange multipliers $\hat{\lambda}$.

Three computational algorithms for solving problem QP-3 are described in the following three sections. The first two algorithms—called LMCS-1 and LMCS-2, respectively—compute $\hat{\lambda}$ and $\hat{s}$ in this order according to the dependence relationship $\hat{s} = 1/2B^t\hat{\lambda}$ described by equation 4.64. The third algorithm—called CSD—computes the clock schedule $\hat{s}$ directly as described by equation 4.74. The algorithms LMCS-1 and LMCS-2 are described in the following first two subsections. The last two subsections describe algorithm CSD, which is shown to be superior to both of the other algorithms, and offer a comparative summary of the results.

Algorithm LMCS-1

As mentioned previously, this algorithm for solving problem QP-3 consists of eliminating $\hat{\lambda}$ from $M\lambda = 2Bg$ (see equation 4.63) then computing $\hat{s}$ according to equation 4.64. To determine the value of the Lagrange multipliers $\hat{\lambda}$ corresponding to the minimization of ε_τ^* in problem QP-3, consider the linear system:

$$M\lambda = (BB^t)\lambda = (I + CC^t)\lambda = 2Bg = 2(g^c + Cg^b), \quad (4.75)$$

which corresponds to the last row of equations 4.61 and 4.67, respectively. As mentioned previously in Section 4.4.3, the symmetric matrix M is always positive-definite[20] and nonsingular, thereby permitting exactly one solution $\hat{\lambda}$ of the linear system described by equation 4.75.

This linear system is a large square system of the type $Ax = b$, where $b \in \mathbb{R}^n$ is a column vector and where the coefficient matrix $A \in \mathbb{R}^{n\times n}$ is dense. Typically, the most effective approach to computing the solution $\hat{x} \in \mathbb{R}^n$ of such systems consists of performing a triangular **decomposition**[21] of the coefficient matrix A followed by the successive solution of two relatively "easy" to solve square linear systems of order $n \times n$. The triangular decomposition of A is of the form $A = LU$, where L and U are a lower triangular and an upper triangular matrix, respectively (Golub and Loan, 1996; Forsythe and Moler, 1967). The solution of $Ax = LUx = b$ is obtained next by first computing the intermediate solution $\hat{y}$ of the system $Ly = b$. Finally, $\hat{x}$ is the solution of the system $Ux = \hat{y}$. Because of the triangularity of the matrices L and U, the vectors $\hat{y}$ and $\hat{x}$ can be computed with relatively little effort. The components of the intermediate solution $\hat{y}$ are obtained by solving the system $Ly = b$—referred to as forward elimination (Golub and Loan, 1996; Forsythe and Moler, 1967)—since the first equation of $Ly = b$ involves only y_1, the second only y_1 and y_2, and so on. Similarly, the components of $\hat{x}$ are obtained from the system $Ux = \hat{y}$ in the reverse order $x_n, x_{n-1}, \ldots, x_1$. The process of solving $Ux = \hat{y}$ for $\hat{x}$ is also called back substitution (Golub and Loan, 1996; Forsythe and Moler, 1967).

Furthermore, the symmetry and positive-definiteness of M can be exploited to obtain a special form of the LU triangular decomposition of M so that the lower and upper triangular matrices in the decomposition are the transpose of each other. This alternative decomposition is known as the **Cholesky** decomposition of M and permits M to be uniquely represented (Golub and Loan, 1996) as the product:

$$BB^t = M = L_1L_1^t, \quad (4.76)$$

where L_1 is a lower triangular matrix. The Cholesky decomposition is computationally more efficient than a general LU decomposition in that the Cholesky decomposition requires about half of the computation time of a general LU decomposition. Finally, the Cholesky decomposition has useful properties related to issues of numerical stability and accuracy. (An in-depth treatment of this subject is discussed in Golub and Loan [1996] and Forsythe and Moler [1967].)

As mentioned previously, the complexity of algorithm LMCS-1 is dominated by the complexity of computing the Lagrange multipliers $\hat{\lambda}$. This computation of $\hat{\lambda}$ consists of a total of:

$$N_1(r, k) = \frac{1}{6}(k-1)^3r^3 + (k-1)^2r^2. \quad (4.77)$$

These Multiplications are distributed among tasks as follows:

Task	← Number multiplications
a. Computing the Cholesky decomposition L_1 of M	$\leftarrow \frac{1}{6}n_c^3 = \frac{1}{6}(k-1)^3r^3.$
b. Forward elimination of ξ from $L_1\xi = 2Bg$	$\leftarrow \frac{1}{2}n_c^2 = \frac{1}{2}(k-1)^2r^2.$
c. Back substitution of $\hat{\lambda}$ from $L_1^t\lambda = \xi$	$\leftarrow \frac{1}{2}n_c^2 = \frac{1}{2}(k-1)^2r^2.$

The maximum memory usage of the algorithm LMCS-1 is:

$$M_1(r, k) = \frac{1}{2}(k-1)^2r^2, \quad (4.78)$$

floating point elements. This memory is used during different tasks in LMCS-1 as follows:

a. Matrix M	$\leftarrow \frac{1}{2}(p-r)^2 = \frac{1}{2}(k-1)^2r^2.$
b. Cholesky decomposition L_1 of M	$\leftarrow$ L_1 overwrites M as is computed.

[20] The positive-definiteness of M follows from $M = BB^t$ where $B = [I \quad C]$ has linearly independent rows. Therefore, the kernel of B^t is $\ker(B^t) = \{0\}$, and the value of the quadratic form $x^tMx = x^tBB^tx$ is positive for any value of $x \neq 0$.

[21] The nonsingularity of A, L, and U is assumed in this discussion.

A numerical example is offered in Appendix A to illustrate how algorithm LMCS-1 is applied to the circuit example C_1 introduced earlier.

Algorithm LMCS-2

The algorithm LMCS-2 described in this section is similar to algorithm LMCS-1 described in the previous subsection: both algorithms follow the same general course of computation. Specifically, algorithm LMCS-2 also first eliminates $\hat{\lambda}$ from $M\lambda = 2Bg$ (see equation 4.63) and next computes $\hat{s}$ according to equation 4.64. To determine the value of the Lagrange multipliers $\hat{\lambda}$, equation 4.63 is solved by finding the matrix inverse M^{-1} and then multiplying the right-hand side (2Bg) by M^{-1}:

$$\hat{\lambda} = M^{-1}(2Bg). \tag{4.79}$$

Note that the matrix inverse $M^{-1} = (I + CC^t)^{-1}$ in equation 4.79 can be expressed using the Sherman–Morrison–Woodbury formula (Golub and Loan, 1996):

$$(D + EF^t)^{-1} = D^{-1} - D^{-1}E(I + F^tD^{-1}E)^{-1}F^tD^{-1}, \tag{4.80}$$

where $D \in \mathbb{R}^{n\times n}$, $E \in \mathbb{R}^{n\times k}$, $F \in \mathbb{R}^{n\times k}$, and both D and $(I + F^tD^{-1}E)$ are nonsingular. When applied to the matrix $M^{-1} = (I + CC^t)^{-1}$, the Sherman–Morrison–Woodbury formula described by equation 4.80 yields:[22]

$$\left.\begin{aligned} D &= I \\ E &= F = C \\ N &= I + C^tC \end{aligned}\right\} \Rightarrow \quad \begin{aligned} M^{-1} &= (I + CC^t)^{-1} \\ &= I - C(I + C^tC)^{-1}C^t\,. \\ &= I - CN^{-1}C^t \end{aligned} \tag{4.81}$$

Note that in equation 4.81, not only can the matrix inverse $N^{-1} = (I + C^tC)^{-1}$ be computed more quickly than M^{-1} (the dimension of N is $n_b \times n_b$ versus $n_c \times n_c = (k-1)r \times (k-1)r$ for M), but the computation of this inverse N^{-1} matrix does *not* have to be explicitly performed to evaluate the product $CN^{-1}C^t$ in equation 4.81. Let the Cholesky decomposition of $N = I + C^tC$ be the following:

$$N = L_2L_2^t, \tag{4.82}$$

and substitute equation 4.82 into the product $C(I + C^tC)^{-1}C^t = CN^{-1}C^t$ in equation 4.81, then:

$$\begin{aligned} M^{-1} &= I - CN^{-1}C^t \\ &= I - C(L_2L_2^t)^{-1}C^t \\ &= I - (C(L_2^t)^{-1})(L_2^{-1}C^t) \\ &= I - X^tX, \end{aligned} \tag{4.83}$$

where X is used to denote the product $(L_2^{-1}C^t)$. The matrix X can be computed by forward elimination according to the matrix equation $L_2X = C^t$, while the product $CN^{-1}C^t$ is equal to the product X^tX. Also, observe that the matrix M^{-1} can be computed one row at a time, thereby drastically reducing the storage requirements of the algorithm. The *j*th row of M^{-1} is computed and used to calculate the Lagrange multiplier $\hat{\lambda}_j$ as the inner product of this *j*th row of M^{-1} and the vector $2Bg$. The memory used to store the elements of the *j*th row of M^{-1} is then overwritten with the elements of the $(j+1)$-th row of M^{-1} and so on. The rows of the matrix M^{-1} can be stored in a disk to permit the rows to be retrieved for future execution.

Just as in algorithm LMCS-1, the complexity of algorithm LMCS-2 is dominated by the complexity of computing the Lagrange multipliers $\hat{\lambda}$. This computation of $\hat{\lambda}$ consists of a total of:

$$N_2(r,k) = \left[\frac{1}{6} + \frac{1}{2}(k-1) + \frac{1}{2}(k-1)^2\right]r^3 + (k-1)r^2. \tag{4.84}$$

These multiplications are distributed among the following tasks:

Task	← Number multiplications
a. Computing the Cholesky decomposition L_2 of N	← $\frac{1}{6}r^3$.
b. Forward elimination of X from $L_2X = C^t$	← $\frac{1}{2}r^2(p-r) = \frac{1}{2}(k-1)r^3$.
c. Evaluate $M^{-1} = I - X^tX$	← $\frac{1}{2}r(p-r)^2 = \frac{1}{2}(k-1)^2r^3$.
d. Evaluate $\hat{\lambda} = M^{-1}(2Bg)$	← $(p-r)^2 = (k-1)^2r^2$.

The maximum memory usage of algorithm LMCS-2 is as written here:

$$M_2(r,k) = (k - \frac{1}{2})r^2 + (k-1)r, \tag{4.85}$$

floating point elements. This memory usage is distributed among different tasks in LMCS-2 as follows:

a. Matrix N	← Requires $1/2r^2$ storage units
b. Cholesky decomposition L_2 of N	← L_2 overwrites N as is computed
c. Matrix X from $L_2X = C^t$	← L_2 Requires $r(p-r) = (k-1)r^2$ storage units
d. Matrix $M^{-1} = I - X^tX$	← Requires $(p-r)=(k-1)r$ storage units for one row of M

Refer to Appendix B for a numerical example illustrating algorithm LMCS-2 as applied to the circuit example C_1 introduced previously.

Algorithm CSD

Unlike algorithms LMCS-1 and LMCS-2, the clock schedule $\hat{s}$ is computed directly in algorithm CSD (i.e., without first computing the Lagrange multipliers $\hat{\lambda}$). With this strategy, the clock schedule $\hat{s}$ is determined according to equation 4.74:

[22] Note that $I + C^tC$ is positive-definite, thus nonsingular.

$$Z = B^t M^{-1} B \Rightarrow \hat{s} = -Zg + g = (-Z + I)g, \tag{4.86}$$

where the matrix Z is introduced in equation 4.86 to simplify the notation. To evaluate Z, the expression described by equation 4.81 is substituted for M^{-1} into equation 4.86, and the product $Z = B^t M^{-1} B$ is evaluated using the same technique as in equations 4.82 and 4.83:

$$\begin{aligned} Z = B^t M^{-1} B &= B^t(I - CN^{-1}C^t)B \\ &= B^t B - B^t C N^{-1} C^t B \\ &= B^t B - B^t C (L_2^t)^{-1} L_2^{-1} C^t B \\ &= B^t B - Y^t Y. \end{aligned} \tag{4.87}$$

The notation

$$Y = L_2^{-1} C^t B \tag{4.88}$$

is introduced in equation 4.87 for simplicity, whereas such as for the previously described algorithm LMCS-2, the matrix Y can be eliminated according to the equation $L_2 Y = C^t B$.

The clock schedule $\hat{s}$ can be computed if the operations described by equations 4.86 through 4.88 are carried on literally. These expressions, however, can be manipulated to significantly reduce both the run time and memory requirements for algorithm CSD. Initially, note that computing each clock skew s_i requires evaluating the inner product of two dense p-element-long vectors—the ith row of the matrix $(-Z + I)$ and g. The evaluation of this inner product requires p multiplications, where p is the number of local data paths in the circuit. Recall, however, that the values of the clock skews from the basis s^b provide sufficient information to reconstruct all clock skews s in a quick fashion. Specifically, once the skews from the basis s^b are known, the skews s^c in the chords of the circuit may be derived through the operation described by equation 4.33:

$$[\,I \quad C\,]\begin{bmatrix} s^c \\ s^b \end{bmatrix} = s^c + Cs^b = 0 \Rightarrow s^c = -Cs^b. \tag{4.89}$$

Since only the basis s^b is evaluated, only the *last* n_b rows of the matrix $(-Z + I)$ are computed, thereby yielding significant savings of computation time. (Note that computing one row of Z requires the evaluation of p row elements, each row requiring r' multiplications in the product $Y^t Y$.) These concepts are illustrated graphically in Figure 4.9.

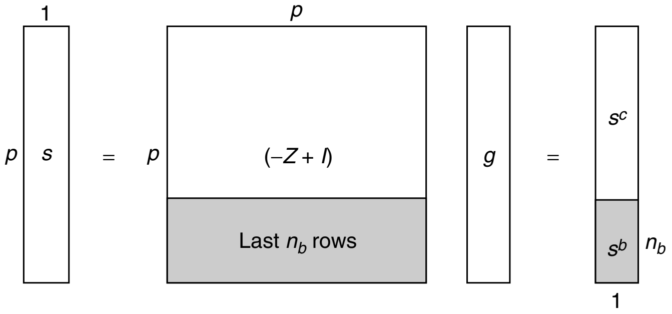


FIGURE 4.9 Computation of the Clock Schedule Basis s^b by Computing Only the Last n_b Rows of the Matrix $-Z + I$

The complexity of the evaluation of $(-Z + I) = (-B^t B + Y^t Y + I)$ can be reduced further by examining the computation of Y. Typically, the direct evaluation of Y—by forward elimination from $L_2 Y = C^t B$—requires $1/2pr^2 = 1/2kr^3$ multiplications. This number can be reduced by noting that:

$$\begin{aligned} C^t B = C^t[\,I \quad C\,] &= [\,C^t \quad CC^t\,] \\ &= [\,C^t \quad N - I\,] = [\,C^t \quad L_2 L_2^t - I\,] \end{aligned} \tag{4.90}$$

$$\text{and } Y = [\,Y_1 \quad Y_2 - Y_3\,], \tag{4.91}$$

where the matrices Y_1, Y_2, and Y_3 can be eliminated from the following dependencies, respectively:

$$L_2 Y_1 = C^t \leftarrow \text{compute } Y_1 \qquad \rightarrow \text{requires } (1/2)(k-1)r^3 \text{ multiplications} \tag{4.92}$$

$$L_2 Y_2 = N \leftarrow \qquad Y_2 = L_2^t \rightarrow \text{already computed} \tag{4.93}$$

$$L_2 Y_3 = I \leftarrow \text{compute } Y_3 \qquad \rightarrow \text{requires } \tfrac{1}{6}r^3 + \tfrac{1}{6}(3r^2 + 2r) \text{ multiplications} \tag{4.94}$$

Finally, the following transformations of equations 4.95 through 4.97 are used to evaluate the matrix $(-Z + I)$:

$$\begin{aligned} B^t B &= \begin{bmatrix} I \\ C^t \end{bmatrix}[\,I \quad C\,] = \begin{bmatrix} I & C \\ C^t & C^t C \end{bmatrix} = \begin{bmatrix} I & C \\ C^t & N - I \end{bmatrix} \\ &= I + \begin{bmatrix} O & C \\ C^t & N - 2I \end{bmatrix}, \end{aligned} \tag{4.95}$$

$$\begin{aligned} V = Y^t Y &= \begin{bmatrix} Y_1^t \\ Y_2^t - Y_3^t \end{bmatrix}[\,Y_1 \quad Y_2 - Y_3\,] \\ &= \left[\begin{array}{cc} V_{11} & V_{12} \\ (L_2 L_2^{-1} C^t - L_2^{-t} L_2^{-1} C^t) & (L_2 L_2^t + L_2^{-t} L_2^{-1} - L_2 L_2^{-1} - L_2^{-t} L_2^t) \end{array}\right] \\ &= \left[\begin{array}{cc} V_{11} & V_{12} \\ C^t - (L_2^{-t} L_2^{-1}) C^t & N - 2I + L_2^{-t} L_2^{-1} \end{array}\right], \end{aligned} \tag{4.96}$$

and

$$\begin{aligned} -Z + I &= -B^t B + Y^t Y + I \\ &= -I - \begin{bmatrix} O & C \\ C^t & N - 2I \end{bmatrix} \\ &\quad + \left[\begin{array}{cc} V_{11} & V_{12} \\ C^t - (L_2^{-t} L_2^{-1}) C^t & N - 2I + L_2^{-t} L_2^{-1} \end{array}\right] + I \\ &= \begin{bmatrix} \cdots & \cdots \\ -(L_2^{-t} L_2^{-1}) C^t & L_2^{-t} L_2^{-1} \end{bmatrix}. \end{aligned} \tag{4.97}$$

Note that only the last r' rows of $(-Z+I)$ are shown in equation 4.97 because only these r' rows are required to compute s^b. Moreover, note that the matrix $Y_1 = L_2^{-1}C^t$ does not require evaluation. Only $Y_3 = L_2^{-1}$ must be determined (from $L_2 Y_3 = \mathrm{I}$) because $L_2^{-t} = (L_2^{-1})^t$.

The computation of the clock schedule $\hat{s}$ in algorithm CSD consists of a total of:

$$N_3(r,\ k) = \frac{1}{2}r^3 + \frac{1}{3}(3k+4)r^2 + \frac{1}{2}r - \frac{1}{6}. \tag{4.98}$$

These multiplications are distributed among the following tasks:

Task	← Number multiplications
a. Computing the Cholesky decomposition L_2 of N	← $\frac{1}{6}r^3$.

A numerical example is provided in Appendix C to illustrate algorithm CSD.

4.5.2 Summary of the Proposed Algorithms

This section concludes with a brief synopsis of the run time and memory requirements of the three algorithms for solving problem QP-3 described in the previous subsections. To summarize the results, each of the three algorithms, LMCS-1, LMCS-2, and CSD, requires $O(r^3)$ floating-point multiplicative operations and $O(r^2)$ floating-point storage units. The numerical constant of the leading terms in the polynomial expressions for both the run time and memory complexity is a function of the ratio $k = p/r$, which is the ratio of the number of local data paths to the number of registers in a circuit.

To gain further insight into the proposed algorithms, the numerical constants of the leading terms in the polynomial run time complexity expressions are plotted versus k in Figure 4.10. Similarly, the numerical constants of the leading terms in the polynomial memory complexity expressions are plotted versus k in Figure 4.11. Note that algorithm CSD outperforms both of the other two LMCS algorithms where the superiority of algorithm CSD is particularly evident with respect to the speed of execution. Thus, algorithm CSD is the algorithm of choice for solving problem QP-3 as introduced in Section 5.4.3.

4.5.3 Unconstrained Basis Skews

Consider again the example circuit C_1 introduced in Section 4.3 (the graph of C_1 is shown in Figure 4.7). A modified version of C_1 with one additional edge—the edge e_6—is shown in Figure 4.12. Also shown with thicker edges in Figure 4.12 is a spanning tree for the modified circuit C_1. Note that the basis edge e_6 does *not* belong to any of the fundamental cycles of the circuit depicted in Figure 4.12. In fact, the edge e_6 does not belong to any cycles of the circuit in Figure 4.12 at all. Such basis edges that do not belong to any cycles are called **isolated** while the rest of the basis edges are called **main**. Note that any isolated edge must necessarily by definition be a basis edge.[23]

Theoretically, a circuit with r registers (the vertices in the circuit graph) may have any number n_i of isolated basis edges

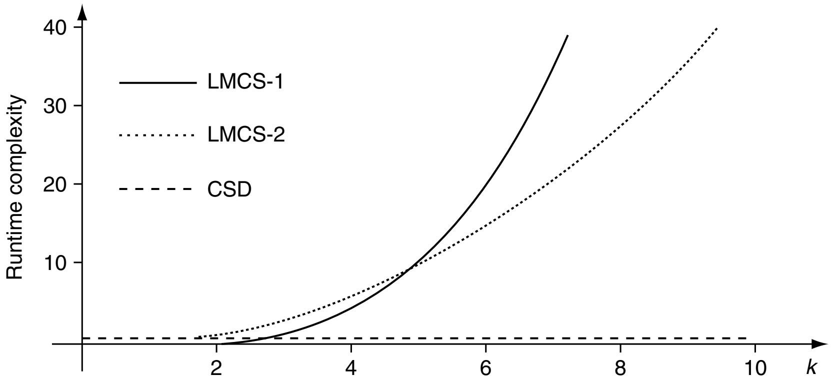

FIGURE 4.10 The Numerical Constants (as Functions of $k = p/r$) of the Term r^3. These are in the run time complexity expressions for the algorithms LMCS-1, LMCS-2, and CSD, respectively.

[23] A chord edge is already a part of a cycle and cannot be isolated.

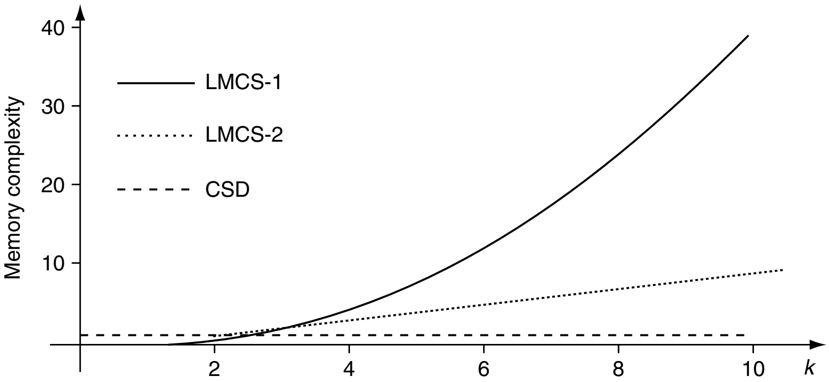

FIGURE 4.11 The Numerical Constants (as Functions of $k = p/r$) of the Term r^2. These are in the memory complexity expressions for the algorithms LMCS-1, LMCS-2, and CSD, respectively.

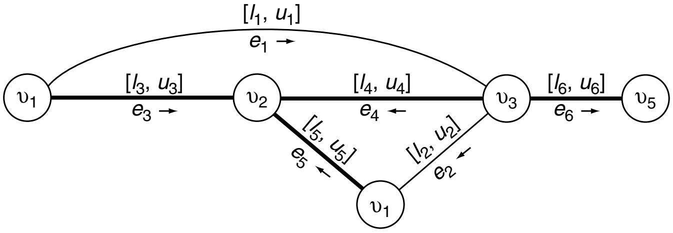

FIGURE 4.12 Modified Example Circuit C_1 to Include an Additional Edge e_6. (C_1 was originally introduced in Section 4.3 and illustrated in Figure 4.7.)

where n_i ranges from zero to $r - 1 = n_b$. A circuit with $n_i = n_b = r - 1$ isolated basis edges does not have any cycles whatsoever—all edges of such circuits are basis edges, and there are no chord edges to complete a cycle. A simple example of such a circuit is a shift register.

Note that since isolated edges do not belong to a cycle, the clock skews on these edges are linearly independent of any other clock skews in the circuit. Intuitively, the clock skew of an isolated edge can be assigned to be any value without contradicting the linear dependencies among the skews in a circuit. Observe, for example, equation 4.31 written for the modified circuit C_1 shown in Figure 4.12:

$$Bs = \begin{bmatrix} 1 & 0 & -1 & 1 & 0 & 0 \\ 0 & 1 & 0 & -1 & 1 & 0 \end{bmatrix} \begin{bmatrix} s_1 \\ s_2 \\ s_3 \\ s_4 \\ s_5 \\ s_6 \end{bmatrix} = 0. \qquad (4.100)$$

All of the elements in the sixth column of B are zeros. Therefore, if s_1 through s_5 are such that equation 4.100 is satisfied, the choice of s_6 does not invalidate this equation.

This fact can be exploited in the mathematical solution of problem QP-1 to decrease the number of variables, thereby decreasing the run time and memory requirements. The only requirement is that the basis skews (the edges) must be enumerated such that the isolated skews are last. In other words, the clock skew vector for equation 4.28 becomes:

$$s = \begin{bmatrix} s^c \\ s^b \\ s^i \end{bmatrix} = \Big[\underbrace{\overbrace{s_1 \ldots s_{n_c}}^{n_c}}_{\text{Chords}} \overbrace{\underbrace{\overbrace{s_{n_c} + 1 \ldots s_p - n_i}^{n_b - n_i}}_{\text{Main basis}} \underbrace{\overbrace{s_{p-n_i} + 1 \ldots s_p}^{n_i}}_{\text{Isolated basis}}}^{\text{Basis with } n_b \text{ elements}} \Big]^t, \qquad (4.101)$$

where s^b stands for the main basis, and the isolated basis is denoted by s^i. With this specific choice of clock skew enumeration, the B matrix in equation 4.31 becomes:

$$B = [\, B_1 \quad 0 \,], \qquad (4.102)$$

where 0 in equation 4.102 is a zero matrix of dimension $n_c \times n_i$.

With this notation, it is straightforward to show that the matrix M in equation 4.62 becomes:

$$M = BB^t = B_1 B_1^t \qquad (4.103)$$

The solution to problem QP-1 equations 4.63 and 4.64 is as follows:

$$\hat{\lambda} = 2M^{-1}Bg = 2M^{-1}[\, B_1 \quad 0 \,] \begin{bmatrix} g^c \\ g^b \\ g^i \end{bmatrix} = 2M^{-1}B_1 \begin{bmatrix} g^c \\ g^b \end{bmatrix}. \qquad (4.104)$$

$$\hat{s} = g - \left(B^t M^{-1} B\right) g = \begin{bmatrix} (I - B_1 M^{-1} B_1^t) \quad \begin{bmatrix} g^c \\ g^b \end{bmatrix} \\ \\ g^i \end{bmatrix} \qquad (4.105)$$

As can be observed in equations 4.104 and 4.105, the following is true:

1. The choice of the objective isolated basis skews g^i has *no* effect on either the Lagrange multipliers of equation 4.104 or the chords and main skew basis from the equation 4.105 solution.
2. The final solution for the clock skews s^i in the isolated basis edges corresponds precisely to the objective skew values g^i for these edges.

Therefore, the isolated basis edges can be completely excluded from consideration when solving problem QP-1. Equations 4.104 and 4.105 demonstrate that the final clock skew values of these edges can be chosen arbitrarily provided these values satisfy the permissible range requirements.

4.5.4 *I/O* Registers and Target Delays

The clock skew scheduling methodology discussed in Sections 4.3 and 4.4 is based on the assumption that complete connectivity and timing information is available for all local data paths in a circuit. This condition may, however, not be realistic. Consider, for example, the input and output registers (also called the *I/O* registers) in a VLSI system. Some *I/O* registers are illustrated in Figure 4.13, where the registers R_1 and R_5 are an input register and an output register, respectively, of the circuit *C*. The register R_3 shown in Figure 4.13 is an internal register because all of the other registers to which R_3 is connected (via local data paths) are inside the circuit *C*.

The timing of the *I/O* registers is less flexible than the timing of the internal registers. Consider, for example, the local data path $R_6 \rightsquigarrow R_1$ shown in Figure 4.13. The register R_6 is outside the circuit *C* that contains the registers R_1 through R_5. It is possible to apply a clock schedule to *S* that specifies a clock delay t_{cd}^1 to the register R_1. However, the timing information for the local data path $R_6 \rightsquigarrow R_1$ is *not* considered when scheduling the clock signal delays to the registers in *C* (including t_{cd}^1). Therefore, a timing violation may occur on the local data path $R_6 \rightsquigarrow R_1$ illustrated in Figure 4.13.

One strategy to overcome this difficulty is to include in the clock scheduling process the timing information of those local data paths that cross the boundaries of the circuit *C*. This approach does not change the nature of the clock scheduling algorithm but rather only the number of timing constraints. Such an optimization scenario, however, is difficult to conceive due to the many instances in which *C* may be used. Therefore, a preferable approach is to set the clock signal delay to the *I/O* registers (such as t_{cd}^1 to R_1) to a specific value with respect to the clock source (shown as the clock pin in Figure 4.13). If this value is specified, all of the necessary timing information is available to avoid any timing violations of the local data paths, such as the path $R_6 \rightsquigarrow R_1$ shown in Figure 4.13. Equivalently, a group of registers (e.g., the *I/O* registers) may be defined, which require that the clock signal be delivered to all of the registers in such a group with the same delay. Application-specific integrated circuits (ASICs) and intellectual property (IP) blocks are good examples of circuits for which the aforementioned strategy may be useful.

Given the difficulty in knowing *a priori* all timing contexts of an integrated circuit, a preferred solution may be to require that all *I/O* registers are clocked at the same time (zero skew). More specifically, all possible explicit clock delay requirements for registers in the circuit fall into one of the following categories:

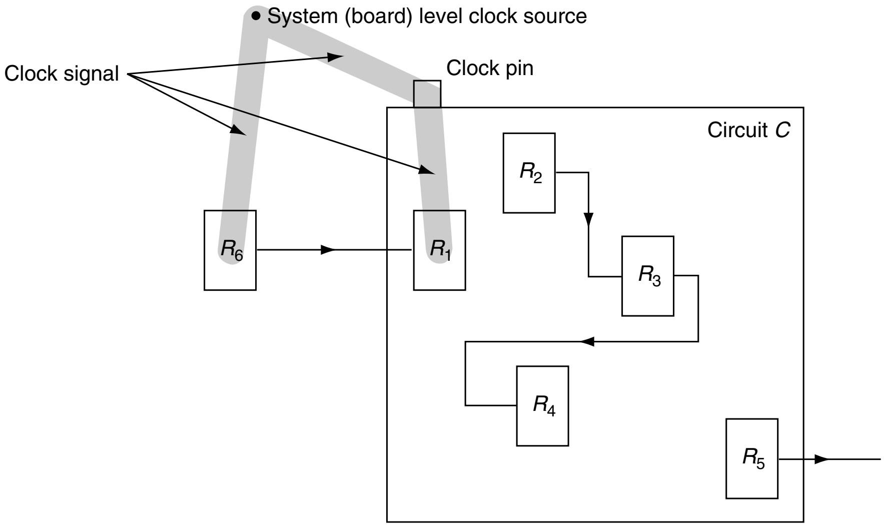

FIGURE 4.13 *I/O* Registers in a VLSI Integrated Circuit. Note that the *I/O* registers form part of the local data paths between the inside of the circuit and the outside of the circuit.

1. **Zero skew island**: The island refers to a group of registers with equal delays.
2. **Target delays**: $t_{cd}^{k_1} = \delta_{k_1}, \ldots, t_{cd}^{k_\alpha} = \delta_{k_\alpha}$, where $k_\alpha \leq r$ and $\delta_{k_1} \ldots \delta_{k_\alpha}$ are explicitly specified clock signal delay constants.
3. **Target skews**: $s_{j1} = \sigma_{j1}, \ldots, s_{j\beta} = \sigma_{j\beta}$, where $j_\beta < n_b$ and $\sigma_{j1} \ldots \sigma_{j\beta}$ are explicitly specified clock skew constants.

Zero skew islands can be satisfied by collapsing the corresponding graph vertices into a single vertex while eliminating all edges among vertices in the island. Note that in this case, it must be verified that zero skew is in the permissible range of each in-island path.[24] Alternatively, the target delays are converted to target skews (category 3 above) for sequentially adjacent pairs or by adding a "fake" edge. Thus, an algorithm to handle only target skews is necessary.

Note first that target values for only $n_f \leq n_b$ skews can be independently specified. As n_f approaches n_b, the freedom to vary all skews decreases, and it may become impossible to determine any feasible s. Given $n_f \leq n_b$, (a) the basis can always be chosen to contain all target skews by using a spanning tree algorithm with edge swapping and (b) the edge enumeration can be accomplished such that the target skews appear last in the basis. The problem is now similar to equation 4.51 except for the change of the circuit kernel equation:

$$C = [\,C_1 \quad C_2\,] \Rightarrow Bs = [\,I \quad C_1 \quad C_2\,] \begin{bmatrix} \hat{s}^c \\ \hat{s}^b \\ \sigma \end{bmatrix} \Rightarrow \hat{B}\hat{s} + C_2\sigma = 0, \tag{4.106}$$

where $\hat{B} = [\,I \quad C_1\,]$, $\hat{s} = \left[\hat{s}^c / \hat{s}^b\right]$, $\hat{s}^c = s^c$, and $\hat{s}^b$ is s^c with the last n_f elements removed. The matrix C_2 in equation 4.106 consists of the last n_f columns of C, while the target skew vector σ is an n_f-element vector of target skews whose elements are ordered in the order of the target edges. The linear system of equation 4.60 becomes:

$$\left| \begin{array}{l} 2\hat{s} + \hat{B}^t \hat{m} = 2\hat{g} \\ \hat{B}\hat{s} + C_2\sigma = 0 \end{array} \right. \Rightarrow \begin{bmatrix} 2I & \hat{B}^t \\ \hat{B} & 0 \end{bmatrix} \begin{bmatrix} \hat{s} \\ \hat{m} \end{bmatrix} = \begin{bmatrix} 2\hat{g} \\ -C_2\sigma \end{bmatrix}, \tag{4.107}$$

with solution:

$$\begin{aligned} \hat{m}^* &= 2\hat{M}^{-1}(\hat{B}\hat{g} + C_2\sigma) \\ \hat{s}^* &= (I - \hat{B}^t \hat{M}^{-1} \hat{B})\hat{g} - \hat{B}^t \hat{M}^{-1} C_2 \sigma. \end{aligned} \tag{4.108}$$

4.6 Experimental Results

A quadratic programming formulation of the clock skew scheduling problem was developed in Section 4.3. This QP problem can be efficiently solved by applying the mathematical procedures developed in Section 4.4. Algorithm CSD as applied to the QP problem described in Section 5.4.3 has been implemented as a C + + program and applied to ISCAS'89 and ISCAS'93 benchmark circuits as well as to industrial circuits (IC1, IC2, and IC3). Results from the application of this computer program are described in this section. Certain characteristics of the implementation are initially described in Section 4.6.1. Graphical illustrations of representative results are shown in Section 4.6.2.

4.6.1 Description of Computer Implementation

The results described in this section are obtained from the execution of a computer implementation of algorithm CSD introduced in Section 4.5. Without unnecessary details, this computer implementation consists of the sequential execution of the following major steps:

Step 1. The circuit timing and connectivity data are read in and compressed and stored in a binary database. The database can be used for fast data access in subsequent algorithmic applications of the same circuit. Furthermore, the data size of the database permits significant space and time savings if the circuit data are exchanged.

Step 2. The circuit data are examined, and the circuit graph is built according to the graph model described in Section 4.2.2. An adjacency lists data structure (Cormen *et al.*, 1989) stored in memory and is used for fast access of the circuit graph data.

Step 3. The circuit graph is transformed according to the transformation rules described in Section 4.2.2 and illustrated in Figure 4.5. Within this step, the permissible range bounds are calculated and directions for the graph edges are determined.

Step 4. The circuit graph is traversed to determine the edges in the skew basis s^b and in the skew chords s^c. This graph traversal is accomplished by using a depth-first search (West, 1996; Reingold *et al.*, 1997; Cormen *et al.*, 1989) algorithm—the classical traversal algorithm of choice for building a spanning tree. Three additional important tasks are accomplished during the traversal step:

1. For circuits with more than one connected disjoint subcircuit, these connected disjoint parts are identified and marked. This step does not incur any computational overhead—it is an inherent feature of the depth-first search graph traversal algorithm to separate a graph into disjoint pieces (if any).

[24] Normally, this would be the case. However, in an aggressive circuit design with a short clock period, it may so happen that zero skew is designed to be out of the permissible range, most likely creating a setup time violation. In these circuits, negative skew is used to increase the overall system-wide clock frequency, thereby removing the setup violation.

2. The skew basis and chords of each disjoint connected circuit subgraph are identified and enumerated.
3. The circuit connectivity matrix B (actually, only the nonidentity matrix C portion of B) is derived for each disjoint connected circuit subgraph. Recall that C contains only elements from the set $\{-1, 0, 1\}$, thus permitting an efficient bit compression scheme to be used to store C in a small amount of memory.

Step 5. Using C, the matrix N is computed as described by equation 4.81.

Step 6. The Cholesky factorization L_2 of N is calculated as described by equation 4.82. Simple, yet efficient, algorithms for computing the Cholesky factorization have long been known and can be found in multiple sources (Farebrother, 1988; Lawson and Hanson, 1974; Golub and Loan, 1996; Forsythe and Moler, 1967; Cormen *et al.*, 1989). Recall that the matrix N is guaranteed to be positive-definite by construction. Therefore, the real (no complex numbers) Cholesky decomposition is guaranteed to exist.

Step 7. The objective clock skews are chosen at the center of the permissible range for all local data paths. The actual clock skews (a consistent clock schedule) are calculated as described by equation 4.97 and as illustrated in Figure 4.9. At this point, each clock skew is verified against the respective permissible range. If all skews are in the respective permissible range bounds, the algorithm concludes. Otherwise, the objective clock skews are modified, and the calculation is repeated again. Only the calculation described in this step must be repeated since all matrices have now been computed.

Different objective clock schedule modification strategies can be used. The most effective strategy to modify the objective clock schedule—resulting in the fastest convergence toward a feasible schedule—is as follows. All objective clock skews are slightly increased or decreased depending on whether the respective calculated clock skew is larger or smaller than the objective one. Using this strategy, a feasible solution is typically reached within a few iterations.

Step 8. The actual clock delays to the individual registers are calculated by traversing the spanning tree (basis) of the circuit graph. The clock delay of the first register is arbitrarily chosen (zero in this implementation). As the spanning tree is traversed, additional vertices adjacent to the current vertex are visited. The clock delay of the visited vertex is determined trivially because both the clock delay of the current vertex and the clock skew of the edge between the current and visited vertex are known.

The results of the application of the algorithm to these circuits are summarized in Table 4.3. For each circuit, the following data is listed—the circuit name in column **1**; the number of disjoint subgraphs in column **2**; and the number of vertices, edges, chords (cycles), main and isolated basis, and target clock period in nanoseconds in columns **3** through **8**, respectively. The number of iterations to reach a solution is listed in column **9**. The average value of ε in equation 4.51 (i.e., $\sqrt{\varepsilon/p}$) is listed in column **10**. The run time in minutes for the mathematical portion of the program is shown in column **11** for a 170-MHz Sun Ultra 1 workstation.

4.6.2 Graphical Illustrations of Results

The application of the computer implementation described in Section 4.6.1 to many of the circuits listed in Table 4.3 is graphically illustrated. Immediately following are illustrations of two circuits shown in Figures 4.14 and 4.15, respectively. Three histograms for a circuit are shown in each graphical illustration. These histograms are as follows:

(A) The distribution of the zero clock skews in the permissible range for the clock period listed in Table 4.3 is illustrated in Figures 4.14(A) and 4.15(A).

(B) The distribution of the nonzero clock skews in the permissible range after one iteration of problem QP-2—as described in Step 7 in Section 4.6.1—is shown in Figures 4.14(B) and 4.15(B). Note that there are frequent lower bound and upper bound violations of the permissible range. These violations are represented by the dark leftmost and rightmost regions, respectively, where the number of violations is also indicated.

(C) The final distribution of the nonzero clock skews within the permissible range—no timing violations—is illustrated in Figures 4.14(C) and 4.15(C). There is a noticeable improvement because most clock skews are concentrated around the center of the permissible range. The majority of the clock skews are within 10% of the safest clock skew value at the center of the respective permissible range of each local data path.

The computer algorithms used to solve the QP problems are numerically exemplified in this appendix for the circuit example C_1 introduced in Section 4.3. The algorithms LMCS-1, LMCS-2, and CSD—introduced in Section 4.5—are illustrated in Appendices A, B, and C, respectively. Note that in all cases, the same final clock schedule is achieved.

Appendix A: Algorithm LMCS-1

Algorithm LMCS-1, originally introduced in Section 4.5, is illustrated numerically in this part of the appendix. Consider the circuit example C_1 introduced in Section 4.3; the corresponding circuit graph and spanning tree are shown in Figures 4.7 and 4.8(A), respectively. The matrices B, M, and L_1 in the Cholesky decomposition of M are as follows:

where the vector of the objective clock skews $g = \frac{1}{4}[1 \quad -2 \quad 5 \quad -11 \quad 1]^t$ is as specified in column four of Table 4.2. The lower triangular system:

$$L_1\xi = \frac{1}{\sqrt{3}}\begin{bmatrix}3 & 0\\ -1 & 2\sqrt{2}\end{bmatrix}\begin{bmatrix}\xi_1\\ \xi_2\end{bmatrix} = 2Bg = \begin{bmatrix}-15/2\\ 5\end{bmatrix}, \tag{4.111}$$

is solved first, yielding (note the order of elimination of unknowns):

$$\xi_1 = -\frac{15}{2\sqrt{3}}, \text{ then } \xi_2 = 5 + \frac{\sqrt{3}}{3}\xi_1 = \frac{5\sqrt{3}}{4\sqrt{2}}. \tag{4.112}$$

Finally, the upper triangular system:

$$L_1^t\lambda = \frac{1}{\sqrt{3}}\begin{bmatrix}3 & -1\\ 0 & 2\sqrt{2}\end{bmatrix}\begin{bmatrix}\lambda_1\\ \lambda_2\end{bmatrix} = \begin{bmatrix}\xi_1\\ \xi_2\end{bmatrix} = \frac{5\sqrt{3}}{2}\begin{bmatrix}-1\\ \sqrt{2}/4\end{bmatrix}, \tag{4.113}$$

is solved through back substitution (note the order of elimination of λ_1 and λ_2) to find the Lagrange multipliers:

$$\lambda_2 = \frac{15}{16}, \text{ then } \lambda_1 = \frac{1}{\sqrt{3}}\left(-\frac{5\sqrt{3}}{2} + \frac{\sqrt{3}}{3}\lambda_2\right) = -\frac{35}{16}. \tag{4.114}$$

The clock skew schedule s is determined from the first row of equation 4.59:

$$\begin{aligned} s = \begin{bmatrix}s_1\\ s_2\\ s_3\\ s_4\\ s_5\end{bmatrix} &= -\frac{1}{2}B^t\lambda + g = \frac{1}{32}\left(\begin{bmatrix}35\\ -15\\ -35\\ 50\\ 15\end{bmatrix} + \begin{bmatrix}8\\ -16\\ 40\\ -88\\ 8\end{bmatrix}\right) \\ &= \frac{1}{32}\begin{bmatrix}43\\ -31\\ 5\\ -38\\ -7\end{bmatrix}. \end{aligned} \tag{4.115}$$

The clock delays t_{cd} corresponding to this schedule are determined from equations 4.39 and 4.40:

$$\begin{aligned} s^b = \begin{bmatrix}t_{cd}^1 - t_{cd}^2\\ t_{cd}^3 - t_{cd}^2\\ t_{cd}^4 - t_{cd}^2\end{bmatrix} &= \begin{bmatrix}1 & -1 & 0 & 0\\ 0 & -1 & 1 & 0\\ 0 & -1 & 0 & 1\end{bmatrix}\begin{bmatrix}t_{cd}^1\\ t_{cd}^2\\ t_{cd}^3\\ t_{cd}^4\end{bmatrix} \\ &= \frac{1}{32}\begin{bmatrix}5\\ -38\\ -7\end{bmatrix} \Rightarrow \begin{bmatrix}t_{cd}^1\\ t_{cd}^2\\ t_{cd}^3\\ t_{cd}^4\end{bmatrix} = \frac{1}{32}\begin{bmatrix}43\\ 38\\ 0\\ 31\end{bmatrix}. \end{aligned} \tag{4.116}$$

Note that the solution given by equation 4.116 corresponds precisely to the solution described by equation 4.21. As a matter of fact, the clock schedule in the latter equation, 4.21, is obtained by applying algorithm LMCS-1 to the circuit C_1.

Appendix B: Algorithm LMCS-2

To illustrate algorithm LMCS-2 (introduced in Section 4.5), consider again the circuit example C_1 introduced in Section 4.3; the corresponding circuit graph and spanning tree are shown in Figures 4.7 and 4.8(A), respectively. The matrices $N = I + C^tC$, L_2, and X, respectively, in equation 4.83 are as follows:

$$\begin{aligned} N = L_2L_2^t &= \begin{bmatrix}2 & -1 & 0\\ -1 & 3 & -1\\ 0 & -1 & 2\end{bmatrix}, \\ L_2 &= \frac{1}{\sqrt{2}}\begin{bmatrix}2 & 0 & 0\\ -1 & \sqrt{5} & 0\\ 0 & -\frac{2}{\sqrt{5}} & -\frac{4}{\sqrt{5}}\end{bmatrix}, \\ \text{and } X &= \frac{1}{2\sqrt{10}}\begin{bmatrix}-2\sqrt{5} & 0\\ 2 & -4\\ 1 & 3\end{bmatrix}. \end{aligned} \tag{4.117}$$

The matrix inverse $M^{-1} = I - CN^{-1}C^t = I - X^tX$ and the Lagrange multipliers $\hat{\lambda}$, respectively, are as written here:

$$\begin{aligned} M^{-1} &= I - X^tX = \frac{1}{8}\begin{bmatrix}3 & 1\\ 1 & 3\end{bmatrix}, \\ \hat{\lambda} = M^{-1}(2Bg) &= \begin{bmatrix}-15/2\\ 5\end{bmatrix} = \frac{1}{16}\begin{bmatrix}-35\\ 15\end{bmatrix}. \end{aligned} \tag{4.118}$$

The values of λ_1 and λ_2 given by equation 4.118 are the same as derived in equations 4.114, and the clock schedule is determined in the same way as described by equations 4.115 and 4.116.

Appendix C: Algorithm CSD

Algorithm CSD was introduced in Section 4.5. To illustrate algorithm CSD, consider again the small circuit example C_1 introduced in Section 4.3; the corresponding circuit graph and spanning tree are shown in Figures 4.7 and 4.8(A), respectively. The matrix N and the Cholesky decomposition L_2 of N are as described by equation 4.117. The matrices $Y_3 = L_2^{-1}$, described by equation 4.94, and $L_2^{-t}L_2^{-1}$, are the following, respectively:

$$\begin{aligned} Y_3 = L_2^{-1} &= \frac{1}{2\sqrt{10}}\begin{bmatrix}\frac{2}{\sqrt{5}} & 0 & 0\\ 2 & 4 & 0\\ 1 & 2 & 5\end{bmatrix}, \\ L_2^{-t}L_2^{-1} &= \frac{1}{8}\begin{bmatrix}5 & 2 & 1\\ 2 & 4 & 2\\ 1 & 2 & 5\end{bmatrix}. \end{aligned} \tag{4.119}$$

The matrix $(-Z+I)$ is written as:

$$-Z+I=\begin{bmatrix} \cdots & \cdots \\ \frac{1}{8}\begin{bmatrix} -3 & -1 \\ 2 & -2 \\ 1 & 3 \end{bmatrix} & \frac{1}{8}\begin{bmatrix} -5 & -2 & -1 \\ -2 & -4 & -2 \\ -1 & -2 & -5 \end{bmatrix} \end{bmatrix}. \quad (4.120)$$

Therefore, the clock schedule basis s^b is the following:

$$s^b=\frac{1}{8}\begin{bmatrix} 3 & 1 & 5 & 2 & 1 \\ -2 & 2 & 2 & 4 & 2 \\ -1 & -3 & 1 & 2 & 5 \end{bmatrix}\left(\frac{1}{4}\begin{bmatrix} 1 \\ -2 \\ 5 \\ -11 \\ 1 \end{bmatrix}\right)=\frac{1}{32}\begin{bmatrix} 5 \\ -38 \\ -7 \end{bmatrix}. \quad (4.121)$$

Trends in Low-Power VLSI Design

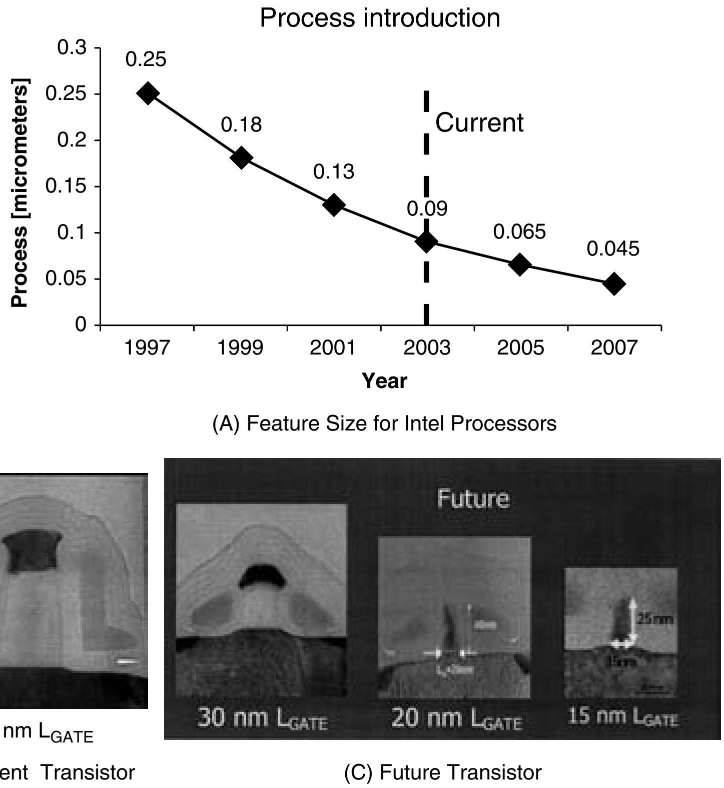
5.1 Introduction

As advances in lithography and fabrication of the N-type metal oxide superconductor (NMOS) technology became possible in the 1970s, the bipolar digital logic, transistor-transistor logic (TTL) lost the battle in the digital design world for exactly the same reasons that caused older technologies, such as the vacuum tube technology, to retire. Circuits implemented in the NMOS technology outperformed the corresponding TTL circuits in terms of power dissipation. One of the main aspects of power consumption is that it puts an upper limit on the number of gates that can be reliably integrated on a single package for any technology. As technology advanced, chips grew, and it was possible to integrate more functions into one chip. Just as for TTL, newer technology, called CMOS, threatened to replace NMOS in the 1980s because CMOS proved to consume even less power. With further advances in technology and fabrication, the integration densities and the rate at which chips operate have increased drastically, causing power consumption to be of primary concern. In addition, the new requirements set by device portability, reliability, and costs have helped in alleviating the power consumption threat in CMOS circuits. Because the power problem is getting more concerning, very large-scale integrated circuit (VLSI) designers need to develop new efficient techniques to reduce the power dissipation in current and future technologies, a task that is full of challenges but yet exciting to explore.

5.2 Importance of Low-Power CMOS Design

With advances in CMOS technology, the potential packing densities increase as the feature size of the MOS devices shrinks, as shown in Figure 5.1. These increases and decreases validate what Gordon Moore once said in the 1960s: the number of transistors that can be integrated on a single die would grow exponentially with time (Moore, 1965). The example that amazingly proved his visionary prediction is best illustrated by tracking the historical evolution of integrated circuit (IC) design in the company he founded in 1972, Intel, and by using the trends in memory evolution. Such observations are evident in Figure 5.2. Figure 5.2(A) shows the trend in the IC logic complexity evolution for Intel processors in the last two decades, whereas Figure 5.2(B) shows the memory integration density as a function of time.



(A) Feature Size for Intel Processors

(B) Current Transistor

(C) Future Transistor

FIGURE 5.1 Packing Density and Feature Size (A) The curve shows the past, current, and future trends for the feature size of the Intel Processes. (B) This image shows a transistor laid out in the 0.09 micrometer or 90 nanometer technology. The gate for that transistor is 50nm. (C) The transistor for future processors is shown here. Courtesy of Intel Corporation.

This increase in the number of transistors per package allowed more functions to be integrated and increased the total logic density of a chip. For example, Figure 5.3(A) indicates that the logic density for the Intel microprocessors doubles every process generation. At the same time, the frequency of operation has dramatically increased due to the device scaling, Figure 5.3(B) shows the introduction of performance boosting techniques, such as pipelining, super-pipelining, and parallel architectures. This increase in operating frequency was driven by the need for fast digital systems realizing powerful personal workstations, sophisticated computer graphics, and multimedia capabilities, such as real-time speech recognition and real-time video (Chandrakasan *et al.*, 1992). When CMOS technology was introduced, it was believed that the power consumption problem was solved. The major concerns of the VLSI designer were mainly speed, cost, and reliability; power consideration was mostly of secondary importance (Pedram, 1995). But as major concerns were being met, the power dissipated in a chip has increased from one generation to another. Figure 5.4 shows the power dissipation of the Intel family of microprocessors.

Figure 5.5 shows some projections for future processors if power continues to dissipate at the same rate. The figure also shows the power density behavior during the last two decades. With the current processors, we have reached the power density of a hot plate. Without limiting power dissipation, we will someday have nuclear reactor-equivalent power dissipated in chips we use at home or in our mobile devices!

Such observations are in contradiction with the scaling theory. VLSI technology scaling has evolved at an amazingly fast pace during the last 30 years; the minimum device size keeps shrinking by a factor $k = 0.7$ per technology generation. The basic scaling theory, known as **constant field scaling** mandates the synergistic scaling of geometric features and silicon doping levels to maintain a constant field across the gate oxide of the MOS transistor (Benini *et al.*, 2001; Panasonic, 2000). According to the constant field scaling theory, power dissipation scales as k^2 and power density (i.e., power dissipated per unit area) remains constant while speed increases as k. Such contradiction between the theory and conclusion from Figure 5.4 and Figure 5.5 has two causes. First, die size has been steadily increasing with technology (Figure 5.6), causing an increase in total average power, as shown in Figure 5.4. Second, supply voltage has scaled much more slowly than device size because supply voltage levels have been standardized and because faster transistor operation can be obtained for higher supply voltage levels.

Hence, this large amount of power dissipation is one of the main motivations for VLSI designers to develop new techniques to reduce the power consumed inside chips; power

is being given comparable weight to area and speed considerations (Najm, 1994). Several important factors have also contributed to this increased concern about power. One of these primary driving factors has been the remarkable success and growth of the personal computing device (e.g., Pass portable desktops, audio- and video-based multimedia products, etc.) and wireless communications systems (e.g., personal digital assistants, personal communicators, etc.) that demand high-speed computation and complex functionality with low-power consumption (Pedram, 1995). Unfortunately, this rapid development in VLSI has not been reflected in developments in battery technology, and without low-power design techniques, current and future portable devices will suffer from either very short battery life or very heavy battery pack (Pedram, 1995; Najm, 1994; Athas *et al.*, 1994; Landman and Rabaey, 1995; Tsul *et al.*, 1995; Chang and Pedram, 1997; Bajwa *et al.*, 1997).

It is clear that in the absence of low-power design techniques, portable and handheld products would suffer from a very short battery life, and packing and cooling them would be very difficult (Tsui *et al.*, 1995; Ko *et al.*, 1995). These factors lead to an unavoidable increase in the cost of the product, as shown in Figure 5.7. In addition, reliability is strongly affected

by power consumption. Usually, increased power dissipation implies high temperature operation, which, in turn, may induce several failure mechanisms in the system (Landman and Rabaey; 1995; Chang and Pedram, 1997; Bajwa *et al.*, 1997).

5.3 Sources of Power Consumption in CMOS

Two types of power consumption exist for digital CMOS. The first, the **dynamic power component,** may be thought of as useful because it establishes information by charging and discharging signal lines; the second type, consisting of **short-circuit** and **static power components**, is waste and comes from short-circuit and leakage currents that flow directly from the power supply to ground. Figure 5.8 shows the relative behavior of these power components with respect to the input switching activity for an inverter. The following subsections introduce the different power components and give their parametric equations. Much of this material can be found in (Smith, 1997; Rabaey, 1996; Weste and Eshraghian, 1993; Kang and Leblebici, 1999).

5.3.1 Dynamic Power Dissipation

The **dynamic power dissipation** is the power required for the circuit to perform its anticipated tasks. In other words, it is the power needed for charging and discharging all nodes in a CMOS circuit. This power is only consumed when the circuit input signals change. In CMOS circuits, the dyanmic power dominates the total power dissipation. Such characteristic is greatly affected by current processes or the deep sub-micron processes (DSM), for which the ratio of leakage power to dynamic power is increasing. More details about this issue are presented in Subsection 5.3.3. Dynamic power dissipation is illustrated in Figure 5.9 for a simple static CMOS inverter. When the input signal falls, the PMOS transistor switches on while the NMOS transistor switches off, creating a path from the supply voltage to the output capacitance, thus allowing the output load to charge up to the supply voltage. On the other hand, when the input signal rises, the opposite scenario occurs: the NMOS transistor switches on, and the PMOS transistor switches off, creating a direct path from the output load to ground and allowing the output load to discharge.

If C_L represents the total capacitance charged per cycle, then the dynamic power dissipation is as follows:

$$P_{\text{dynamic}} = C_L \times Vdd \times Vdd \times f \times \alpha, \qquad (5.1)$$

where Vdd is the supply voltage level, f is the frequency of operation, and α is the switching activity of the capacitive node C_L on each clock cycle.

Even though the above analysis is for a simple inverter, a similar approach can be followed to evaluate the dynamic power dissipation for a circuit with n nodes; in such a case, the total dynamic power dissipation is evaluated as follows:

$$P_{\text{dynamic (total)}} = Vdd \times Vdd \times f \times \left(\sum_{i=1}^{n} \alpha_i \times C_i \right), \qquad (5.2)$$

where α_i is the switching activity of node i with capacitance C_i. If C_{eff} represents the average switching capacitance per cycle, then the corresponding power dissipation equation represents the average dynamic power dissipation:

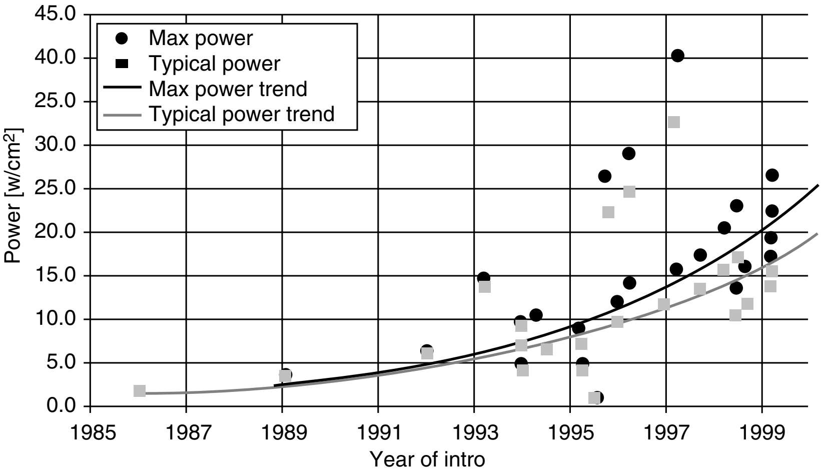

FIGURE 5.4 Power Trends for the Intel Processors Through Time. Courtesy of Intel Corporation.

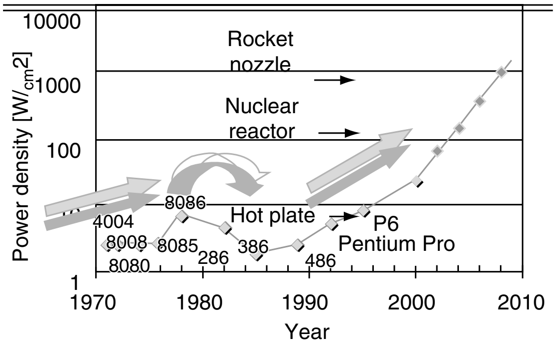

FIGURE 5.5 Power Density Trend for the Intel Processors with Future Projections

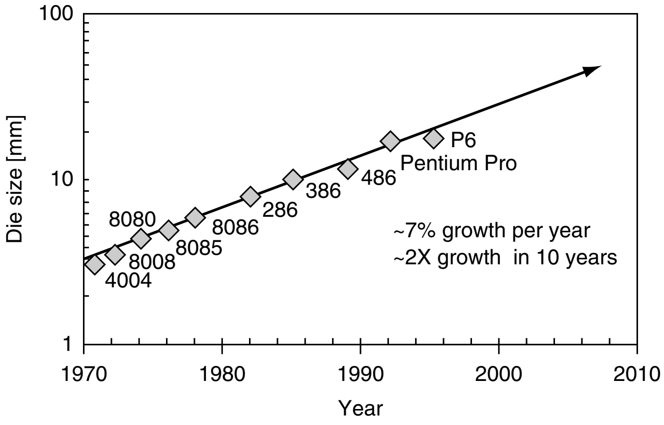

FIGURE 5.6 Die Size Increase Through Time

$$P_{\text{dynamic(average)}} = Vdd \times Vdd \times f \times C_{eff}. \tag{5.3}$$

Even though the device dimensions, and thus the device capacitances, are scaled down with newer technologies, the total integration per chip is increasing, causing the total capacitance per chip to increase. In addition, two of the main requirements of current applications are speed and real-time operation. As such, the frequency of operation is meant to increase drastically especially in the microprocessor area. In addition, supply voltage is not scaled at the same rate as the device scaling for a specific technology. From these facts, it is quite easily understandable that in scaling technology, the relative power is increasing with respect to that of predecessor technologies (refer to Figure 5.4).

As Section 5.4 and Section 5.7 explain, these equations are vital in investigating new techniques targeting lower power dissipation of CMOS chips and are important for addressing the dynamic power dissipation that is the dominant factor in the total power dissipation of CMOS circuits.

5.3.2 Short Circuit Power Dissipation

The dynamic power dissipation equation is derived usually by assuming that the inputs have zero rise and fall times, or, in other words, that the NMOS and PMOS devices are never on simultaneously. But in reality, such assumption is not valid, and input signals have nonzero rise and fall times; hence, a direct current path exists between *Vdd* and *GND* for a short period of time during input switching, in which case the PMOS and the NMOS devices are simultaneously conducting. This power component is consumed without attributing to the circuit behavior; thus, it is considered redundant.

Figure 5.10 shows the short circuit power dissipation for the case of the simple static CMOS inverter. The short circuit power dissipation can be stated as follows:

$$P_{\text{short circuit}} = I_{sc} \cdot Vdd, \tag{5.4}$$

(B) The waveform shows the function of the inverter output (out) with respect to the input (in) (C) Shown here is the circuit equivalent when the input falls and the corresponding output rises. (D) The figure illustrates the circuit equivalent when the input rises and the corresponding output falls.

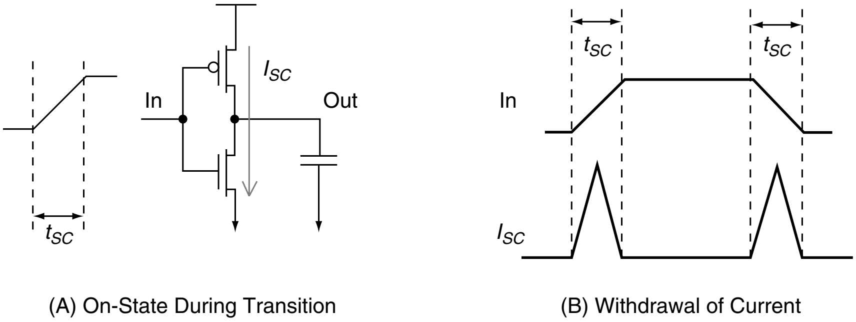

FIGURE 5.10 Short Circuit Power Dissipation. (A) The nonzero input transition time causes both transistors to be on for the duration of the transition, t_{sc}. (B) As a result, a current, i_{sc}, is withdrawn from the supply voltage.

where I_{sc} is the current leaking when both transistors are on during switching. For a system with n gates, the total short circuit power dissipation can be expressed as follows:

$$P_{\text{short circuit (total)}} = Vdd \times \sum_{i=1}^{n} \alpha_i \times I_{sc_i}. \tag{5.5}$$

5.3.3 Static Power Dissipation

Ideally, the static power consumption of static CMOS circuits is assumed to be zero, as the PMOS and the NMOS devices are never on simultaneously in steady-state operation. But in reality, the drain current through the CMOS transistor does not drop to zero once the gate voltage goes below the threshold voltage. There is, unfortunately, always a leakage current, which is primarily determined by the fabrication technology. Historically, the contribution of the static power dissipation to the overall power dissipation is in general very small and can be ignored. However, with the current technologies, for which reductions in the device threshold voltage are employed for achieving better performance, the percentage of the static power dissipation from the total power has increased as shown in Figure 5.11.

A variety of leakage currents are steadily flowing through various parts of the transistor, including a subthreshold current through the channel. Those currents are small, but they are becoming increasingly important in low-power applications. Not only do many circuits need to operate under very low current drains, but subthreshold currents are also getting relatively larger as transistor sizes shrink.

Leakage currents come from a variety of effects in the transistor (Wolfe, 2002; Wei *et al.*, 2000), as in Figure 5.12:

- The weak inversion current (also known as subthreshold current) is carried through the channel when the gate voltage is below threshold, and it flows between the source and drain of a MOS transistor. It increases exponentially with the reduction of the device threshold voltage, making it critical for low-voltage, low-power circuit design.

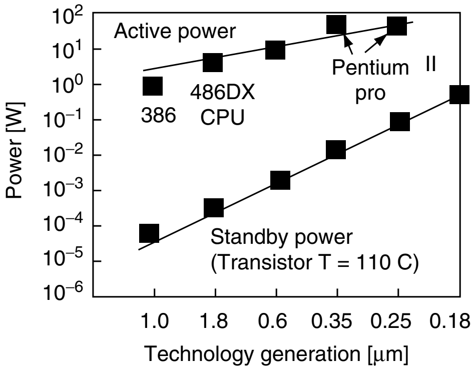

FIGURE 5.11 Static Power Evolution with Respect to Technology

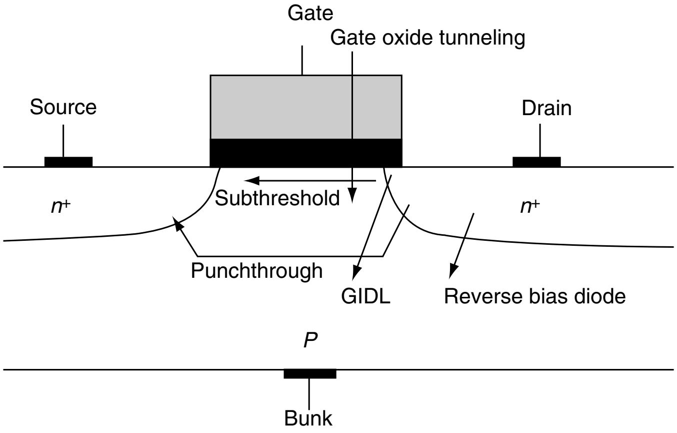

FIGURE 5.12 The Different Sources of Leakage Current in MOS Transistors

- Reverse bias *pn* junctions in the transistor, such as the one between the drain and its well, carry small reverse bias currents. Carrying these currents results from the minority carrier drift near the edge of the depletion region and the electron hole pair generation in the depletion region.

- Gate-induced drain leakage (GIDL) current exists around the electric field under the gate/drain overlap.
- Punchthrough currents flow when the source and drain depletion regions connect in the channel.
- Gate oxide tunneling currents are caused by the high electric fields in the gate.

Reverse-bias current, GIDL, punchthrough, and gate-oxide tunneling are all caused by high electric fields, and, for low-voltage circuits, they can be neglected. Only the subthreshold voltage is the dominant component of the leakage current for low-voltage, low-power circuits.

If I_{static} is the total current leaking in steady-state, then the static power dissipation component can be written as:

$$P_{\text{static}} = I_{\text{static}} \times Vdd. \tag{5.6}$$

Thus, the total amount of power consumed by a CMOS circuit can be stated as follows:

$$\begin{aligned} P_{\text{total}} &= P_{\text{dynamic}} + P_{\text{short circuit}} + P_{\text{static}} \\ &= C_L \times Vdd \times Vdd \times f \times \alpha + I_{sc} \times Vdd + I_{\text{static}} \times Vdd \\ &= Vdd(C_L \times Vdd \times f \times \alpha + I_{sc} + I_{\text{static}}) \end{aligned} \tag{5.7}$$

To develop techniques to reduce the power dissipation, the factors present in equation 5.7 need to be thoroughly analyzed.

5.4 Power Consumption Considerations

The dependence of the power consumption on many parameters allows the VLSI designer to have a large number of techniques available to reduce the power dissipation. From the equations presented in the previous section, the following parameters should be considered when designing for low power: power-supply voltage, device-threshold voltage, physical node capacitance, and switching frequency.

5.4.1 Supply Voltage Level

Equations 5.3, 5.5, 5.6, and 5.7 show that all power consumption components (static, short circuit, and dynamic) linearly depend on the **supply voltage level**, *Vdd*, except the dynamic power component. The dynamic power component is not only in quadratic relation with *Vdd*, but it is also the dominant component of the total power dissipation. As such, scaling down the supply voltage has a profound effect in reducing the total power dissipation of the whole circuit in hand (Chang and Pedram, 1997; Wei *et al.*, 2000). Indeed, reducing the supply voltage is the key to low-power operation, even after taking into account the modifications to the system architecture, which is required to maintain the computational throughput (Chandraksan *et al.*, 1992). Once applied, scaling down will result in power saving that has a global effect, experienced not only in one subcircuit or block of the chip but throughout the entire design. Because of this, designers are often willing to sacrifice increased physical capacitance or circuit activity for reduced voltage. Unfortunately, a speed penalty is paid for supply voltage reduction, with delays drastically increasing as *Vdd* approaches the threshold voltage V_t of the devices. This tends to limit the useful range of *Vdd* to a minimum of about 2 to 3 V_t (Pedram, 1995; Chandraksan *et al.*, 1992). Effectively, speed optimization techniques are applied and then the supply voltage is scaled which bring the design back to its original timing but with a lower power requirement Benini *et al.*, 2001.

5.4.2 Device Threshold Voltage

When scaling the supply voltage down, one can compensate for the speed loss by altering the **device threshold voltage**. Reducing the V_t (achieved by changing the substrate and channel dopant concentrations) allows the supply voltage to be scaled down without loss in speed. Unfortunately, such scaling leads to an exponential increase in the subthreshold leakage current (Wei *et al.*, 2000). The limit of how low the V_t can go is determined by the requirement to set adequate noise margins and control the increase in subthreshold leakage currents, as shown in Figure 5.13. The optimum V_t must be determined based on the current drives at low supply voltage operation and control of the leakage currents (Pedram, 1995). If the threshold voltage is reduced, then the whole characteristic curve moves toward the left, as Figure 5.8 illustrates. Thus for low threshold voltages, the device cannot be properly switched off (when $V_{gs} = 0\ V$) and there is significant short circuit current. The subthreshold currents can result in significant static power dissipation. Essentially, subthreshold leakage occurs due to carrier diffusion between the source and the drain when the gate-source voltage V_{gs} has exceeded the weak inversion point but is still below the threshold voltage V_t, where drift is dominant.

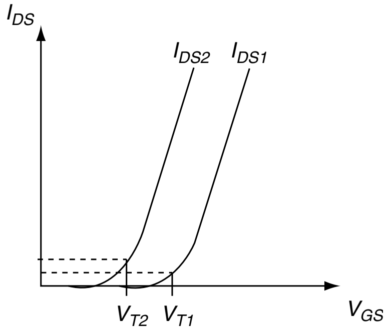

FIGURE 5.13 ($I_{DS} - V_{GS}$) Characteristic Curve for a Typical MOS Transistor. As the threshold voltage V_T decreases, the curve shifts to the left, and the subthreshold current increases.

5.4.3 Physical Capacitance

Dynamic power component is the power expended while charging and discharging the capacitive nodes. This physical capacitance is attributed to the transistor parasitic capacitance and the interconnect capacitance. Reducing these capacitive nodes could result in substantial power reductions across the whole system, as equation 53 shows. So, minimizing capacitances offers another option for minimizing power consumption. Estimating this capacitance at the behavioral or logical levels of abstraction, however, is difficult and imprecise if gate mapping into a cell library is not done (Pedram, 1995).

The capacitance load of a circuit is made of two components: intrinsic and extrinsic. **Intrinsic capacitance** refers to internal parasitic capacitances of the circuit, and they consist of drain and source to substrate and overlap capacitances. The extrinsic capacitances are the parasitic capacitances of the fan-out, driven by the circuit (normally gate and overlap capacitances) and the routing capacitances resulting from the routing between the circuit and its fanout gates (Rabaey, 1996). Accordingly, capacitances can be kept at a minimum by using less logic, smaller devices, and fewer and shorter interconnects.

5.4.4 Switching Frequency

Dynamic power dissipation is only consumed when there is switching activity at some nodes in a CMOS circuit. For example, a chip may contain an enormous amount of capacitive nodes, but if there is no switching in the circuit, then no dynamic power will be consumed (Chandraksan *et al.*, 1992). The **switching frequency**, which is $\alpha \times f$, determines how often the switching occurs. Normally, f increases with technology scaling, but for a given technology, double-edge-triggered flip-flops may be used to reduce the dynamic power dissipation of the clock distribution network, which could in turn result in significant savings in the total power dissipation. The node switching activity per cycle, α has two components: **useful data switching activity** (UDSA) and **redundant spurious switching activity** (RSSA).

The UDSA can be interpreted as the probability that a useful power consuming transition will occur during a single data period. The calculation of this term is difficult because it depends on the input switching activity, logic function implemented, and the spatial and temporal correlations among the circuit inputs. Several attempts to estimate this switching activity can be found in the literature (Najm, 1994).

For certain logic styles, however, RSSA or glitching can be an important source of signal activity. **Glitching** refers to spurious and unwanted transitions that occur before a node settles down to its final steady-state value that occurs due to partially resolved functions. Glitching often arises when paths with unbalanced propagation delays converge at the same point in the circuit. Because glitching can cause a node to make several power-consuming transitions, it should be avoided whenever possible (Pedram, 1995).

In some work, the capacitive loads and switching frequency are combined to give the switched capacitance per cycle (SCPS). Usually, optimization approaches that have a lower impact on performance, but that allow significant power savings, are those targeting the minimization of the SCPS.

5.5 Energy Versus Power

The terms **power consumption** and **energy consumption** are often interchanged. It is important to distinguish between the two especially in the context of mobile applications. Mobile systems run on the limited energy available in a battery. The energy consumed by the system determines the length of the battery life, so the reduction in the energy consumed by executing system's tasks is necessary.

Energy is a measure of the total number of joules [J] dissipated by a circuit, whereas **power** refers to the number of joules dissipated over a certain amount of time. The average power consumed by a circuit is given by:

$$P_{av} = \frac{1}{T}\int_0^T P(t)dt = \frac{V_{\text{Supply}}}{T}\int_0^T i(t)dt = I_{av} \times V_{\text{Supply}}, \qquad (5.8)$$

where P is the average power, I is the average current, and V_{supply} is the supply voltage.

Because power is the rate at which energy is consumed, the energy equation can be written as:

$$E = P \times t = V \times I \times t. \qquad (5.9)$$

The energy consumed by a circuit to perform a specific task is as follows:

$$E_s = P \times T_S = P \times \frac{N_s}{f} = P \times N_s \times \tau, \qquad (5.10)$$

where T_s is the total time needed to finish the task s. N_s is the number of clock cycles taken by the task s, f is the operating frequency, and τ is the clock period.

A battery is simply a storage component that contains a certain amount of power available for a circuit to dissipate. The power that can be drawn from a battery depends on other things besides the charge itself. Figure 5.14 shows battery discharge lines for three different discharge rates with three different values for the average current (Panasonic, 2000).

Figure 5.14 shows that the power drawn from a battery highly depends on the average current. More current means more power. So, average current should be reduced to a minimum. Energy sources, namely batteries, are more efficient

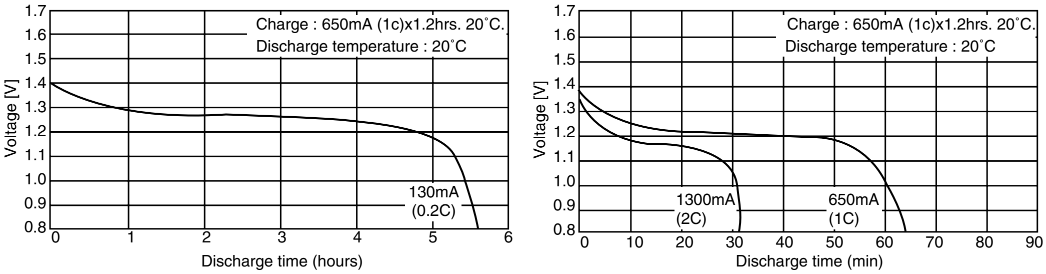

FIGURE 5.14 Indicates that the Battery Life Depends on the Amount of Average Current Discharged, Noting that the Charging Process was Identical in the Three Cases and More Current Means More Power Withdrawn; the figure shows three different average discharge currents values: 130 mA, 650 mA, and 1300 mA. The 130 mA average discharge current gave the longest discharge time of all three and the 1300 mA average discharge current gave the shortest time.

when they are discharged with current bursts instead of a steady flow.

5.6 Optimization Metrics

During the optimization process, power minimization is never the only optimization objective. Performance is always implicitly of ultimate importance in the design of any digital system. Unfortunately, meeting both requirements is very hard if not impossible. Major techniques that target one objective have side effects with respect to the other. For this reason, several metrics for joint power performance have been proposed in the past. In many designs, the power-delay product (PDP, or the energy) is an acceptable metric. Energy minimization rules outdesign choices that heavily compromise performance to reduce power consumption. When performance has priority over power consumption, the energy-delay product (EDP) can be adopted to tightly control performance degradation (Burd and Brodersen, 1996).

Alternatively, a constrained optimization approach can be taken. In this case, performance degradation is acceptable to a given *bound* that is represented by performance or timing constraints. Thus, power minimization requires optimal exploitation of the slack on performance constraints. Besides power versus performance, another key trade-off in VLSI design involves **power versus flexibility** (Benini *et al.*, 2001). Several researchers have observed that application-specific designs are characterized by orders of magnitude more power efficient than general-purpose systems programmed to perform the same computation (Nielsen *et al.*, 1994). On the other hand, flexibility (programmability) is often an indispensable requirement, and designers must strive to achieve maximum power efficiency without compromising flexibility (Benini *et al.*, 2001).

5.7 Techniques for Power Reduction

In general, power minimization targets maximum instantaneous power or average power. As stated in Section 5.5, the latter impacts battery lifetime and heat dissipation system cost, while the former constrains power grid and power supply circuit design (Benini *et al.*, 2001).

Optimizations can be achieved by facing the power problem from different perspectives: design and technology. Enhanced design capabilities mostly impact switching and short-circuit power; technology improvements, on the other hand, contribute to reductions of all three components (Benini *et al.*, 2001).

From a design perspective, circuit designers can choose from a number of options to reduce the power dissipation ranging from the highest levels of abstraction (architecture level) to the lowest levels of abstraction (physical or technology level) (Alidina *et al.*, 1994). In each level of abstraction, there exists a number of techniques that can be employed to effectively reduce the power dissipation of CMOS circuits, all of which can be obtained from the power dissipation equations mentioned in the previous section. As each technique has its own figure of merit, it usually affects one or more aspect of the system being optimized. As such, attempts are always being made to find a compromise that can effectively present a fair and reasonable solution among conflicting objectives like power dissipation and performance, where improving one generally means degrading the other!

Actually, addressing the power problem from the very early stages of design development offers enhanced opportunities to obtain significant reductions of the power budget and to avoid costly redesign steps. Power-conscious design flows must then be adopted; these require, at each level of the design hierarchy, the exploration of different alternatives as well as the availability of power estimation tools that could provide accurate feedback on the quality of each design choice (Benini and de Micheli, 1999). This section studies the various techniques that can be effectively used to reduce the power consumption during the VSLI system design cycle. The stages during the design involve the **system, architectural, logic, circuit**, and **physical levels**.

5.7.1 System Level

At the highest level of abstraction, a system is viewed as an integrated entity that consists of a hardware infrastructure executing software programs. The hardware platform mainly consists of execution units, storage units, and communication and interface networks, whereas the software part consists of application and system software. Addressing the power dissipation at this level has the greatest influence on power dissipation; as much as a 400% power savings could be achieved (Stammerman *et al.*, 2001). The effective techniques at this level include but are not limited to instruction-level optimization, hardware–software codesign, memory design techniques, dynamic power management, and variable-voltage techniques. Most of the material related to system-level optimization techniques can be found in Benini and de Micheli (1999) and (2000).

Instruction-Level Optimization

Techniques involving **instruction-level optimization** target programmable cores such as general-purpose microprocessors, DSP, and microcontrollers. In these techniques, power optimization is achieved by selecting a minimum power instruction mix for executing application software. Tiwari *et al.* (1994) describe a power dissipation reduction of up to 40% that could be achieved by rewriting code. In another work by Woo *et al.* (2001), an instruction encoding technique is used for low-power instruction fetches. The basic approach is that instruction fields of a binary program are re-encoded so that the number of bits switched from the neighboring fields of consecutive instructions is minimized; this technique allowed up to a 62% reduction in switching activities. Similar techniques can be found in Stammerman *et al.* (2001) and Choi and Chatterjee (2001). Another approach that can reduce the power dissipation of a system is devising a low-power system compiler in which high-level code is transformed into machine code characterized by its low-power consumption. The design of such a compiler requires knowledge of the hardware architecture that will execute the machine code.

Hardware–Software Codesign

Hardware–Software Codesign techniques target system-on-chip (SoC) design or embedded core design that involves integration of general-purpose microprocessors, DSP structures, programmable logic (FPGA), ASIC cores, memory block peripherals, and interconnection buses on one chip. Traditionally, a system is divided into hardware and software sections that are designed independently except for some common standards required for compatibility concerns, shown in Figure 5.15(A). With systems growing larger and power consumption becoming of great importance, a new wave came forth to consider the whole system design process and attempt to partition the various tasks of the system between hardware and software from the early stages of the design process to reduce many design problems, as indicated by Figure 5.15(B). These techniques attempt to find an optimal partitioning and assignment of tasks between software running on microprocessors or DSPs and hardware implemented on ASIC or FPGA for a given application. In Henkel (1999), a system-level power optimization approach that deploys hardware–software partitioning based on a fine-grained (instruction/operation-level) power estimation analysis is proposed that achieves up to 94% savings in energy consumption. In this approach, the system tasks are partitioned into software

sections running on a general microprocessor core and into hardware sections implemented in application-specific cores to minimize the total power dissipation.

Memory Design Techniques

Memory design techniques techniques are mainly focused on reducing the power consumed by memories, such as creatively exploiting caching to reduce power consumption (Pedram and Rabaey, 2002). Increasing memory blocks on-chip can reduce the overall power consumption of a processor because the power dissipation of an external memory access is at least an order of magnitude higher than that of an on-chip access (Ko *et al.*, 1998). The discrepancy is due mainly to the relatively large capacitive overhead in driving device *I/O*, board traces, and discrete memory components. For optimizing internal memories, Lee and Tiwari (1996) analyze memory allocation of variables in embedded DSP software to maximize simultaneous data transfers from different memory banks to registers. A memory allocation technique based on simulated annealing is proposed. Experimental results demonstrate that energy reduction of up to 47% can be achieved using this approach. In work by Wen-Tsong *et al.* (1999), a relation between energy consumption and cache design (i.e., cache size, line size, set associativity, and tiling) is established.

Dynamic Power Management

Dynamic power management techniques allow systems or system's blocks to be placed in low-power sleep modes when the systems are inactive. Normally, not all blocks of a system participate in performing different functions, and it is useful to shut down inactive blocks to reduce power consumption. For example, in a general microprocessor, a register-based instruction does not access the data memory and some other modules, so these components can be deactivated to achieve power savings. In this case, more control is involved, but it is true that the waking up of these deactivated blocks is expensive in terms of speed or performance.

Variable-Voltage Techniques

As stated before, the most effective way to reduce power consumption is to lower the supply voltage with **variable voltage techniques**. With the availability of almost "limitless" number of transistors, parallelism can be employed at the chip level, providing significant power savings by reducing the supply voltage level (Chandraksan *et al.*, 1992).

If both the technology and architecture are fixed, the determining factor in power dissipation is timing: at higher voltages, the circuits operate faster but use more energy. Some techniques adjust the circuit during operation to achieve power savings. For example, with the use of a dynamically adjustable power supplies technique (Gutnik and Chandraksan, 1997), power can be reduced substantially without sacrificing performance in fixed-throughput applications by slowing the clock and lowering the supply voltage instead of idling when the computational workload varies, as shown in Figure 5.16. The basic idea is to lower the supply voltage and slow the clock during reduced workload periods instead of working at a fixed speed and idling.

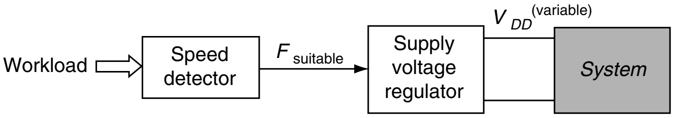

FIGURE 5.16 Variable Voltage Scheme. A speed detector is used to sense the suitable frequency and execute some workload; consequently, the supply voltage regulator will generate a suitable supply voltage level for this specific frequency.

5.7.2 Architectural Level

At the architectural level, a digital system consists of the structural view of the data path and a logical view of the control unit of a circuit. The data path consists of a set of interconnected functional units (arithmetic, logic, memory, and registers) and steering units (multiplexers and busses), while the control unit sends signals to the data path to schedule the appropriate sequence of operations in time.

At this level of abstraction, the VLSI designer has a lot of freedom in employing many techniques to reduce the power dissipation. Normally, decisions at this level have a global effect on the whole system. For example, inactive hardware modules may be automatically turned off to save power; modules may be provided with the optimum supply voltage and interfaced by means of level converters. In the following subsections, different techniques that are applied at this level are presented, namely parallelism and pipelining exploitation, block-disabling techniques, clock gating, and intercommunication and interconnect optimization.

Parallelism and Pipelining Exploitation

One effective technique to reduce energy dissipation is to reduce the supply voltage level by employing **pipelining** and **parallelism** which has an immense effect in reducing the overall power consumption and compensating for the resultant speed loss. This technique is used in general for data path sections. Assuming performance reduces by half when the supply voltage is lowered, the hardware can be duplicated to produce outputs at twice the slower rate to achieve the initial performance before lowering the supply voltage level, as shown in Figure 5.17.

Block-Disabling Technique and Clock Gating

Because not all blocks in an architecture are simultaneously operating, one can disable the blocks (**block-disabling technique**) that are not in use during some particular clock cycles with the objective of limiting the power consumption. In fact, idling or stopping these units causes a decrease in the overall

FIGURE 5.17 Exploiting Parallelism. (A) This figure shows a path with modules supplied from a high Vdd; the path length is T (C). Reducing the supply voltage causes the path to produce the output after $2T$ seconds (D). Duplicating the modules with the lower Vdd (B) causes the parallel structure to produce two outputs every $2T$ seconds, which is equivalent to one output every T seconds (E).

switching capacitance of the system, thus reducing the switching component of the power dissipation. Optimization techniques based on this principle belong to the broad class of dynamic power management methods. Clock gating provides a way to selectively stop the clock and thus force the original circuit to make no transition whenever the computation to be carried out by a hardware unit at the next clock cycle is useless.

Intercommunication and Interconnect Optimization

A significant portion of the power in high performance CMOS VLSI circuits is dissipated in busses or global communications (Mehendale *et al.*, 1998; Winzker, 1998). Global communication typically involves the switching of large capacitive loads, such as *I/O* ports and the clock distribution network, that inherently require significant power (Mehendale *et al.*, 1998a; Stan and Burleson, 1997). Some of the techniques used to reduce the power dissipation in communication networks inside a chip include **data encoding techniques** and **low-swing signaling**.

In (Stan and Burleson, 1997), data encoding or compression methods are used to reduce the power dissipation by reducing the switching activities on global busses. Depending on the data type, compression can have a very high impact on switching activity. For example, an address bus tends to have sequential behavior, and a Gray code is optimal in such a case (Mehendale *et al.*, 1998a, 1998b; Su *et al.*, 1994) (as much as a 50% reduction is cited in (Mehendale *et al.*, 1998a). Another similar technique is the asymptotic zero-transition encoding used in Benini *et al.* (1997). Taking this further, there is really no need to actually send a new sequential address for burst transfers on a synchronous bus; only the first address is actually transferred, whereas the next addresses in the burst are locally generated. Another low-power encoding scheme is to add redundancy in a controlled manner such that the correlation in time between successive data values reduces the switching activity. One example of these techniques is the bus-invert encoding (BIE) (Fujiwara and Pradhan, 1990; Stan and Burleson, 1995) used for buses with lengths $K > 2$. The idea is to use one extra bus line, called an invert. The method computes the Hamming distance between the present *encoded* bus value and the next data value. If the distance is greater than $K/2$, then the transmitter *inverts* the next value and signals the inversion with invert $= 1$. Otherwise, the next value is not inverted and invert $= 0$. The value of invert must be transmitted over the bus to recover the correct information at the receiver; hence, the method increases the number of bus lines by one.

The BIE uses redundancy in space (number of bus lines) for reducing the switching activity. One problem with such encoding techniques is that the required number of extra bus lines increases exponentially as the transition activity is reduced. An alternative is to keep the number of bus lines constant and inject redundancy in time by using extra transfer cycles. In the deep-submicron era, interconnect wires (more specifically global wires, such as buses and clock signals) and the associated driver and receiver circuits are responsible for a large fraction of the energy consumption of an integrated circuit (Zhang and Rabaey, 1998). The low-swing signaling technique is used for information transfers on long wires where wires achieve low-power consumption as they assume reduced voltage swings on the transmitted signals. Such technique requires special transmitter and receiver circuits to provide and sense the low swing voltages on signals flowing in these busses; normal circuits cannot detect these low swing circuits correctly. Examples of these interfacing circuits can be found in (Nakagome *et al.*, 1993; Burd, 1998; Colshan and Jaroun, 1994; Hiraki *et al.*, 1995).

5.7.3 Logic Gate Level

Logic synthesis is the process by which a behavioral or RTL design is transformed into a logic gate level net list using a predefined technology library (Devadas *et al.*, 1994). The trivial attempt for low-power design is to target a library in which the components are designed to be low power. However, other techniques are needed since there are opportunities that are not exploited by the use of a low-power library.

Constrained Optimization

As mentioned in Section 5.6, power optimization can take the form of a constrained optimization problem where performance degradation is acceptable to a given bound. Thus, power minimization requires optimal exploitation of the slack on performance constraints. To this end, many CAD tools that implement optimization algorithms were developed to optimize an architecture from a power point of view given some timing constraints with other specifications.

Path Equalization: Lower Vdd

Between two consecutive registers, one can identify a number of paths, the most important of which is the critical path. The critical path is characterized by the fact that it takes the most time, with respect to the other paths, to traverse between these registers. The other paths will be faster, and one can lower the supply voltage for these fast paths until their delay becomes similar to the critical path, such as in Figure 5.18.

Path Equalization: Resizing

For path equalization, another alternative to lowering the supply voltage is to use gate resizing (See Figure 5.18). Sizing here again focuses on the noncritical paths or the fast paths where gates along these fast paths are downsized to reduce their input capacitances. Reducing these capacitances yields savings in power consumption. Resizing does not always imply downsizing. Power can also be reduced by enlarging heavily loaded gates to increase their output slew rates. Fast transitions minimize short-circuit power of the gates in the fan-out of the gate that has been sized up, but the gate's capacitance is increased. In most cases, resizing is a complex optimization problem involving a trade-off between output switching power and internal short circuit power on several gates at the same time with the constraint being set on performance by the critical path timing.

Glitch Avoidance and Local Transformations

Spurious switching, as mentioned before, is due to the existence of unequal paths to outputs. Path equalization techniques help in reducing these glitches, consequently resulting in less power dissipation. Other logic-level power minimization techniques involve local transformations, including refactoring, remapping, phase assignment, and pin swapping. All the material in this section is from Benini *et al.* (2001). All these techniques can be classified as local transformations. They are applied on gate net-lists and focus on nets with large switching capacitance. Most of these techniques replace a gate or a small group of gates around the target net in an effort to reduce capacitance and switching activity. Similarly to resizing, local transformations must carefully balance short circuit and output power consumption.

Logic-level power minimization is relatively well studied and understood. Unfortunately, due to the local nature of most logic-level optimizations, a large number of transformations have to be applied to achieve sizable power savings. This is a time-consuming and uncertain process during which uncertainty is caused by the limited accuracy of power estimation. In many cases, the savings produced by a local move are below the "noise floor" of the power estimation engine. As a consequence, logic-level optimization does not result in massive power reductions. Savings are in the 10 to 20% range, on average.

5.7.4 Circuit Level

Only local optimizations are possible at this level; more specifically, the low-power techniques are applied for simple primitive components that assume some specific input and output characteristics, such as input rise and fall times and output load capacitance. The techniques at this level are **library cell design, transistor sizing**, and **circuit design style**.

Library Cell Design

The low-power **library cell design** lies at the heart of the circuit level techniques to reduce power consumption. From the power viewpoint, the most critical cells in a design library are the timing elements—flip-flops and latches—

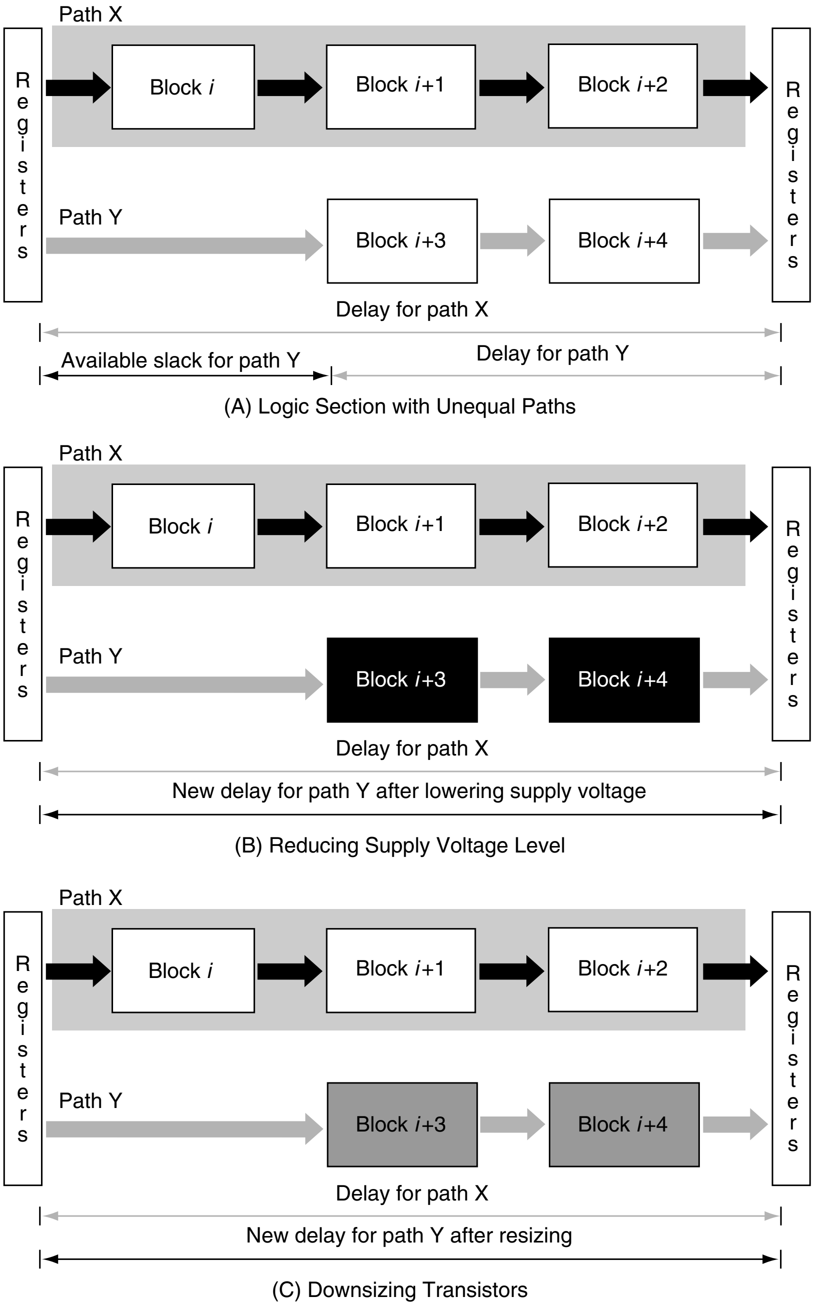

FIGURE 5.18 (A) This Part of the Figure Shows Logic Section with Unequal Paths to the Output. (B) One Can Reduce the Supply Voltage Level of the Units on the Fast Section, in this Case Path Y, to Match the Speed of the Stage Critical Path, Path X. (C) Alternatively, one Can Downsize the Transistors of the Units on Path Y where Speed Is Bound by that of the Critical Path to Reduce the Capacitances. In either case, one can achieve a considerable power reduction on path Y.

because of two reasons. First, these timing elements are extensively used in almost all digital systems where many storage units and pipelining are used. Second, it is well known that a significant fraction of the system power is dissipated in the clock distribution network that drives all timing elements. Consequently, the design of low-power sequential primitives is of great importance where flip-flop design for low power focuses on minimizing clock load and reducing the internal power when the clock is toggled (Pedram and Rabacy, 2002).

Another extensively used element in VLSI designs is the adder cell, which is considered the basic building block for all arithmetic and DSP functions. The literature describes many adder cells with different characteristics such as transistor count, speed, power consumption, and driving capabilities. The choice of a library element not only depends on its power characteristics but depends on the other characteristics of the chosen component and the design specification (such as area and speed). The choice also depends on the context in which such an element is used, which specifies the inputs driving the library element and the output loads of the driven components.

Transistor Sizing

While building a library, it is quite useful to design the components with different sizes for a wide range of gate loads; each component is thus sized to optimally drive a certain load. **Transistor sizing** at the circuit level complements design techniques at the gate level, where logic level sizing can help the synthesis tool in selecting the component with optimum sizing for low-power consumption. Another sizing example is to effectively drive a large load from a source with low driving capability. One could insert a large buffer between the driving circuit and the load to effectively drive the load, but this solution will not solve the problem; it will only change the problem to effectively drive the large buffer. A traditional solution for this problem is to use a chain of successively larger buffers, each driving an appropriate load, as shown in Figure 5.19. Too many buffers result in more stages with large propagation delay and more capacitive nodes with more power consumption. On the other hand, two few buffers will lead to output slopes that are not steep, resulting in larger delays and more short circuit power consumption. One traditional solution to effectively drive the large load can be found in work by Mead and Conway (1980) as well as by Cong and Koh (1994).

Circuit Design Style

Currently, the majority of digital VLSI systems are designed using **static CMOS** (**SCMOS**) **circuit style**. The main reasons for adopting SCMOS in designing VLSI systems are robustness (i.e., low sensitivity to noise) and low power with no static power consumption. SCMOS circuits are characterized by almost ideal voltage transfer characteristic (VTC) curves—symmetrical shape, full logic swing, and high noise margins. Such characteristics simplify the design process considerably and open the door for design automation. Another major attractor for SCMOS, the main concern of this chapter, is its low-power consumption feature. The static power consumption component is almost absent in the steady-state operation mode, except for some leakage that is mentioned in Section 5.3. The world of the SCMOS, however, is not so perfect; there are some disadvantages associated with SCMOS circuit style, more specifically performance and number of transistors. The SCMOS design family has almost double the number of transistors compared to other families and has inferior performance especially when compared to dynamic CMOS (DCMOS) style. Figure 5.20 compares the general structure for SCMOS and DCMOS styles.

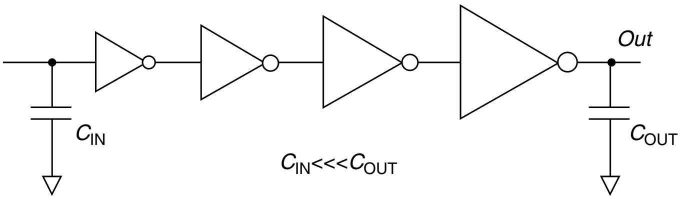

FIGURE 5.19 Multistage Buffer Insertion with Buffer Sizing to Effectively Drive the Large Load

Despite the aforementioned advantages over SCMOS, DCMOS is not widely used because of more serious problems, namely higher power consumption, charge sharing, cascading, and noninverting drawbacks. The higher power consumption results from dynamic circuits requiring two phases of operation: precharging and evaluation. Due to the inherent structure of dynamic circuits, output nodes are precharged every clock cycle, which results in a switching activity equivalent to the system operating frequency. Since the power consumption is proportional to switching activity, more dynamic and short circuit power consumption are associated with DCMOS. Charge sharing is the process by which the output node charge

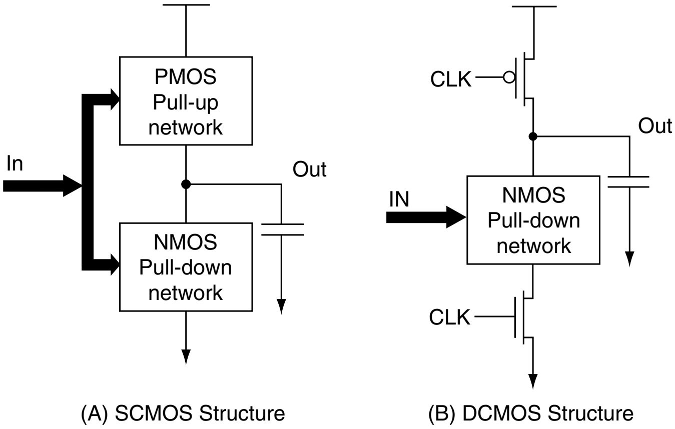

FIGURE 5.20 (A) SCMOS general structure has two complementary networks: PMOS pull-up network for charging the output into Vdd, and NMOS pull-down network to discharge the output to *GND*. The SCMOS style requires $2N$ transistors to implement a function. (B) DCMOS general structure has only an NMOS pull-down structure. The DCMOS style operates in two phases controlled by a clocking signal, *CLK*. When $CLK = 0$, the DCMOS gate is in the precharge state, where the PMOS transistor controlled by *CLK* is on allowing the output to charge to *Vdd*. At the same time, the pull-down network is off since the NMOS transistor controlled also by *CLK* is off ($CLK = 0$). When $CLK = 1$, the evaluate state takes place, allowing the output to be evaluated as a function of the input. DCMOS style requires $N + 2$ transistors to implement a function.

leaks to some internal nodes via paths set by certain changing inputs during the evaluation cycle. This problem results in spurious glitches at the outputs not only to affect output stages driven by the dynamic stage but also to result in additional power dissipation. Many solutions, such as static bleeder and precharging internal nodes, will help alleviate the charge-sharing problem but will result in more power dissipation and more transistors!

Lastly, DCMOS circuits cannot be cascaded; they have to be interleaved by inverting functions for proper operation, a solution provided by Domino logic circuits. In addition, Domino circuits are noninverting in nature and cannot implement all functions. All these problems have aided in ruling out the use of DCMOS and favoring the use of SCMOS style. Another approach to design low-power circuits is to use complementary-pass-transistor logic (CPL) or transmission gate theory. CPL features low-power consumption and a reduced number of transistors. In addition, certain functions are more efficiently implemented using this family, such as XOR gates and MUXs. One major drawback of this family is the weak driving capability with reduced swing outputs, which limits the number of CPL stages that can be cascaded.

5.7.5 Physical Level

Techniques at this level are technology dependent and are produced at the fabrication stage. Ideally speaking, scaling the MOS transistor feature size causes the power to scale down by the same scaling factor and the power density to remain constant. But such observation is too far from reality when using actual implementation products, and it lends itself to two reasons: (1) historically, the supply voltage level scaling does not follow the feature size scaling theory, and (2) more transistors are incorporated per chip with the die size increasing from one generation to the next. For older technologies down to 0.5 micrometer technology, the supply voltage level has been standardized (5 V, then 3.3 V), but for the deep-submicron, DSM, regions when feature size is less than 0.5 micrometers, probably the most widely successful power reduction technique is the power-driven voltage scaling. At this point, it is important to mention that transistor speed does not depend on Vdd alone but also on the gate overdrive, as shown in this equation:

$$V_{\text{Gate Over Drive}} = Vdd - V_T, \qquad (5.9)$$

where V_T is the device threshold voltage set more or less by the technology. It is important to mention also that the current flowing across the transistor channel is inversely proportional to V_T so a decrease in V_T will lead to an increase in the current and faster switching, as shown in Figure 5.21. At this level, one can reduce the power consumption by using techniques such as joint supply voltage–threshold voltage reduction as well as multiple threshold and variable threshold techniques (Pedram and Rabaey, 2002).

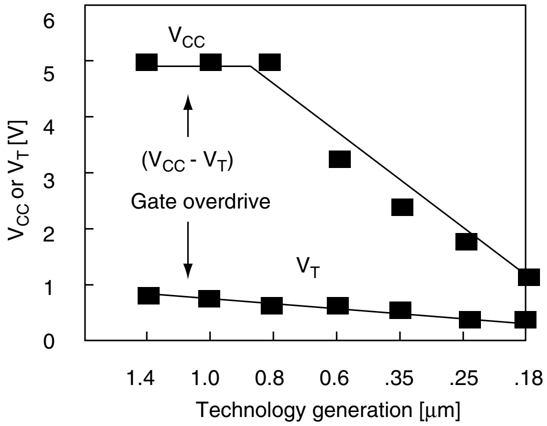

FIGURE 5.21 Supply Voltage Scaling and Threshold Voltage Scaling with Technology Advancement. The gate overdrive is shown.

In the joint supply voltage–threshold voltage reduction, the supply voltage can be reduced to decrease the power consumption and at the same time decrease the threshold voltage to compensate for the speed loss. The decrease in the threshold voltage, however, will cause more static power dissipation due to the increase in the leakage current. One alternative is to use multithreshold devices where different devices with different threshold voltages are used across the design to limit the amount of leakage current. Another alternative is the use of variable threshold devices where the threshold voltage is dynamically controlled through substrate biasing.

Production and Utilization of Micro Electro Mechanical Systems

6.1 Introduction

Many micro electro mechanical systems (MEMS) devices are now on the market. They are available for use as components in diverse systems with many applications. Some MEMS devices are used primarily for their planned employment. Systems of micromirrors for transmitting and displaying information are examples. Other MEMS components are finding opportunistic applications in the hands of creative system engineers. Pressure sensors and accelerometers are prime examples. MEMS are already important devices in several major industries. Both the variety of available mechanical microdevices and their applications will grow rapidly in the foreseeable future.

This chapter first provides an overview of MEMS. The sequential steps in their production are then reviewed, namely design, simulation, fabrication, packaging, and testing. The reliability of MEMS is considered from the viewpoint of their performance in actual applications. The applications of micromachined static MEMS, micromechanical MEMS sensors and actuators, and functional MEMS systems are also surveyed. Examples of MEMS use in the transportation, communication, analytical, and medical industries are provided. The Appendix at the end of this chapter lists more than 30 books on MEMS that have been published in the past decade.

6.2 Overview of MEMS

Micro electro mechanical systems are devices that have static or moveable components with some dimensions on the scale of a micrometer to nanometer. For comparison, a human hair is about 80 micrometers in diameter. MEMS combine microelectronics and micromechanics and sometimes microoptics and micromagnetics. A decade ago, hundreds of MEMS components were prototyped and dozens were commercially available. Many people then viewed the technology as the classical "solution looking for a problem to solve." The situation changed markedly during the 1990s when the market for MEMS took off in a manner reminiscent of the sales growth of integrated circuits in the 1960s. At present, roughly 100 million MEMS components are being sold annually. Patents on MEMS are being granted at the global rate of about one per workday or 200 annually. While MEMS devices will not be used as commonly as integrated circuits, they will be found in a great diversity of products and installations. Just as most people in technological societies own products with integrated circuits and microlasers, pervasive ownership and use of MEMS are clearly in prospect. It is estimated that there are 1.6 MEMS devices per person in the United States (*1*). Micromechanical devices will both improve the performance of existing systems and enable entirely new applications.

Dozens of companies make and sell MEMS. Now that MEMS devices are available in a greater variety and in large numbers, it is possible for the applications engineer to incorporate them in many different products. Most products are the systems for which particular MEMS were designed, but others are targets of opportunity. That is, the MEMS components are simply devices that are available for incorporation into whatever systems can use them.

Figure 6.1 shows the dollar volume for MEMS products as a function of year as compiled and projected by several studies. It is striking that the compilations vary so widely in their absolute value and in their rate of growth. The variance in values is due to differences in what is included in the study: for example, are micromachined ink jet print heads counted as MEMS or not? Some studies also include products enabled by the availability of MEMS devices. However, all the studies indicate that the production of MEMS is already a multibillion dollar industry that doubles every 2 to 4 years. The associated growth rates of 17 to 35% are noteworthy.

The first micromechanical device made by modern manufacturing techniques was demonstrated in the mid-1960s. Significant commercial production of MEMS started in the 1980s, with the appearance of pressure sensors for automotive and medical applications. Then, in the 1990s, microaccelerometers were mass-produced for air bag triggers in cars. Volume production of microfluidic devices also began in that decade. Optical MEMS for displays came to market a few years ago, and micromirrors for switching signals in fiber networks are poised to enter the volume production stage. MEMS switches for control of radio-frequency signals and microwave signals is the next predictable market for MEMS devices. Devices for dense data storage and many new medical applications are also in prospect.

The integration of microelectronics and micromechanics is a historic advance in the technology of small-scale systems and is very challenging for designers and producers of MEMS. We will show examples of monolithic (single substrate) and hybrid (two substrate) MEMS later in this review. We now pause to

appreciate the scope and impact of integrating microelectronics and micromechanics. One way to do this is to consider Figure 6.2. It is arguably the most important graphic in the entire field of MEMS. We note that the microelectronic personal computer and Internet revolutions all occurred using components without moving parts. The addition of micromachined parts to microelectronics opens up a large and very important parameter space to technological development and exploitation. The figure also shows the regions into which fall both current and future applications of MEMS. Most commercial MEMS have only a few electronic and mechanical components. Two commercially important exceptions are the ADXL microaccelerometers from Analog Devices and the Digital Mirror Display (DMD) from Texas Instruments. These are reviewed in the upcoming paragraphs. The variety of potential applications shown in Figure 6.2 is remarkable. The impacts of MEMS will increasingly be felt in many industries and by many consumers.

This chapter surveys some of the current and projected applications of MEMS. Before getting to these applications, we consider in the next section the means by which MEMS are produced. On a macroscopic scale, carpenters do not make engines, and machinists do not produce buildings. That is, the characteristics and performance of large engineered systems depend on the materials and tools used to make them. On a microscopic scale, the uses of MEMS similarly depend on the performance specifications that result from the design and manufacturing phases, especially the behavior of materials and processes at small scales. Section 6.3 surveys the computer and other tools that are available currently for designing, simulating, manufacturing, packaging, and testing MEMS devices. Having some appreciation of these key aspects of MEMS technologies, we then review diverse applications of MEMS structures, sensors, actuators, and systems on a chip. One potential but uncertain use of MEMS is their employment for information storage devices with terabit per square centimeter data densities, which could challenge the dominance of magnetic storage systems.

There are now many books on MEMS and related technologies. Some are quite comprehensive, and others are more detailed. The Bibliography contains a list of the books on or closely related to MEMS. A few Web sites are also good gateways to obtaining information on MEMS.

6.3 From Design to Reliable MEMS Devices

The sequential steps common to making many engineered components also apply to MEMS: **design**, **simulation**, **fabrication**, **packaging**, and **testing**. Figure 6.3 shows these steps. The results of these actions determine both the performance and the price of devices like integrated circuits and MEMS as well as their reliability. Hence, they are considered a necessary prelude to understanding practical applications of MEMS.

6.3.1 Design and Simulation

Computer-aided design (CAD) software is necessary not only for the design of systems and devices that go into MEMS devices but also for the simulation of their expected behavior. Design of MEMS devices is markedly different from the design of integrated circuits. For MEMS devices, the designer should be completely aware of the processing steps and of the materials to be used and their properties. This is in contrast to the design of integrated circuits, in which case the design and the processing steps are separate, and the designer does not have to know the exact details of the process steps. However, for MEMS devices design, the designer has to make many decisions, some determined by processing, and be aware of many constraints to realize the desired device.

The first step in designing an MEMS device is to decide on the materials to be used for a particular device. There are varieties of materials to choose from, and the designer has to choose materials that are compatible and that yield the maximum performance of the device. The designer should have an understanding of the physical properties and knowledge of the physical or chemical techniques required to etch or to deposit these materials. In addition, the designer should know the effects of any of these processing steps on the properties of the materials used and, hence, on the performance of the

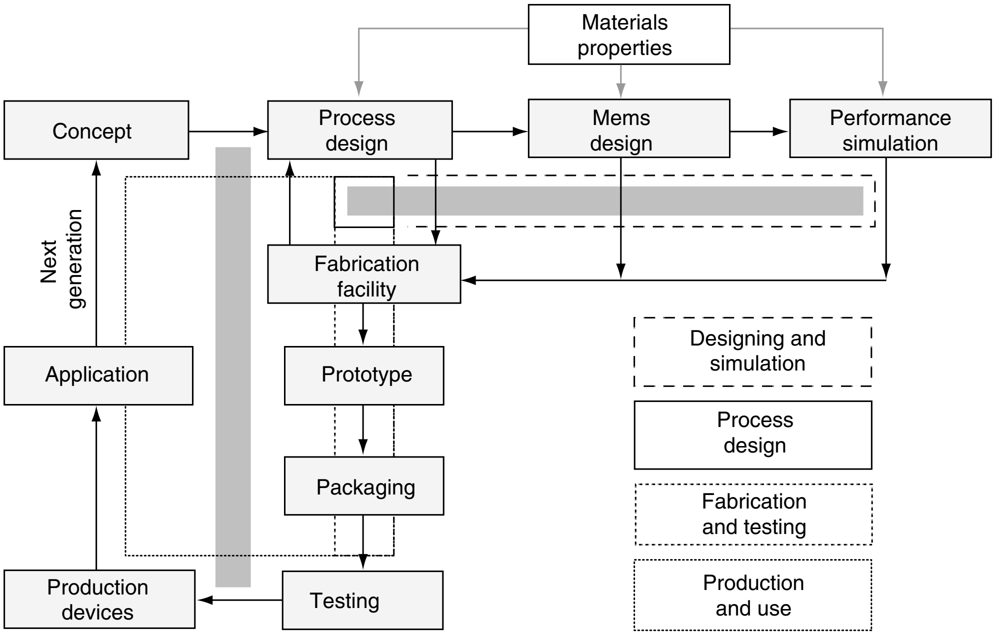

FIGURE 6.3 Flow Diagrams for the Design and Simulation (Horizontal Grey Rectangle) and for the Production, Packaging, Testing, and Use of MEMS Devices (Vertical Grey Rectangle). device. After specifying all the materials properties to be used and the processing steps to be followed, the designer then has to decide on the dimensions of the design so that the optimal device dimensions will yield the maximum performance. The dimensions of the device have to be compatible with the process steps and also with the general design rules of the particular technology.

After choosing the materials and dimensions, the designer is ready to start simulating the device to verify that the specified materials and dimensions would yield the required performance. The relationship of the design and simulation phases of MEMS development can be considered by reference to the diagram in Figure 6.3. As noted in that figure, material properties impact both the design and simulation phases. That is, the properties must be known adequately for the particular processes and equipment in the fabrication facility or else the simulated performance will not be accurate.

There are now many software packages and suites available for the design and simulation of MEMS devices. In a very fundamental way, they are more complicated than the software for design of either solely electronic devices or solely mechanical devices. This is due to the close coupling of both electrical and mechanical effects in many MEMS. Consider a microcantilever that is pulled down by electrostatic forces. Its simulation has to take into account both the flow of electrical charge and mechanical elasticity in an iterative and self-consistent fashion. Thermal, optical, magnetic, fluidic, and other mechanisms are also active in some MEMS and have to be handled self-consistently in the simulation phase.

Two basic approaches addressing the need for specialized software for the design and simulation of MEMS have been taken in the past decade. In the first, CAD design tools and available software from electronics were modified to accommodate the requirement for MEMS design. In the second, software from mechanics was applied to MEMS. Some of the software from Tanner Tools VLSI design suite is used for MEMS (e.g., MEMSPRO and the popular mechanical engineering software from ANSYS). New suites of software developed specifically for MEMS have also been marketed. Most of them include electronic, mechanical, and thermal mechanisms, and some have other physical or chemical mechanisms. In addition, some of them also have process simulation tools. Examples are the software that is available from Algor, CFD Research Corporation, Coventor (formerly called Microcosm Technologies), MEMSCaP, and Corning IntelliSense Corporation. We will summarize some of the features of the two software suites, those from MEMSCaP and Corning IntelliSense Corporation, as illustrations of current capabilities.

MEMSCaP is based on CADENCE set of tools, which are the most popular IC design tools (www.memscap.com). MEMSCaP enables the design flow either from the bottom up or the top down and incorporates the MEMS design environment into an existing and well-known IC environment. It permits easy IP or design reuse and the ability to exchange data between multidisciplinary teams. Because the MEMSCaP simulator is based on CADENCE environment, the designer can simulate a MEMS device using the IC schematics or hardware definition language (HDL) approaches. Models can be generated from ANSYS finite element codes or from written analytical equations. Behavior models and scalable symbolic views can be generated. Verilog-A models can also be generated. MEMS Xplorer in MEMSCaP offers a complete environment for MEMS design by combining leading-edge IC design environment (CADENCE) and FEM tools (ANSYS). The generated model can be used to perform optimization simulations inside the environment or to realize a system-level simulation. In addition, emulators are available for isotropic or anisotropic etching and for sacrificial etching.

Intellisuite is another integrated software system that assists designers in optimizing MEMS devices by providing the needed manufacturing databases, allowing them to model the entire device manufacturing sequence, and to simulate the behavior without having to enter a manufacturing facility (http://www.corningintellisense.com). The system can be used to predict the behavior of complex structures to within a 10% accuracy by utilizing fully coupled thermoelectromechanical analysis. Intellisuite incorporates three extensive material, design, and fabrication databases from respected sources. These databases are integrated, and users can easily add custom information to any of them. Intellisuite uses a process sequence builder to emulate the actual process steps that go into building a device in a fabrication facility. For example, the steps in a typical MEMS process (e.g., laying down the silicon substrate, cleaning, deposition, mask layout, implantation, and etching) are incorporated in the software database. Once the user inputs the process sequence or uses a process template, an expert system process checker debugs the process to ensure completeness and continuity of the defined steps. A solid modeler will then create a three-dimensional structure upon combining the fabrication information from the process sequence builder and planar geometry information from the mask layout editor. Surface and volume meshes are generated automatically for the purpose of simulation of the device performance. The simulation allows the specification of voltage, temperature, mechanical stress, thermal stress, and residual stress for a fully coupled analysis. At any process step, the designer can access the material database, MEMaterial, to investigate the effects of process parameters on the structure. For example, the user can investigate the stress of a silicon nitride thin film by varying parameters such as the temperature and pressure of deposition, the radio frequency and power, and gas partial pressures. Once an acceptable stress is achieved, the material properties and fabrication information are automatically used for device simulation.

It is clear from this discussion that CAD tools for MEMS vary widely in the materials parameters and mechanisms that they include, the details of design and simulation of devices, and the fabrication facilities with which they interface. The choice of which software to use for MEMS design and simulation is still challenging.

6.3.2 Materials and Processes

Many options for the fabrication of MEMS devices are now available. This stage, however, is also a daunting part of producing MEMS. The first complexity involves the wide range of materials and associated processes that can be employed.

The fact that the field of MEMS largely grew out of the IC industry has been noted often. There is no doubt that the use of fabrication processes and associated equipment developed initially for semiconductor industry has given the MEMS industry the impetus needed to overcome the massive infrastructure requirements. Less discussed is the additional fact that the field of MEMS has gone far beyond the materials and processes used for IC production. The situation is indicated schematically in Figure 6.4. Less than ten materials, notably silicon and its oxide and nitride, and a similar number of processes, such as lithography and ion implantation, are generally employed to make ICs. The set of materials for IC devices has expanded to include, for example, both low and high dielectric constant materials. However, compared to MEMS a relatively small number of materials and processes are employed now to make IC chips.

Many MEMS can be made with the same set of materials and processes that are used for microelectronics. One of the hallmarks of the emerging MEMS industry, however, is the use of numerous other materials and processes. Substrates other than silicon are being employed for MEMS. Silicon carbide has been demonstrated to be a good basis for many mechanisms that can stand higher temperature service than silicon. In addition there is early and strong interest in the use of synthetic diamond substrates. MEMS are also being made out of plastic, glass, and ceramics. Processes for taking MEMS made out of various materials and putting them on plastic or steel tapes have also been developed.

Diverse materials can be used in MEMS devices. Although aluminum and copper are the metals used in IC devices,

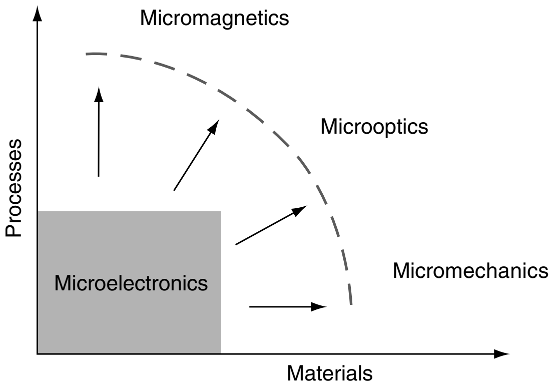

FIGURE 6.4 MEMS Materials and Processes. The number of materials and processes employed to make other microtechnologies greatly exceeds those used to manufacture integrated circuits.

micromachining of many other metals and alloys has been demonstrated. The so-called "shape memory" alloys are used for actuators in several types of MEMS (e.g., microfluidic pumps and valves). Magnetic materials have been incorporated into some MEMS devices. Piezoelectric materials are especially attractive for MEMS because of their electrical–mechanical reciprocity. That is, application of a voltage to a piezoelectric material deforms it, and application of a strain produces a voltage. Zinc oxide and lead zirconium titinate (PZT) are important piezoelectric materials for MEMS. Many other examples of materials employed for MEMS could be given. However, the point is clear: micromechanics are made of many more kinds of materials than microelectronics.

Because materials go hand in hand with the processes for producing and modifying them, the range of processes for making MEMS has also widened far beyond those found in the IC industry. There is something more fundamental at work, however, when it comes to processes for making MEMS. Integrated circuits are monolithic, and, despite having 30 layers in some cases, are made by largely two-dimensional (2-D) thin film processes that yield what some people call 2.5-D structures. By contrast, micromechanical devices must have space between their parts so they can move, and the dimension perpendicular to the substrate is often very fundamentally necessary for their performance. Development of processes to make micrometer-scale parts that can move relative to each other was the breakthrough that enabled MEMS. Such micromachining processes fall into three major categories, which are now reviewed briefly:

A. **Surface micromachining** involves the buildup of micromechanical structures on the surface of a substrate by deposition, patterning, and etching processes. The key step is the etching away of a formerly deposited and patterned sacrificial layer to free the mechanism. This process was first demonstrated almost 40 years ago, when a MOSFET with a cantilever mechanical gate was produced (Nathanson *et al.* 1967). The most common sacrificial material now is silicon dioxide, which is conveniently dissolved from under a moveable part using hydrofluoric acid. Surface micromachining has been used to produce an amazing variety of micromechanical devices, some of which are now in large-scale production. Microaccelerometers and MEMS angle rate sensors are examples.

B. As the name implies, **bulk micromachining** involves etching into the substrate to produce structures of interest. It can be done with either wet or "dry" plasma processes, either of which can attack the substrate in any direction (isotropically) or in preferred directions (anisotropically). Bulk micromachining has two primary variants. The first depends on the remarkable property of some wet chemical etches to attack single crystal silicon as much as 600 times faster along some crystallographic directions compared to others. This anisotropic process is called orientation-dependent etching (ODE). It was known long before the emergence of MEMS technologies and has become a mainstay of the industry. ODE is especially useful for producing thin membranes that serve as the sensitive element in MEM pressure sensors. It is employed for production of these and other commercial MEMS devices. The second approach to bulk micromachining is using plasma-based etching processes that attack the substrate, usually silicon, in preferential directions. Deep reactive ion etching (DRIE) is a plasma process that is used increasingly to make MEMS. It can produce structures that are over ten times as deep as they are wide.

C. Producing structures and mechanisms on a micrometer scale is possible with a **collection of numerous and varied techniques**. Laser-induced etching and deposition of materials, electroetching and electroplating, ultrasonic and electron discharge milling, ink-jetting, molding and embossing are all available to the MEMS designer. Wafer-to-wafer bonding to buildup MEMS devices, or to vacuum package them, is also an important process.

Like integrated circuits, MEMS devices are made using creative combinations of materials and processes noted in this subsection. Some remarkable micromechanisms have been demonstrated, largely in academic fabrication facilities, and commercialized using diverse foundries.

6.3.3 Fabrication Foundries

The next concern after designing and simulating MEMS, that is, deciding on the materials they will contain and the processes needed to make them, is which fabrication facility to employ. The designer can choose from a wide range of facilities. Sometimes a standard IC facility can be used with postprocessing of the CMOS to remove material from the bulk substrate and create a suspended structure on top of an etched pit. For example, the micro-hot plate shown in Figure 6.5 was realized in CMOS technology made through MOSIS, with a postprocessing step of bulk micromachining to produce the suspended thin film with a resistive heater. The small mass of the heated element permits temperature changes of over 300 °C in a few milliseconds. Many MEMS structures and devices have been produced by such postprocessing of CMOS chips. Other techniques, which are not compatible with CMOS, were also used, in which case surface micromachining techniques produced mechanical structures on top of the substrate. Micromirrors fabricated using surface micromachining are example of such devices.

Several foundries exist specifically or primarily for the production of MEMS. The fact that the design rules in MEMS are roughly two generations behind those in ICs is significant. This enables MEMS foundries to buy used equipment from the microelectronics industry. Mass production of many MEMS is done using 100- and 150-mm wafers. Several companies and organizations in the United States and abroad offer fabrication services for MEMS that are somewhat analogous to what MOSIS does for ICs. Companies include BFGoodrich

Advanced MicroMachines (Ohio), CMP (France), Cronos Integrated Microsystems (the former Microelectronics Center of North Carolina, known as MCNC), CSEM (Switzerland), Institute of Microelectronics (Singapore), Corning IntelliSense (Massachusetts), ISSYS (Michigan), Kionix (New York), Standard Microsystems (New York), and Surface Technology Systems (United Kingdom).

Most of these foundries have all the facilities in-house to produce complete MEMS devices. The wide variety of materials and processes that can be designed into MEMS means, however, that it is not always possible to find all the needed tools under one roof. Hence, several years ago, the Defense Advanced Research Projects Agency instituted a new type of foundry service called the MEMS-Exchange. This organization contracts with diverse industrial and academic fabrication facilities for a wide range of services, such as deposition of zinc oxide piezoelectric materials. The MEMS designer can draw from any of the facilities and processes. A completed design and funding are sent to the MEMS-Exchange, which handles scheduling, production, billing, and other factors, such as the protection of proprietary designs.

6.3.4 Packaging and Testing

The various systems and materials used for sealed packaging of electronic chips certainly are complex. Packaging of MEMS is usually more difficult because of their mechanical motions or other reasons. During the manufacturing of ICs, some testing can be done at the wafer level as well as after packaging. With most MEMS, performance can only be tested after packaging. Hence, both the packaging and testing of MEMS are significantly more complicated and more expensive than for ICs. Some aspects of both are surveyed in the following paragraphs.

Packaging of MEMS is more challenging than the already quite complex packaging of ICs for a sequence of reasons. Some MEMS can be sealed in prescribed atmospheres in the same kinds of packages as ordinary chips. Microaccelerometers are an example. Many MEMS, however, require vacuum packaging to avoid air damping of vibratory structures or deleterious thermal conductivity. Microresonators for frequency standards and uncooled infrared sensor arrays fall in this category. The MEMS that are used to measure ambient effects must be open in some way to atmospheric conditions. Pressure sensors are an example; they have compliant seals that transmit pressure but not humidity or chemical vapors. However, MEMS designed to measure the latter quantities must be fully open to the atmosphere. Maintenance of performance over their shelf lives and during use is a problem. Some MEMS, such as those mounted on the surface of a structure to control motion, notably vibrations or airflow, are not in separate packages. They have to be mounted on open surfaces, so they offer another set of challenges.

The testing of MEMS devices is intrinsically more complex than the testing of ICs because of the integrated electronic and mechanical characters of MEMS. That is, both the electronic and the micromechanical aspects of a chip with moving parts have to be tested at some point in the prototype and mass production stages. For ICs, testing involves only electronic inputs and outputs although temperature, radiation, and other effects are also of interest. For MEMS, the inputs can also be vibrations and other accelerations or particular conditions of pressure, humidity, and chemical vapor composition, among many other ambient parameters. The production of the required input conditions for the operational testing of diverse MEMS devices is complex and costly as is the measurement of “cross” sensitivities (e.g., the influence of unavoidable temperature and humidity variations on chemical sensors). Only limited testing of MEMS can be done at the wafer level. Testing of fully packaged devices is usually needed. The ability of MEMS to withstand aging of the sensitive components can be problematic to determine in a testing laboratory. The calibration of MEMS sensors, to obtain their quantitative input–output relationships, is another important and nontrivial part of their testing. Setting up the correct environments for MEMS calibration and determining their conditions independent of the MEMS to be calibrated are also challenging. Testing and calibration of MEMS are frequently done in the same experimental arrangements.

In summary, just as the design, simulation, and fabrication of MEMS are more complex than similar functions for microelectronics, the packaging and testing of MEMS are also more difficult than those functions for integrated circuits. The fact that MEMS are newer than ICs and have lower volume further complicates these functions for MEMS. It is widely reported that the packaging of MEMS is often more than half, sometimes 90%, of the cost of the devices. Similar general figures for the testing and calibration of MEMS do not seem to be available.

6.3.5 Reliability

The long-term reliability of MEMS components is essential to their utility for consumer, industrial, and military applications, no matter whether they are used continuously or intermittently. Reliability can be either an enabler for applications or else a "show stopper." Hence, there have been questions and concerns about the reliability of MEMS devices from about 1980 when they first appeared on the market. A great deal of work has been done to determine the ability of MEMS to operate for long times and in diverse environments. This section is a summary of some of the highlights of that work. A few references on MEMS reliability include Miller *et al.* (1998), Stark (1999), Lawton (2000), and the www.sandia.gov/mems/micromachine/biblog_char.html web site.

There are three basic approaches to determining the reliability of MEMS. The first is to make **physics-based estimates** of the likelihood of different potential failures in various conditions. This bottom-up approach to reliability can yield useful understanding of the relevant parameters, but it is plagued with large uncertainties. The second approach involves **laboratory or factory testing** for significant periods of time, as indicated in Figure 6.6. It has the advantage of being experimental, and it permits the calculation of statistics from the measured times or cycles to failure. Further, the ambient conditions can be varied in this type of testing to obtain information on the susceptibility to diverse kinds of failures of particular MEMS that are operated in specific conditions. This class of reliability testing, however, rarely duplicates the conditions that will actually be encountered by MEMS components in their "real-world" employment. Further, companies that do lifetime and reliability testing on their devices are often reluctant to disclose the data, the methods by which the data were obtained, or the conditions of the tests.

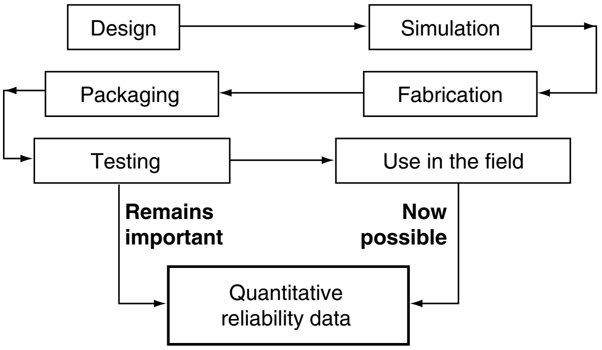

FIGURE 6.6 Types of Testing. Testing in the laboratory or factory and use in the field both produce experimental data on the reliability of MEMS.

The third and most important and relevant data on reliability of engineering components and systems in general and MEMS in particular is **user field data**. In the mid-1990s, significant data of this kind only existed on micromachined pressure sensors. Manifold air pressure sensors had already proven to be reliable in automobile engines, and disposable blood pressure sensors also operated satisfactorily in their one-time uses. The situation for reliability data on MEMS used by customers has changed quantitatively since the middle of the last decade, as indicated in Figure 6.6. Tens of millions of MEMS devices, most notably air bag triggers in cars and micromirrors in conference room projectors, have proven to be remarkably reliable. It is now possible to make quantitative estimates of the reliability of some major MEMS devices in use by large numbers of customers.

MEMS accelerometers are made or sold by dozens of companies. Of these micro-accelerometers, those from Analog Devices are noteworthy and will be discussed in the subsection on MEMS sensors. Unlike most commercial microaccelerometers, the analog devices accelerometer (ADXL) components have the microelectronics and micromechanics integrated on the same silicon substrate. The company has sold a 100 million of the components, primarily for triggers for air bags, since the mid-1990s. An employee of Analog Devices stated that there have been only a small number of failures involving deployment in an accident or deployment without a crash. Assuming that the annual sales rate is constant and that cars are driven about 300 hours per year, a simple calculation gives reliability better than one failure per 10^{10} hrs more than 1 million years). The rate of failure could also be calculated per turn-on of the car (when the ADXL goes through a self-test routine). Since the deceleration history of cars in actual use is generally unknown, it is not possible to compute failures per various levels of deceleration. The rarity of failures, however, ensures that such numbers would be very small. Further, because the ADXL MEMS components are part of an air bag subsystem, it is not clear whether it was the MEMS device or some other part of the subsystem that failed. It is possible that failure of the MEMS device is rarely the cause of an improper event.

The Digital Mirror Device (DMD) developed and sold by Texas instruments has also been on the market for several years. It is a display device used in projectors for conference rooms and movie theaters. It will be noted in the subsection on actuators. The DMD contains more than one-half million micromirrors in one version and more than one million mirrors in another. There are reports of more than 100,000 of the DMD already being sold. Each of the mirrors has an operating goal of 10^{10} cycles for more than 10 years (essentially running at 30 Hz for that entire period). No specifics on DMD failures are available, but the number is said to be small. Here again, simple estimates yield a remarkable value for the temporal failure rate, namely one failure in 10^{14} cycles, which exceeds 10^9 hours. The salient point is that DMDs that pass the manufacturer's tests have proven to be very reliable in actual use.

Optical MEMS switches for fiber communications systems have been developed and tested by a wide variety of small and large companies. Their testing data, however, is not available, and such switches have not yet found widespread use in actual systems. In a similar fashion, MEMS switches for radio-frequency (RF) and microwave systems have been widely developed and tested. Some company test data are available, even though the RF MEMS switches have yet to find their way into large numbers of commercial products. Raytheon has reported testing capacitive-style stitches to over 10^8 cycles. Motorola tested metal-to-metal RF switches to over 4×10^9 cycles. Such reliability is adequate for some applications of RF MEMS switches but not for the most demanding defense applications. The Defense Advanced Research Projects Agency currently has a development program underway to produce MEMS switches for RF systems that will work for 10^{12} cycles.

The already large and fast-growing database on MEMS reliability, both during pre-use laboratory tests and during field use, indicates that sophisticated MEMS devices can be very reliable. This high reliability derives from the same wafer production technologies that make microelectronics reliable as well as relatively cheap. The general situation on MEMS reliability can be summarized along the lines of the different kinds of MEMS. Those devices that are micromachined but do not have moving parts (like nozzles and microchannels) and those devices that actually move but do not touch (like pressure and acceleration sensors) are highly reliable. Even some MEMS components, notably the DMD, that involve internal contact for many cycles can be very reliable. Only in the most demanding situations, namely actual contact for about a trillion cycles, do MEMS remain to be proven as reliable.

The much-improved state of knowledge about MEMS reliability in recent years does not mean that some concerns about MEMS reliability will not persist. Engineering designers in many large and necessarily conservative applications have to be concerned about the specifics of the devices *and* conditions relevant to their application. The reliability of MEMS devices depends on their packaging. For example, the long-term performance of RF resonators and infrared imagers depends on long-lived vacuum packaging. Shock and vibration resistance of MEMS devices is critical to many prolonged applications, and much more data are needed in this arena. MEMS with built-in test capabilities are sometimes possible, and they are highly desirable for improved system-level reliability. The small size and low cost of MEMS devices make it possible to enhance system-level reliability by the use of redundant devices, which has also been done with microelectronics in satellites for a long time.

6.4 Diversity of MEMS Applications

The MEMS structures and devices that result from the sequence of design, simulation, fabrication, packaging, and testing can be classified into four major groups. The first includes **passive**, or **nonmoving, structures**. The second and third involve **sensors** and **actuators** that have micromechanical components. These are conceptually reciprocal: sensors respond to the world and provide information and actuators use information to influence something in the world. The fourth class includes **systems that integrate both sensors and actuators** to provide some useful function. This classification, like most, is imperfect. For example, some devices that are dominantly sensors have actuators built into them for self-testing. Air bag triggers are an example. However, the taxonomy provides a simple but quite comprehensive framework for considering MEMS devices.

The applications of MEMS are conveniently grouped according to major industries. This approach also raises questions. For example, should the transportation industry, which has very large components, (e.g., the automotive or aerospace industries) be considered as one entity or be subdivided into its units? Similarly, the communications industry embraces both fiber optic and wireless radio-frequency networks. It is simple and useful to group applications of MEMS as indicated in Figure 6.7. We will provide an overview of the types of MEMS in each of the four major categories, including details on particular applications in some of the large industries shown in the top of Figure 6.7.

6.4.1 MEMS: Structures

Immobile structures made by micromachining generally provide a means for guiding the motion of signals or fluids. Optical waveguides that channel photons along the surfaces of chips are a prime example. Waveguides for transmission of electronic signals at microwave frequencies are another. Channels in systems for the analyses of both gaseous and liquid samples are also micromachined structures with no moving parts. Microstructures find applications in the communications, analytical, and medical industries. Static structures integrated with electronics form the basis of infrared imagers that are of use in the transportation industry, for civilian security, and military operations. Because these imagers are sensors, they will be discussed in the next subsection.

Micromachining is already being used commercially to produce passive channels in microfluidics devices, in which control of the motion of the sample and reagent fluids is

accomplished by application of voltages or externally generated pressures. A few established and about 20 new companies are offering systems, such as the so-called "lab on a chip," for analysis of biomedical materials in research laboratories and for clinical medicine. These companies include Agilent, the formed Hewlett Packard division (which is teamed with Caliper Technologies), and newcomers, such as Aclara, Micronics, and Nanogen. Figure 6.8 shows a microfluidics substrate from Micronics. The approach to DNA, protein, and cellular analyses taken by these companies generally involves the use of small plastic or glass microfluidics systems for mixing of samples and reagents and for separations, in some cases. The microfluidic elements are inserted into desktop machines that provide other needed functions, such as power, control, and display. The microfluidic structures are disposable, so they avoid sample cross contamination. The small size of the key microfluidic elements raises the possibility of having entire handheld systems. This means that medical analyses can be performed immediately at the point of care rather than later at a central laboratory. Only very small samples (e.g., a drop of blood) are needed for microfluidic analyzer systems. Cephied, another microfluidics start-up, is designing a handheld blood analyzer containing micromachined fluidic elements.

6.4.2 MEMS: Sensors

Most MEMS sensors involve moving elements. However, detectors with no moving parts for sensing optical, infrared, and microwave signals are also made by micromachining. We will review important newly developed infrared sensor arrays before turning to the more familiar and already commercially successful micromechanical MEMS sensors.

The detection of infrared radiation with arrays of small elements enables night vision, which has numerous civil and military applications, especially for security and safety. Warm objects, such as humans and animals, emit infrared radiation. There are two basic approaches to imaging infrared radiation with arrays of small elements. The first involves cooling an array of narrow band-gap semiconductor elements to low temperatures to reduce the thermal noise level and allow measurement of weak thermal radiation. The second is to isolate the infrared absorbing element from surrounding solids that would couple energy from the element. Doing so involves etching away a sacrificial layer under each picture element (pixel), leaving it suspended by fine legs that conduct relatively little heat from the element. The legs are also the current paths used for measuring the resistance of the material on each element that absorbs infrared radiation. The associated heating, actually only a few one-thousandths of a degree, is enough to produce a measurable change in the resistance of the pixel. This MEMS approach has the tremendous advantage of not requiring a cooling system, so it is simpler and cheaper than semiconductor infrared detector arrays although it is not as sensitive to weak signals.

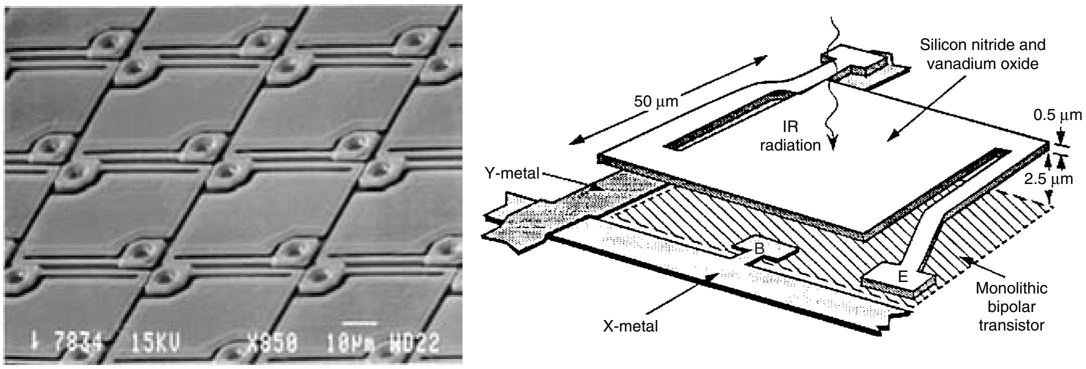

FIGURE 6.9 Honeywell Array and Schematic. This figure shows the scanning electron micrograph and schematic of the micromachined pixels in the Honeywell uncooled infrared imaging array. The sacrificial layer under the pixels was 2.5, micrometers thick. Figure adapted from Wood *et al.* (1993).

Honeywell and Raytheon developed uncooled, micromachined thermal imagers. Figure 6.9 includes both a micrograph of part of the Honeywell array and a schematic showing its construction. In the recent past, micromachined arrays of uncooled infrared detectors were incorporated into some Cadillac vehicles. The systems permit the driver to see the thermal images from people or animals in the road far beyond the range of the headlights.

Micromachined devices with moving parts are at the heart of most of the MEMS sensors already prototyped, many of which are in production. Basically, some condition, be it physical, chemical, or biological, induces motion in the MEMS device that can be sensed by any of several mechanisms. For example, resistive or capacitive sensing of the deflection of a thin, small membrane is used in various MEMS to measure pressure and ultrasound levels. The most important MEMS sensors detect pressure and acceleration; devices for measurement of angular rates are now moving to large-scale production, largely for automotive applications.

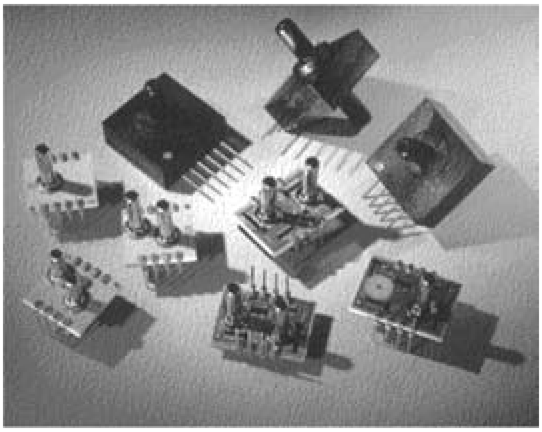

FIGURE 6.10 Pressure Sensors. Photograph of various micromachined pressure sensors from Silicon MicroStructures, now part of ORI Systems. Image courtesy of Novasensor.

MEMS pressure sensors cover a wide range of pressures and have very diverse applications. Commercial parts can measure pressures from about 1% of one atmosphere to over one thousand atmospheres. Figure 6.10 shows a variety of devices from one of several manufacturers. Two major areas of application are in the automotive and medical industries. MEMS pressure sensors are employed for measurement of the air pressure in engine manifolds, oil and fuel pressures, and the pressure in tires. Medical uses include the measurement of blood pressure. Medical applications are based on the fact that MEMS pressure sensors can be made cheaply and discarded after use to avoid contamination. Such measurements can be done on catheters inserted into the body because of the small size of the sensors or outside of the body when a needle and tube permit access to the internal blood pressure. Because MEMS pressure sensors are catalog items, they are available for a wide variety of uses, many of them well beyond the initially envisioned applications. They can be found in small weather stations, monitors for heating, ventilation and airconditioning systems, sensors for water and other fluid systems, and recreational engineering projects such as payloads for amateur rockets.

Microaccelerometers, like MEMS pressure sensors, have been on the market for several years, with well over 10 million sold annually. The first market for MEMS accelerometers was the automobile industry for air bag triggers. Initially, single axis devices were offered, and then two axis components became available. The next big application for the two-dimensional micro-accelerometers was in personal entertainment systems to detect the motion of joy sticks. Packaging of micro-accelerometers started with transistor cans. Next came surface mount packages, and leadless devices are now available. Figure 6.11 shows exterior of a two-axis accelerometer with a range of plus or minus twice-normal gravity and a micrograph of the chip. The integration of the single moving element and its associated electronics in and on the silicon substrate is note-

worthy. Figure 6.12 shows two other commercial microaccelerometers in which the manufacturers have used separate substrates for the electronic and mechanical elements. A remarkable feature of the available microaccelerometers is the very low mass, on the order of a microgram, for the moving element. A cube of water 100 μm on an edge weighs 1 μg! Despite this miniscule mass, the sensitive electronics enable the devices to measure a few one-thousandths of normal gravity. Prototype MEMS devices have measured accelerations exceeding 10,000 times normal gravity.

The microaccelerometers are the best example of MEMS components being employed for opportunistic applications. The ability to measure tilt has led to their incorporation into a sensor system for workers who have to lift heavy objects. If the person bends his or her back excessively while lifting, the system sounds a warning. MEMS accelerometers are being used by researchers in sleep studies. A glove equipped with such components on each finger is under development as a training aid for American Sign Language. Microaccelerometers are being used for studies of other motions of the human body, especially in sports. They are also being incorporated into sports equipment, including golf clubs and tennis racquets. Amateur scientists have used them to record accelerations during roller-coaster rides and to make backyard seismometers.

Integrated into the MEMS accelerometers from Analog Devices are capacitor structures that act as electrostatic actuators. When a voltage is applied to them, the moving part of the device deflects, which produces a signal similar to that generated by an input acceleration of a specific value. This feature enables a built-in test capability that allows the device to automatically assay its performance. This is an example of the melding of actuators into MEMS devices that are made for sensing.

6.4.3 MEMS: Actuators

There are many MEMS components whose primary function is to move some small structure to accomplish a useful function. The signals that cause such motion are entirely electronic in the case of electrostatic actuators. In some cases, electrical energy is first turned into thermal or magnetic energy to induce motion on the micrometer scale. Some MEMS actuators depend only on thermal effects. One type is based on the atomic-scale phase transformation of "shape memory" alloys that automatically assume a form given to them at one temperature when they are returned to that temperature. Whatever the physical origin of the small but effective forces in MEMS actuators, interesting and useful changes in positions of a micromechanical structure can result. Some of these will be discussed in the rest of this section.

MEMS and optical signals have a natural synergism. Many small mirrors for redirecting light beams and fine-scale diffraction gratings that can be dynamically reconfigured to analyze optical spectra have been demonstrated and are being manufactured. Micromechanisms with dimensions from a few to a few hundred micrometers are small enough to be moved easily by microactuators and large enough to manipulate small beams of light. In most cases of commercial interest, the actuation is accomplished by application of electrostatic forces to nearby parts in the MEMS device.

The first micromirror device to make it to market is also one of the most remarkable. It is called the digital mirror device (DMD) and made by Texas Instruments for display of images.

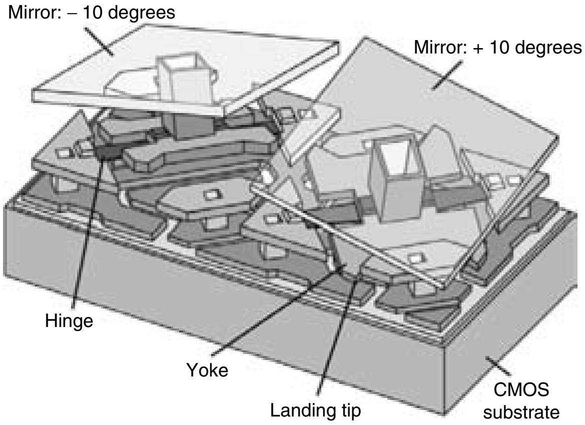

FIGURE 6.13 Drawing of Two Pixels of the Digital Mirror Device Manufactured by Texas Instruments. The torsional hinges are 5 by 1 μm in area and about 100 nms thick. The individual mirrors are 16 μm square. Over 500,000 of them are found in a single device, making this the system with the most moving parts produced in the history of mankind. The inventor, Larry Hornbeck, and the company received television Emmy Awards in 1998 for outstanding achievement in engineering development. Figure provided by Hornbeck (1993).

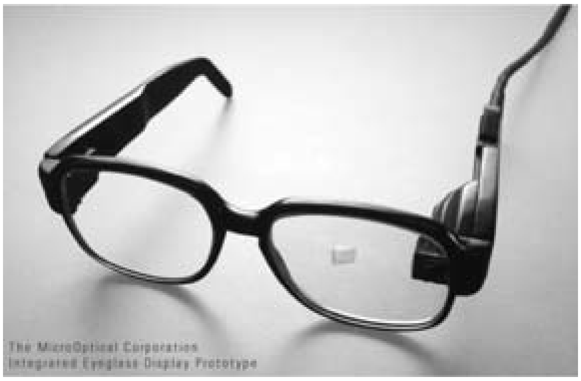
The operation can be understood with reference to the schematic shown in Figure 6.13. Each picture element of the DMD has three operational levels. The lowest is electronic. It contains the CMOS electronics that control the operation of the device by applying voltages that produce electrostatic forces on the movable elements. The second layer is mechanical. It has the torsional hinges that allow the mirror to be tipped 10 degrees one way or the other. The top layer is optical, consisting of the aluminized mirrors that reflect the light falling on it either into a beam dump or else through a projection system onto the screen. The light originates in a xenon arc lamp and then passes through a rotating red–green–blue filter that cycles at 60 Hz. During each color phase of each cycle, the mirrors tilt to pass light to the screen for no time, some time, or all of the time. This serves to adjust the relative brightness of each color during each cycle.

DMD have been incorporated into what are called display engines and sold to manufacturers of conference room projectors for several years. It is estimated that some tens of thousands of these display engines are sold annually. Texas Instruments has started testing their use in movie theaters. This will enable digital distribution of movies so that handling of celluloid rolls for distribution of movies to theaters will no longer be necessary. In the future, DMD might be employed in homes as a replacement for the large and heavy tubes in current television sets. The bright and high-resolution character of images displayed using DMD technology is attractive. The DMD, however, is in competition with other MEMS display devices and with liquid crystal display technologies.



The MicroOptical Corporation
Integrated Eyeglass Display Prototype

FIGURE 6.14 Prototype Integrated Eyeglass Display from MicroOptical Corporation. The mirror in the middle of one lens permits viewing of a video image produced in the structure on the left ear piece of the glasses. Image courtesy of MicroOptical.

Another very different optical display might be enabled by the small size and high performance of MEMS actuators. Figure 6.14 is a photograph of a prototype display integrated into a pair of eyeglasses. The video signal fed to the left earpiece produces a very small image that can be viewed by looking at the small mirror mounted in the center of the left lens. The wearer can look at the world in a normal manner through most of the lens or view dynamic colored images by looking at the mirror on the one lens. A two-dimensional MEMS scanning micromirror is a candidate technology for production of the image. This approach to a "heads-up display" is substantially lighter than its competitors. Repair personnel could view manuals while working on a system such as an automobile. Voice activation would be used for turning pages and enlarging the images of diagrams.

Micromirrors are also at the heart of optical signal routers for a coming generation of the Internet that will contain "all optical" components. Optical fibers can carry more than one hundred signals using different photon wavelengths ("colors"). Switching this flood of information requires converting the light signals for each color to electronic signals, manipulating them and regenerating light pulses for continued transmission down other fibers. The great advantage of MEMS mirrors for fiber network switches is that switching can be done entirely in the optical domain. There is no need to turn the optical signals into electrical signals for routing and then to produce other light pulses for further transmission. Hence, this is called "all optical" networking (even though the production and detection of the light bundles still involves electronics!). The MEMS approach is faster and requires less hardware. During the year 2000, because of the explosive growth of the Internet, six small MEMS companies were bought by suppliers of hardware for fiber communications systems. Two of them sold for $750 million, one went for $1.25 billion, and another sold for $3.25 billion (with all of these values in stock prices

for that time period). Clearly, there was exploding interest in MEMS components for fiber optic networks. Lucent Technologies has been one of the major developers of MEMS mirror switches for optical networks. The company's technology is shown in Figure 6.15. Lucent and other companies making switches to transfer optical signals from one fiber to another are field-testing programs. Major, indeed massive, usage of such switches might occur in the next few years.

The small actuators that result from MEMS technology are also useful for switching microwave-frequency electronic signals on chips. Micromechanisms can be employed to make tunable capacitors and resonators for manipulation of such signals. These technologies for the microwave and nearby frequencies are now under intense development and should come to market within a few years. Such devices are expected to have major impacts on wireless communication systems and short-range radars for automobile collision avoidance, among other products.

A wide variety of MEMS switch designs for high frequencies has been prototyped. In general, they have very low insertion losses (when closed) and excellent isolation (when open). Raytheon has developed a capacitively coupled switch, as shown in Figure 6.16. Rockwell has produced MEMS metal-to-metal switches as well as interdigitated capacitors for use in microwave circuits. The University of Michigan has the highest frequency MEMS resonators. A device based on a beam with both ends free (similar to a xylophone key) has exhibited resonance at 92 MHz. Its vibratory displacement is on the order of a nanometer. Other designs based on the expansion and contraction of disc-shaped structures were developed at the University of Michigan for operation at frequencies approaching 1 GHz. Few microwave MEMS devices are on the market now, but this situation will change markedly in the coming years because of the wireless revolution.

The final application of microactuators that deserves attention is in the field of microfluidics. Micrometer-scale actuators have been used to move pumps and valves in microfluidic systems. The small forces available from most MEMS actuators limit the pressures that can be developed and switched and also limit the flow rates, but the performance is adequate for small-scale analytical systems, notably the "lab on a chip."

6.4.4 Integrated MEMS: Systems

The last letter in MEMS stands for systems, which is appropriate because the MEMS device is quite complex in itself. MEMS

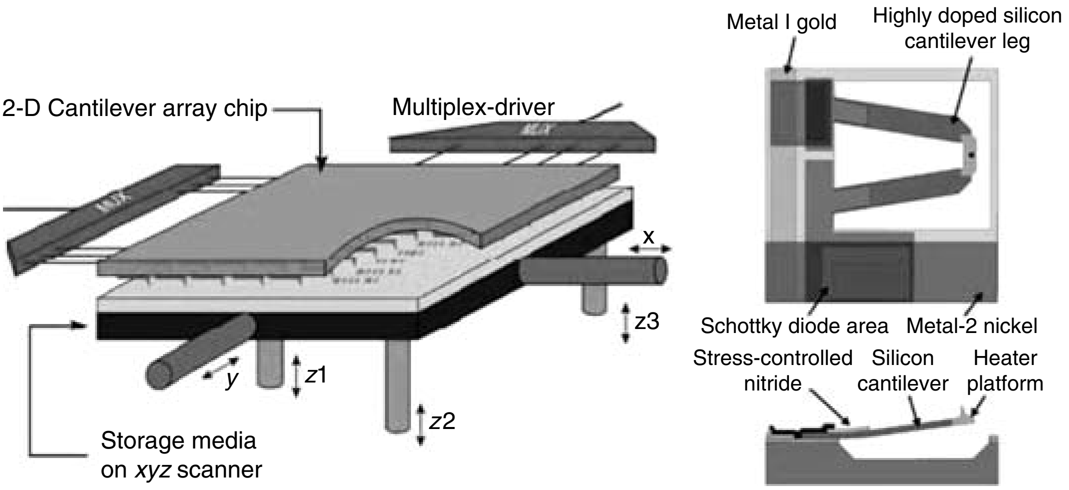

FIGURE 6.17 "Millipede" Data Storage Technology Developed by IBM. Schematic (left) of the electromagnetically actuated stage and recording media under an array of microcantilevers with fine tips for thermally recording and reading nanoscale bits of information. devices, however, are only components that are used in larger and more complex systems. That is, individual sensors or actuators can be used as components and incorporated into subsystems or systems to perform some useful function. The accelerometer in the air bag subsystem of an automobile and the DMD in a projection system in a theater are examples. It is also possible to closely couple both MEMS sensors and actuators into miniature systems all on one substrate. These are called "systems on a chip." Microfluidics with all the needed functionality on a substrate, including pumps and valves, as well as channels, mixers, separators and detectors, are under development for compact analyzers. These will be relatively evolutionary advances over current microfluidic chips. High-density data storage systems with both actuation and sensing functions represent a more revolutionary example of integrated microsystems.

In the last decade, it was shown that scanning instruments with very sharp tips could modify surfaces as well as make images of them, both on an atomic scale. The techniques involve the use of scanning tunneling or atomic force microscopes called **proximal probes.** The ability to make a dot with several atoms or molecules of a material (a bit) at a location on a surface raises the possibility of producing integrated MEMS devices that could store terabits of information in a square centimeter. Such a density would exceed the projected capabilities of magnetic storage. Hence, MEMS technology holds the possibility of displacing part of the giant hard disk market. Thousands of fine tips would be employed in a square centimeter. Each tip would be mounted on a micromachined and electrostatically actuated mechanism that can be independently scanned in two dimensions, as sketched in Figure 6.17. Tips would first write bits and later sense their presence or absence, analogous to the function of the magnetic head in a disk drive. The individual bits would have dimensions and spacings of a few molecular diameters. This nascent technology has been called **nanocuneiform** after the production of marks in clay tablets by people in Mesopotamia (at about 10 bits/cm^2). Methods for erasing bits are contemplated, so the MEMS data storage devices would be comparable in behavior to current magnetic media. This approach to data storage is being pursued by IBM and a few other companies. The initial MEMS data storage products would offer densities near 30 Gbits/cm^2. It is interesting that while an entirely new MEMS technology is being developed to displace disk drives, MEMS actuators could be incorporated into the arms in magnetic drives to give finer control of the read/write heads, which decreases the track spacing and increases storage density.

6.5 Summary

The variety of commercially available MEMS and their applications have both increased dramatically in recent years. The production of MEMS is now more than a 20-billion dollar industry worldwide, with about 100 million devices marketed annually. Although this industry grew out of the microelectronics industry, it is more complex in many important ways. Most fundamentally, it requires the integration of both microelectronics and micromechanics. Many MEMS involve several closely coupled mechanisms, some of which behave differently on the micrometer spatial scale than on familiar macroscopic scales. This complicates both the design and simulation of MEMS. Complications also arise from the much wider variety of materials and processes used to make MEMS compared to microelectronics. Because many MEMS have to be open to the atmosphere, their packaging, calibration, and testing are all complex. Questions about the long-term reliability of MEMS are being answered as MEMS devices spend more years in use by consumers and industries.

Despite such engineering challenges, MEMS offer high performance and are small, require low power, and are relatively cheap. They both improve on some existing applications and enable entirely new systems. Some of their applications are targeted from the outset of design, but others are opportunistic; that is, the large number of MEMS components on the market make them available to design engineers for a very wide variety of uses.

It is noteworthy that many large companies have strong positions in the manufacturing and use of MEMS. Several of them were mentioned in this chapter. Being a relatively new field, MEMS technology has also been the basis for the creation of many new companies, especially in the optical networking industry, a significant fraction of which have been bought by larger companies.

The transportation industry has benefited most from the availability of MEMS to date. The impact of MEMS on the analytical and medical industries has already been significant, and major growth in these arenas can be expected. The promises of optical MEMS in the fiber communication industry, and of RF MEMS in the wireless industry, have yet to be realized. Their impact on these communication modes, however, is only a matter of time and timing. Defense industries will similarly see ever increasing utilization of MEMS.

The entire field of MEMS has “turned the corner” in the past decade from gradual growth to rapid exponential growth. MEMS are not likely ever to be so important as integrated circuits. However, they will be a part of the fabric of life in the new century, embedded in many products owned by most people in technological societies.

Appendix: Books on MEMS

A great deal of information on the design, simulation, fabrication, packaging, testing, and applications for MEMS is available. Information can be found in journals, conference proceedings, and on the World Wide Web. In the past several years many books on MEMS have been published. They are listed in this Appendix. It is possible to group them by subject. This is complicated by the fact that some books cover several main subdivisions of MEMS. Hence, we content ourselves to list them chronologically by the year of their appearance.

Noise Analysis and Design in Deep Submicron Technology

7.1 Introduction

Traditionally, area minimization and speed maximization were the only axes with respect to which a design's effectiveness was measured. Low-power, high-throughput, and computationally intensive circuits are critical application domains (Rabaey and Pedram, 1996). In addition to these three design parameters, **area**, **speed**, and **power**, there are two design metrics that have been of great importance to current designs. These metrics are **noise** and **reliability**. The five metrics are shown in Figure 7.1 with an arrow associated with each to show whether the particular metric should be increased or decreased.

The current trend of technology scaling is predicted to continue. Feature sizes will continue to shrink to very deep submicrometer (VDSM) dimensions and clock frequencies to increase. Shrinking feature size implies not only shorter gate lengths but also decreasing interconnect pitch and device threshold voltages (Shepard and Narayanan, 1998). Now a single integrated circuit (IC) can contain an entire system (a system-on-a-chip [SOC]), and the interconnections can have many interleaved signal layers and multiple planes of interconnect. Die sizes remain relatively constant. Reduction in the top and bottom areas of a minimum-width wire means that total wire capacitance is decreasing. Resistance, however, is increasing faster, despite efforts not to scale metal thickness. Practical efforts to control resistor-capacitor (RC) delays through the use of low-resistivity metal (copper), low-dielectric-constant insulators, and wide, thick wiring will require future interconnection analysis to consider inductance and inductive coupling. It is projected that use of a lower resistivity metal (copper) and that replacement of silicon dioxide ($k \sim 4$) with various insulating materials of progressively lower dielectric constant ($k \sim 2 - 3$) will be adopted in the chip fabrication process. Use of copper will reduce degradation of signal propagation delay time due to voltage drop on power lines. Use of low k dielectric will decrease the degradation of signal propagation delay time by reducing capacitive coupling.

Although technology scaling results in lower threshold voltages, the threshold voltage magnitude determines noise immunity in these circuits.

7.1.1 Noise

The term **noise** in digital VLSI systems has come to mean any unwanted deviation in the voltages and currents at various nodes in a circuit. When noise acts against a stable logic level on a circuit node, it can transiently destroy logical information carried by the node. If this ultimately causes an incorrect

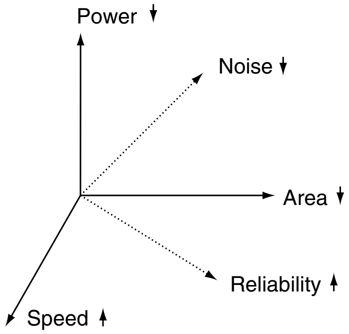

FIGURE 7.1 Design Metrics

machine state stored in a latch, functional failure will result. Even when noise does not cause functional failure, it has an impact on timing, affecting both delay and slew. Noise can also cause the dissipation of extra power due to incorrect switching.

Digital circuits create deterministic noise several orders of magnitude greater than noise from stochastic physical sources. Problems due to these noise sources were first observed in mixed signal applications that plunged highly noise sensitive analog circuits into a noisy digital environment. Although digital circuits create much more noise than analog circuits, digital systems are prevalent because they are inherently immune to noise. Figure 7.2 shows valid voltage ranges for defining the digital 0 and 1.

The inherent noise immunity of digital circuits is due to the presence of high-gain restoring logic gates such as the inverter shown in Figure 7.3, which has a very nonlinear voltage transfer characteristic. As power supply levels have decreased, however, this advantage has diminished. Thus, the problem of noise has increased in importance such that on-chip noise is the main research area for continuing the growth in integrated circuit density and performance.

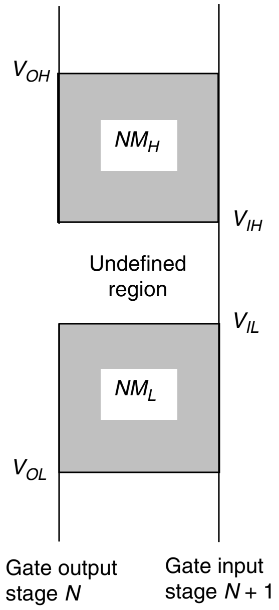

FIGURE 7.2 A Range of Analog Voltages Defining the Digital 0 and 1

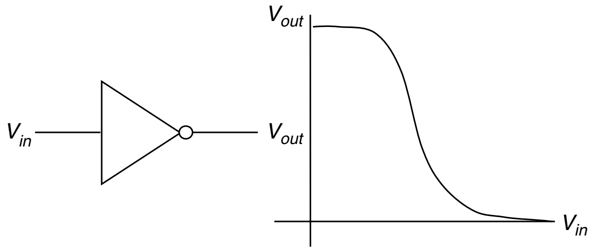

FIGURE 7.3 The Inherent Noise Immunity of Digital Circuits

With technology scaling, noise is a problem affecting all types of designs from custom microprocessors to standard-cell application specific integrated circuits (ASICs). A noise analysis solution must be capable of analyzing tens of millions of transistors, considering both circuit and interconnect noise, and evaluating the distinct noise tolerances of each node in the circuit. Successful design methodologies incorporate a three-level noise strategy. The first line of defense is a set of noise avoidance rules to guide circuit and interconnect design. These rules should prevent most noise problems without introducing too much area or timing constraints. Next, a detailed static noise analysis of the design should find all possible noise failures. Finally, careful circuit simulation should determine whether the design could tolerate some failures flagged by static noise analysis.

7.1.2 Reliability

One of the most important attributes of any system is its reliability. It is imperative to design reliability into complex chips even more carefully as the chip functionality increases almost without limit. This important issue was addressed by Kang (2000) with emphasis on incorporating reliability from early design phases rather than treating reliability assurance as a back-end manufacturing process. As computer-aided design (CAD) tools have played key roles in developing integrated circuits and systems, new reliability analysis tools need to be developed and used in SOC development. For more than a decade, new CAD capabilities have been developed with reliability focus, in particular to address reliability concerns about hot carrier-induced degradation of circuits, electromigration, electrostatic discharge (ESD), cross talk, leakage currents, and high-power dissipation.

It was also reported in the International Technology Roadmap for Semiconductors (Semtech, 1999) that computer-aided design (CAD) tools would need to incorporate contextual reliability considerations in the design of new products and technologies. It is essential that advances in failure mechanism understanding and modeling, which result from the use of improved test methodologies, be used to provide input data for these new CAD tools. With these data and smart reliability CAD tools, the impact on product reliability of design selections can be evaluated. New CAD tools need to be developed that can calculate degradation in electrical performance of the circuit over time. The inputs used would be the predicted resistance increases in interconnect wires and vias in the circuit based on the following:

- Wire length
- Current densities expected for the currents required by the circuit
- Calculated local operating temperature, which includes the effects of joule heating in the circuit element and elsewhere

These tools will need to become an integral part of the circuit designer's tool set to help predict product reliability before processing begins and to develop solutions that anticipate technology and thereby accelerate their introduction.

7.2 Noise Sources

Serious on-chip electrical problems are being encountered in deep submicron (DSM). These problems include signal distortion along coupled interconnect lines, voltage variations in the power supply distribution, substrate coupling, charge sharing, charge leakage, process variation, thermal noise, and alpha particles. Each one is a major source of on-chip noise in VLSI circuits.

7.2.1 Interconnect Crosscapacitance Noise

Interconnect crosscapacitance noise refers to charge injected in quiet wires (victims) by neighboring switching wires (aggressors) through the capacitance between them (crosscapacitance). The resulting noise has the form of a pulse in which the leading edge is determined by the switching slew of the aggressor, and the trailing edge is determined by the restoring time constant of the victim. This is perceived to be the most significant source of noise in current processes (see Figure 7.4). If the net is a dynamic node, the restoring time is infinite, and the node will never recover. It can lead to setup violations in downstream latches or flip-flops. In addition, when the aggressors are switching in the same direction of the victim, the transport delay and slew decreases, leading to hold-time violations.

7.2.2 Charge Sharing Noise

Charge sharing noise is caused by charge redistribution between a dynamic evaluation node and intermediate nodes in pull-up or pull-down logic stack, as in Figure 7.5. This primarily impacts domino nodes, weakly driven pass gate latches, and dynamic latches. The primary technology variable here is the ratio of junction capacitance to gate and interconnect capacitance. For most circuits, this noise is not dramatically changing with technology scaling.

7.2.3 Charge Leakage Noise

Charge leakage noise is mainly composed of subthreshold conduction in nominally off transistors. This current can either charge/discharge a dynamic node or cause the stable state of a weakly held node to be significantly different from rails. This is mainly a concern for wide domino NOR, PLA, and memory arrays. This current rises exponentially with reduction in the threshold voltage and is becoming very significant in DSM. It is helped greatly by feedback devices.

7.2.4 Power Supply Noise

Power supply noise is the difference between the local voltage references of the driver and the receiver. The increased amount of current on power supply lines causes a raise in IR drop on voltage references. This makes the gate have higher sensibility to noise spikes. This low frequency component (IR drop) is managed well by flip-chip C4 packaging, which provides a very low resistance current path. Besides, the higher speed transients allowed by scaled transistor sizes are associated to higher *L di/dt* due to the large inductances of the package and on-chip. Furthermore, the decoupling capacitance of the circuit is decreased due to the reduced sizes of the gates. Power supply noise is a dominant factor in the design of wide domino circuits and in circuits using contention where the alternating current (ac) logic level is shifted with respect to power supply rails. To counter these problems in high-speed designs, several physical design techniques have been proposed: (1) sizing up the P/G lines to accommodate the large current peaks and to minimize the IR and *L di/dt* voltage variations in these lines (Su *et al.*, 2000), (2) increasing the number of P/G pins, and (3) deploying decoupling capacitors in the P/G lines (Bakoglu, 1990; Zhao *et al.*, 2001). In addition, a designer could perform clock skew scheduling to minimize the number of simultaneous switching (Lam *et al.*, 2002). He or she could also use copper in place of aluminum to overcome the increased resistance of scaled interconnect.

7.2.5 Mutual Inductance Noise

Mutual inductance noise occurs when signal switching causes transient current to flow through the loop formed by the signal wire and current return path (Intel, 2001), thereby creating a changing magnetic field (see Figure 7.6). This induces a voltage on a quiet line, which is in or near this loop. These noise sources can be cumulative if there are several signals switching simultaneously in a bus. Mutual inductance is a long-range phenomenon and hence is worse in the presence of wide busses. High-speed switching and synchronous bus structures are making this noise very significant in current technologies. Inductive noise can combine with capacitive noise to cause even worse noise than that shown in Figure 7.6. Because the analysis of inductive effects is highly dependent on layout and is quite complex, the approach is usually to design the problem out through rules rather than analyze arbitrary configurations.

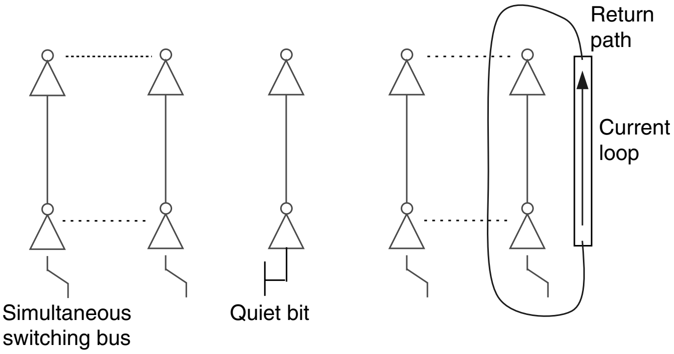

FIGURE 7.6 Mutual Inductance Noise From Simultaneous Switching on a Wide Bus

7.2.6 Thermal Effects

Thermal effects are an inseparable aspect of electrical power distribution and signal transmission through the interconnects due to self-heating (or joule heating) caused by the flow of current. Thermal effects impact interconnect design and reliability in the following ways. First, they limit the maximum allowable RMS current density (since the RMS value of the current density is responsible for heat generation) in the interconnects to limit the temperature increase. Second, interconnect lifetime (reliability), which is limited by electromigration (EM) (transport of mass in metals under an applied current density), has an exponential dependence on the inverse metal temperature. Hence, temperature rise of metal interconnects due to self-heating phenomena can also limit the maximum allowed average current density because EM capability is dependent on the average current density (Liew *et al.*, 1990). Third, thermally induced open-circuit metal failure under short-time high peak currents (including ESD) is also a reliability concern (Banerjee *et al.*, 1997) and can introduce latent EM damage that has important reliability implications (Banerjee *et al.*, 1996). It has been argued that thermal effects will increasingly dominate interconnect design rules that specify maximum current densities for circuit designers (Chatterjee *et al.*, 1995). Recently, Hunter (1997) has followed up on this issue by solving the EM lifetime equation for Al-Cu and the ID heat equation in a self-consistent manner. In this approach, both EM and self-heating can be comprehended simultaneously.

7.2.7 Process Variation

The typical characteristics of a process like the gate oxide process can vary among wafers or even on a single die. The devices and their properties are defined only in a certain margin and, hence, affect the performance of the circuit.

7.3 Noise Reduction Techniques

Noise reduction techniques can be categorized into four main categories: **signal-encoding schemes**, which have been proposed to minimize transition activities on buses; **circuit techniques** to make circuits more immune to noise; **interconnect structures techniques**, which are changing the interconnect topology, wire sizing and spacing, and buffer locations; and

high-level synthesis techniques. Of course, a designer can also overcome noise by using new materials in interconnect, including fiber optics or electromagnetic transmission and three-dimensional interconnects that use multiple levels of active devices. New packaging methodologies can also be used to reduce noise (Sematech, 2001).

The most common techniques for reducing noise in digital circuits include disallowing:

- Pass gates at the ends of long wires
- Long wire runs feeding domino gate inputs
- Single *n*-FET or *p*-FET pass gates because of the V_t voltage drop they cause
- High-beta static circuits feeding low-beta static circuits or vice versa

7.3.1 Signal Encoding Techniques

Increased coupling effect between interconnects in ultra deep submicron technology not only aggravates the power-delay metrics but also deteriorates the signal integrity due to capacitive and inductive cross talk noises. Conventional approaches to interconnect synthesis are aimed at optimal interconnect structures in terms of interconnect topology, wire width and spacing, and buffer location and sizes (Cong, 1999).

Signal encoding schemes have been proposed to minimize transition activities on busses while ignoring crosscoupled capacitances. When statistical properties are unknown a priori, the bus-invert method (Stan and Burleson, 1995) and the on-line adaptive scheme (Benini *et al.*, 1999) can be applied to encode randomly distributed signals. On the other hand, highly correlated access patterns exhibit a spatiotemporal locality that can be exploited for energy reduction (Panda and Dutt, 1996) in Gray code (Mehta *et al.*, 1996; Su *et al.*, 1994), the TO method (Benini *et al.*, 1997), the working-zone encoding (Musoll *et al.*, 1998), the combined bus-invert/TO (Benini *et al.*, 1998), and the coupling-driven method (Kim *et al.*, 2000). Lower bounds for minimum achievable transition activity have been derived for noiseless busses in (Ramprasad *et al.*, 1999) and for noisy busses in Hegde and Shanbhag (1998). In Zhang *et al.*, (1998), a segmentation method was introduced to reduce power consumption. Specification transformation approaches have also been used to reduce the number of memory accesses at the behavioral level (Catthoor *et al.*, 1994). The effectiveness of various encoding schemes was compared at the system level by Fornaciari *et al.* (1999).

Bus-Invert Encoding

The **bus-invert encoding** has been introduced to reduce the bus activity: the encoding is derived from the Hamming distance between the consecutive binary numbers. If the Hamming distance of the two consecutive binary numbers is more than half of the word length, the latter binary number is sent in inverted polarity by asserting an additional signal line that indicates bus inversion (Stan and Burleson, 1995). The number can be used to reduce the weight (the number of ones or zeros) of the binary numbers if the bus-inversion decision is made when the weight is more than half of the bus width. The bus-invert method is as follows:

1. Compute the Hamming distance (the number of bits in which they differ) between the present bus value (also counting the present invert line of Figure 7.7) and the next data value.
2. If the Hamming distance is larger than $n/2$, set invert equal to 1 (and thus make the next bus value equal to the inverted next data value).
3. Otherwise let the invert equal 0 (and make the next bus value equal to the next data value).
4. At the receiver side, the contents of the bus must be conditionally inverted according to the invert line unless the data are not stored encoded as they are (e.g., in a RAM). In any case, the value of the invert must be transmitted over the bus (the method increases the number of bus lines from n to $n+1$).

The **Gray code** has only a 1-bit difference in consecutive numbers for addressing. Due to locality of program execution, Gray code addressing can significantly reduce the number of bit switches. Experimental results show that for typical programs running on an RISC microprocessor, using Gray code addressing reduces the switching activity at the address lines by 30 to 50% compared to using normal binary code addressing.

In **TO** Encoding, the bus transitions are reduced by freezing the address lines when consecutive patterns are found to be sequential. An extra bus line is employed to inform the receiver side regardless if the current pattern is sequential.

The basis of the **working zone encoding** (WZE) technique is as follows:

1. The WZE takes into account the locality of the memory references: applications favor a few working zones of their address space at each instant. In such cases, a reference can be described by an identifier of the working zone and by an offset. This encoding is sent through the bus.
2. The offset can be specified with respect to the base address of the zone or to the previous reference to

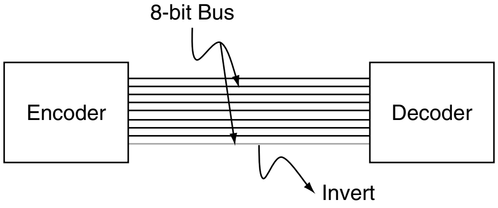

FIGURE 7.7 Invert Signal in Bus-InvertMethod

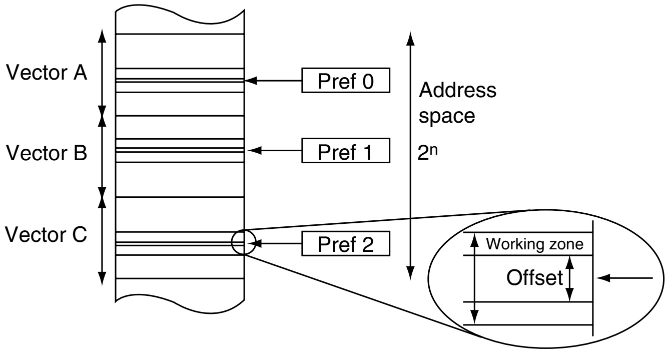

FIGURE 7.8 Address Space for Three Vectors. Adapted from Musoll *et al.* (1998). © 2004 IEEE.

that zone. Because all small offsets should be encoded in a one-hot code, the latter approach is the most convenient. As a simple example, consider an application that works with three vectors (A, B, and C) as shown in Figure 7.8. Memory references are often interleaved among the three vectors and frequently close to the previous reference to the vector. Thus, if both the sender and the receiver had three registers (henceforth named p) holding a pointer to each active working zone, the sender would only need to send:

a. The offset of the current memory reference with respect to the one associated with the current working zone
b. An identifier of the current

To reduce the number of transitions, the offset is encoded in a one-hot code. Because the one-hot code produces two transitions if the previous reference was also in the one-hot code and an average of $n/2$ transitions when the previous reference is arbitrary, using a transition-signaling code reduces the number of transitions (Musoll *et al.*, 1998).

Coupling-Driven Signal Encoding

The key idea in **coupling-driven signal encoding** is that transforming the signal sequences traveling on-chip busses that are closely placed could alleviate coupling effects (Kim *et al.*, 2000). Small blocks of encoding and decoding logic are employed at the transmitter and receiver of on-chip busses as shown in Figure 7.9.

There are four types of possible transitions when dynamic charge distribution is considered over cross coupling capacitances as in Figure 7.10. Two parallel wires are placed with minimum spacing. A type I transition occurs when one of the signals switches while the other stays unchanged such that the cross coupling capacitance is then charged up to $k_I C_x V$, where the coefficient k_1 is introduced as a reference for other types of transition. In a type II transition, one bus switches from low to high while the other switches from high to low. The effective capacitance will be larger than k_1 by a factor of k_2, the value of which is usually $k_2 = 2$. In a type III transition, both signals switch simultaneously, and C_x will not be charged. Because of possible misalignment of the two transitions, however, the amount of power consumption varies according to the dynamic characteristics by a factor of k_3. In a type IV transition, there is no dynamic charge distribution over cross coupling capacitance. Thus, k_4 is set to zero.

There are some assumptions. First, synchronous latches are located at the transmitter side, thus all the transitions take place at the same time on the bus. The simultaneous transitions exclude type III transitions by setting $k_3 = 0$. The achieved results are on the lower end of power savings. Second, statistics on the information source are not given in advance. Hence, this scheme is suitable for data bus encoding, where it is difficult to extract accurate probabilistic information offline. An enumeration method is employed to represent the coupling effect. If a bus line Bi is located between two other lines, a signal transition on B_i can trigger charge shifts on both coupling capacitances connected to B_{i-1} and B_{i+1}, respectively. In other words, two couplings can be initiated at most by a

signal transition. Thus, 2(N-1) bits are sufficient to represent the whole set of couplings in an N-bit bus per bus cycle. According to the types of correlated transition between neighboring busses, the coupling encoder generates a codeword as follows: 00 for a type III or IV transition, 01 for a type I transition, and 11 for a type II transition. The reason 11 is assigned to a type II transition is that switchings in different directions require the change in polarity of the charge stored in the coupling capacitance, hence consuming about twice the amount of charge required for a type I transition. The codeword 11, instead of 10, helps to make a decision on data inversion using a majority voter because the majority voter outputs high when at least eight input lines are high out of fifteen inputs. The majority voter can be implemented by using either full-adder circuitry or resistors and a voltage comparator. The control signal inv can be transmitted to the receiver using extra bus lines or extra transfer cycles. One problem of additional bus lines for control is the area overhead that may not be allowed due to physical constraints. In some cases, widening the space between signal bus lines can reduce the coupling effects more effectively than introducing extra control lines because the coupling capacitance is inversely proportional to net space. Temporal redundancy is an alternative and uses extra clock cycles to transfer control signals.

7.3.2 Circuit Techniques

One way to effectively increase noise immunity is to increase the switching threshold voltage V_{th} of the gate. V_{th} is defined as the input voltage at which the output changes state. Increasing the V_{th}, on the other hand, has an adverse effect on the performance, such as on speed and power consumption, which are the prime features of dynamic circuits.

Gated-Vdd Technique

Gated-Vdd is used to decrease the leakage power. The key idea for gated-Vdd (Powell *et al.*, 2000) is to introduce an extra transistor in the supply voltage (Vdd) or the ground (Gnd) path as in. The extra transistor is turned on in the used section and off in the unused section gated. It maintains the performance and advantages of low-power supply and threshold voltages while reducing leakage and leakage energy dissipation. The fundamental reason for the reduction in leakage is the stacking effect of self-reverse-bias series-connected transistors. However, the transistor impacts the switching speed due to a nonzero voltage drop across the gated-Vdd transistor between the supply rails and the "virtual Gnd" for NMOS gated Vdd (Figure 7.11) or the "virtual Vdd" for PMOS gated-Vdd.

Dual Threshold Technique

Dual threshold technique (Kao and Chandrakasan, 2000) is used to reduce leakage power by assigning high threshold voltage to some transistors in noncritical paths and using low threshold transistors in critical paths. To achieve the best leakage power savings under target performance constraints, an algorithm is presented for selecting and assigning an optimal high threshold voltage. Results show that dual threshold technique is good for power reduction.

Dynamic Threshold Technique

Dynamic threshold MOS (DTMOS), as noted by Fariborz *et al.* (1997), is a scheme that allows for a self-adjusting threshold voltage. By tying the gate to the body, the threshold voltage decreases as the gate voltage increases and vice versa. In this manner, a higher zero-bias threshold can be used to reduce the leakage current. In a speed-adaptive threshold-voltage CMOS (SA-Vt CMOS) circuit miyazaki (1998) the substrate bias is controlled so that delay in the circuit stays constant. Distributions of device speeds are squeezed under fast-operation conditions. With a ring oscillator using 0.25-mm CMOS devices as a test circuit, the worst-case operating frequency was improved from 20 MHz to 55 MHz, and the fluctuation of the operating frequency was suppressed from 44 to 15%; the supply-voltage variation was under 0.1 V with a 1.8-V supply voltage.

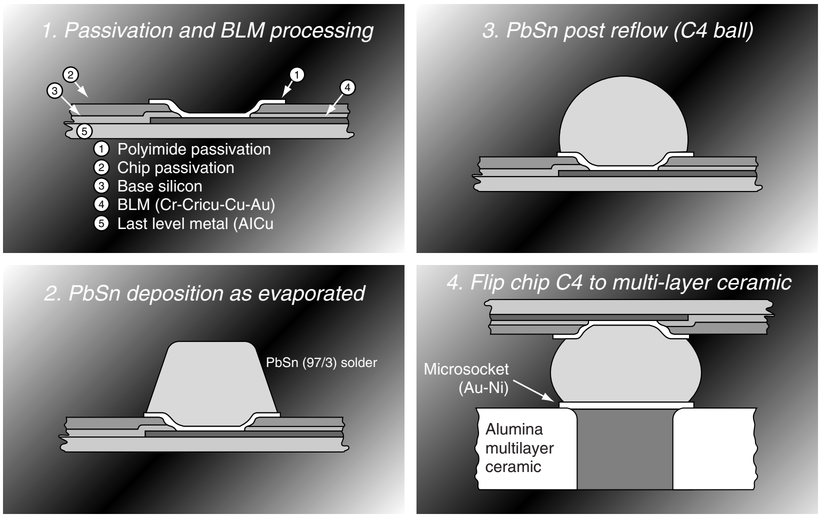

FIGURE 7.12 C4 Flip-Chip

C4 Flip-Chip

The **C4 flip-chip** is used to manage the IR drop. IBM researchers developed C4 technology in the 1960s (see Figure 7.12). The bonding process is characterized by the soldering of silicon devices directly to a substrate (e.g., organic). The chip faces the substrate as opposed to wire bonding, hence the name flip-chip bonding. There are two main salient features of this packaging methodology. One involves solder bumps that are distributed on metal terminals of the chip itself. These solder bumps are typically composed of 97% lead and 3% tin. The substrate has identically placed metal pads on its surface. The second feature is that the chip is turned over and the metal pads are aligned to solder bumps; metal reflow is used to form connectivity between the substrate and chip.

The advantages of C4 technology are numerous and important. They include (comparisons refer to wire bonding):

- Increased *I/O* density (C4 bumps may be placed over the entire area of the chip, called area array, rather than simply the periphery)
- Self-aligning process step (due to surface tension)
- Reduced die size for previously pad-limited designs
- Reduced simultaneous switching noise due to smaller inductance of bumps compared to wire leads
- Better thermal properties as the backside of the wafer is now available for heat sinking
- Much better power distribution capabilities as circuits in the middle of the die can now access Vdd/Gnd directly
- Low cost and high throughput (all connections for one chip are made simultaneously in C4 as opposed to one-by-one in wire bonding)
- Shorter wire lengths and fewer global wires ease wiring requirements

The main drawbacks to C4 regard the use of lead in the solder bumps that lead to the emission of alpha particles, which, in turn can lead to circuit failure in sensitive circuits such as DRAMs. Restricting the placement of solder bumps over these sensitive areas' however, can minimize this effect. Research is ongoing to find alternate materials for solder bumps as well. In addition, the use of C4 packaging allows designers to do many different things in the floor planning and routing stages of a design. Commercial tools for place-and-route and other such designs are predicated on the use of peripheral wire bonding for *I/O* pads. New tools need to be in place for designers to take full advantage of flip-chip's advantages.

Pseudo-CMOS

Pseudo-CMOS, shown in Figure 7.13, provides the logic capability of Domino and the noise robustness of CMOS.

PMOS Pull-Up Technique

The **PMOS pull-up technique** (DiSouza, 1996) (as shown in Figure 7.14) uses a pull-up device to increase the source

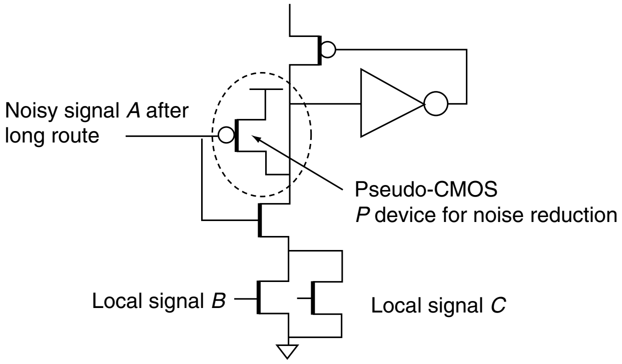

FIGURE 7.13 Pseudo-CMOS

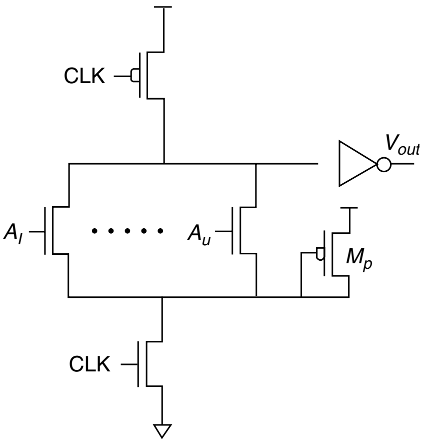

FIGURE 7.14 The PMOS Pull-Up Technique

potential of the NMOS network, thereby increasing the transistor threshold voltage V_t and V_{st} during the evaluate phase. This technique suffers from large-static power dissipation.

CMOS Inverter Technique

The **CMOS inverter technique** (Covino, 1997) uses a PMOS transistor for each input, thereby adjusting V_{st} to equal that of a static circuit. This technique cannot be used for dynamic NOR-type circuits because certain logic combinations will short V_{dd} to Ground (GND).

The Mirror Technique

The **mirror technique** (Wang and Shanbhag, 1999) (see Figure 7.16) uses two identical NMOS evaluation networks and one additional NMOS transistor M_1 to pull up the source node of the upper NMOS network to $V_{dd} - V_t$ during the precharge phase, thereby increasing V_{st}. The mirror technique guarantees zero dc power dissipation, but a speed penalty is incurred if the transistors are not resized.

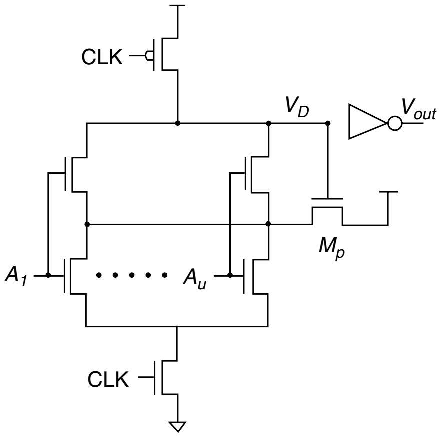

FIGURE 7.16 The Mirror Technique. Adapted from Wang and Shanbhag (1997). © 2004 IEEE.

The Twin Transistor Technique

The **twin transistor technique** (see Figure 7.17) uses an extra transistor for every transistor in the pull-down network to pull up the source potential (Balamurugan and Shanbag, 1999, 2000). The twin transistor technique consumes no dc power.

7.4 Noise Analysis Algorithms

Some amount of noise is unavoidable in digital circuits. The question concerns whether the noise causes function failure.

7.4.1 Small-Signal Unity Gain Failure Criteria

Traditional analysis of noise margins rely on the **small-signal unity gain** failure criteria [4]. As illustrated in Figure 7.18, for a small change in input noise to a circuit biased at an operating point, the resultant change in output noise is measured. If |*d*

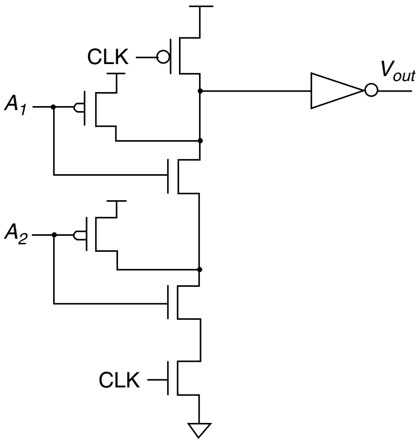

FIGURE 7.15 The CMOS Inverter Technique. Adapted from Covino (1997).

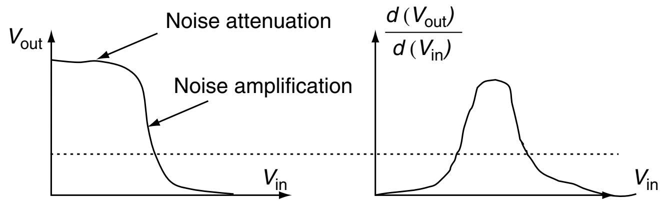

FIGURE 7.18 Direct Current Transfer Function of an Inverter Illustrating Small-Signal Unity Gain

(output)/d (input)| > 1 then the circuit is considered unstable. Unity gain is a good design metric but is neither necessary nor sufficient for noise immunity.

Most aggressively designed paths have some noise-sensitive stages interspersed with quiet stages. Some noise amplification needs to be allowed in the sensitive stage because it should be attenuated in the quiet stage.

7.4.2 Intel Failure Criteria

In this subsection, guidelines and steps followed by Intel in determining a circuit failure are listed.

- Break the circuit into circuit stages.
- Track the noise propagation across these stages by ac circuit simulation.
- Measure if any circuit stage failed because of the following:
  - Injected noise
  - Noise propagated from previous stages
- Noise can propagate across any number of stages, eliminating the need for any unity gain budgeting.
- Combination of noise sources and simultaneous noise on multiple inputs should be considered.
- The peak noise in the event of two simultaneous couplers on a line is larger than the sum of these two events.
- The simultaneous occurrence of different parallel inputs have to be considered.
- New transistor level (symbolic circuit) simulation should be found because SPICE is very slow.
- Solving the differential equation symbolically in a piecewise linear manner can decrease the CPU time needed with good accuracy.

7.4.3 Design Flow

The traditional design flow in Figure 7.19 (Sylvester and Keutzer, 1998) contains a separation between the logic synthesis step and the physical design step. For designs with aggressive performance goals, Sylvester and Keutzer (1998)

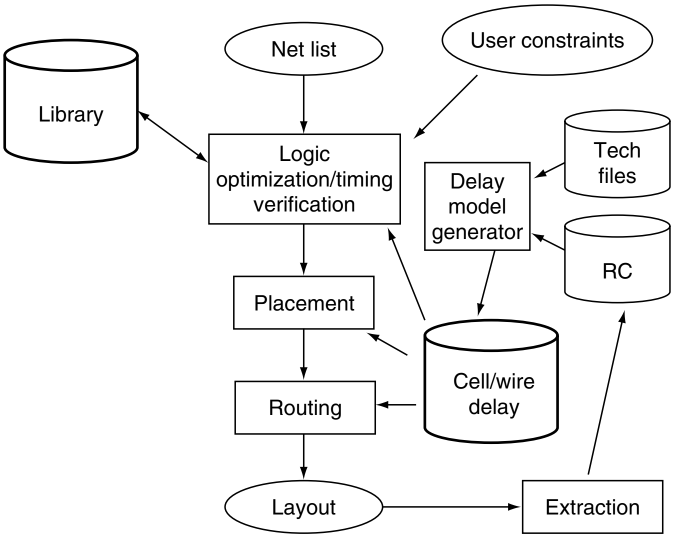

FIGURE 7.20 Today's High-Performance Logical/ Physical Flow. Adapted from Sylvester and Keutzer (1998). © 2004 IEEE.

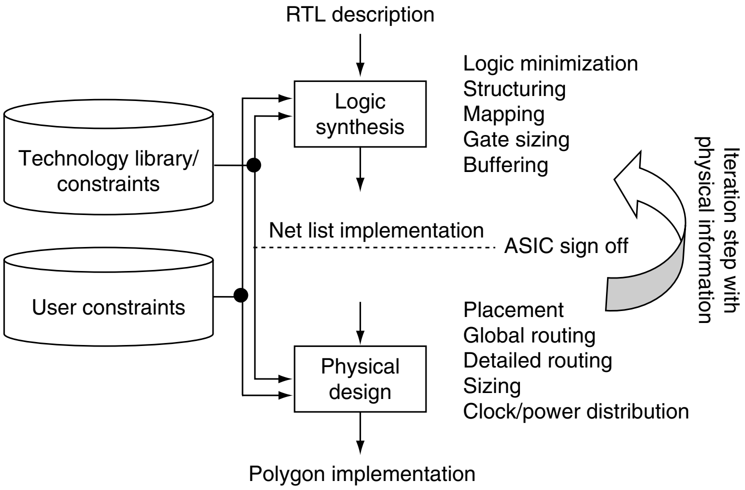

FIGURE 7.19 Traditional ASIC Design Flow

found that several iterations between synthesis and physical design are required to converge to a desired implementation.

As a result, design teams have begun to bring more of the backend design flow in-house, and the handoff to the semiconductor–vendor occurs only at the end. This approach is shown in Figure 7.20 and is known as the customer-owned tooling (COT) approach.

Interconnect Noise Analysis and Optimization in Deep Submicron Technology

8.1 Introduction

The current trend of technology scaling is predicted to continue. Feature sizes will continue to shrink and clock frequencies will continue to increase. Shrinking feature size implies not only shorter gate lengths but also decreasing interconnect pitch and device threshold voltages (Shepard and Narayanan, 1998). The total wire area capacitance will decrease due to the reduction of the areas of a minimum-width wire. Resistance, however, is increasing faster despite efforts not to scale metal thickness. Moreover, the crosscoupling capacitance between neighboring wires will increase due to the decrease in spacing between wires. The expectation for the die sizes is to remain constant in spite of the feature size shrinking. This is due to the integration of more functionality on a single chip. Practical efforts to control RC delays through the use of a low-resistivity metal (copper), low-dielectric-constant insulators, and thick wiring that is wide will require interconnection analysis to consider inductance and inductive coupling. Figures 8.1 and 8.2 show the difference between older silicon technology and the current deep submicron technology.

The function of interconnects or a wiring system is to distribute clock and other signals and to provide power/ground to and among the various circuits/systems functions on a chip. Current leading-edge logic processors have seven to eight levels of high-density interconnect, and current leading-edge memory has three levels (Sematech, 1999). There are three types of wiring to distribute the clock and signal functions (local, intermediate, and global). Local wiring, consisting of very thin lines, connects gates and transistors in an execution unit or a functional block (such as embedded logic, cache memory, or address adder) on the chip. Local wires usually span a few gates and occupy first and sometimes second metal layers. Intermediate wiring provides clock and signal distribution in a functional blocks with typical lengths up to 3 to 4 mm. Intermediate wires are wider and taller than local wires to provide lower resistance signal/clock paths. Global wiring provides clock and signal distribution between the functional blocks and delivers power/ground to all functions on a chip. Figure 8.3 shows the delay of local and global wiring in future generations. Repeaters can be incorporated to mitigate the delay in global wiring but consume power and chip area (Sematech, 1999).

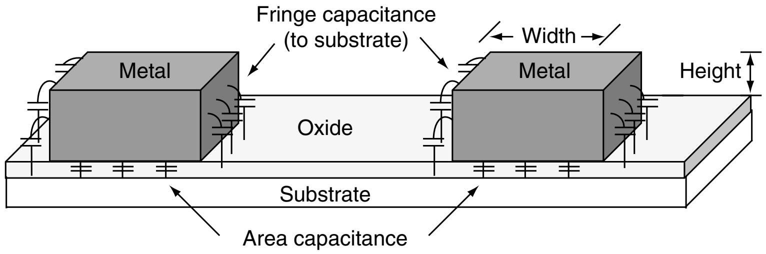

FIGURE 8.1 Older Silicon Technology. Adapted from Synopsys (1999).

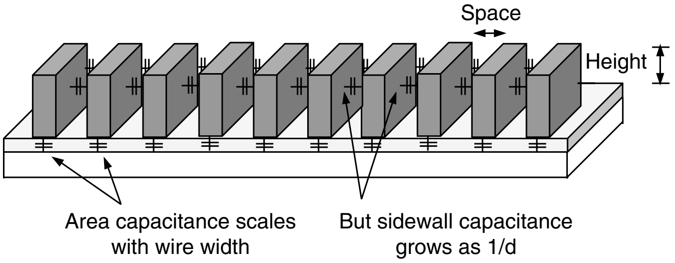

FIGURE 8.2 Deep Submicron Technology. Adapted from Synopsys (1999).

In the long term, new design or technology solutions (such as coplanar wave guides, free space RF, and optical interconnect) will be needed to overcome the performance limitations of traditional interconnect (Sematech, 1999). Inductive effects will also become increasingly important as frequency of operation increases, and additional metal patterns or ground planes may be required for inductive shielding. As supply voltage is scaled or reduced, cross talk has become an issue for all clock and signal wiring levels; the near term solution adopted by the industry is the use of thinner metallization to lower line-to-line capacitance. This approach is more effective for the lower resistivity copper metallization, for which reduced aspect ratios (A/R) can be achieved with less sacrifice in resistance

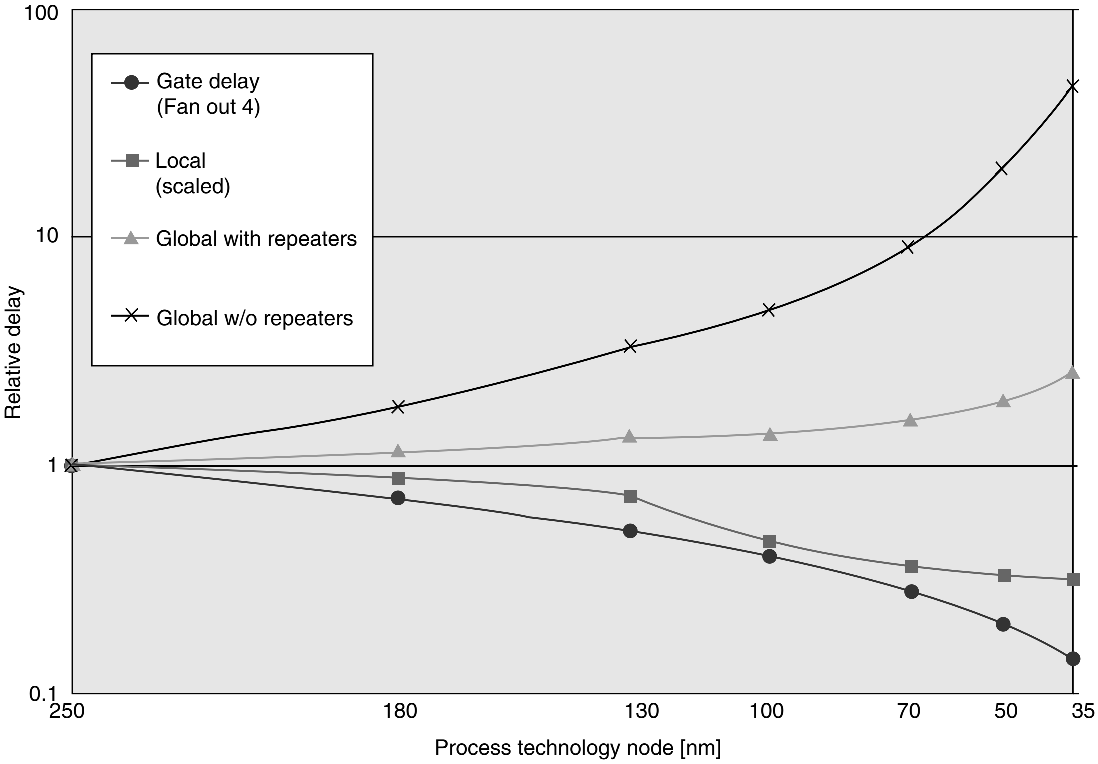

FIGURE 8.3 Delay for Local and Global Wiring Versus Feature Size. Adapted from Sematech (1999).

as compared with aluminum metallization. The 1999 Roadmap [25] reflects this design trend by featuring reduced aspect ratios (as an alternative means of reducing capacitance) and less aggressive scaling of a dielectric constant.

With technology scaling, noise is a problem affecting all types of designs from custom microprocessors to standard-cell application-specific integrated circuit (ASICs). A noise analysis solution must be capable of analyzing tens of millions of transistors, considering both circuit and interconnect noise, and evaluating the distinct noise tolerances of each node in the circuit.

In this chapter, we survey new trends for interconnect synthesis and optimization techniques. We emphasize interconnect delay and noise models, techniques and algorithms to optimize them, and advantages and drawbacks of each. Finally, we focus on which area we can extend our research.

8.2 Interconnect Noise Models

Analytical expressions are preferred in analyzing interconnect noise because simulation is always expensive and ineffective to use with designs containing millions of transistors and wires. Analytical expressions, however, are not sufficiently accurate and do not consider all of interconnect and driver parameters. Different design stages have different requirements for accuracy of modeling interconnect cross talk noise effects. Many studies have been conducted to model metal lines and cross talk effects. For the purpose of the timing verification, ideal ground-based RC or RLC-distributed-circuit models for interconnect lines have been widely used (Sakurai). The conventional ideal RC or RLC transmission line model of the IC interconnects without considering that the following detailed physical phenomena are not accurate enough to verify the picosecond level timing of high performance VLSI circuits (Woojin *et al.*, 2000). These phenomena are the **silicon substrate effect**, the **skin effect**, and the **proximity effect**.

Most of the research efforts have been focused on developing formulas for the peak noise pulse amplitude. The pulse width of the cross talk noise and the peak noise occurring time, which are of similar importance for circuit performance as the peak amplitude, should also be considered. Since digital gates are inherently low-pass filter, they can filter out noise pulses with high amplitude provided that the noise pulse width is sufficiently narrow. Dynamic noise-immunity metrics, such as the noise-immunity curve (NIC), are required (Elgamel *et al.*, 2002).

8.2.1 Lumped Interconnect Model

The interconnect analytical model could be categorized into two categories: lumped and distributed models. In the lumped model, the total capacitance and resistance values are used. Figure 8.4 shows a simple coupling circuit structure with one victim and one aggressor. This is not the practical case because there is always more than one aggressor coupled to the victim line. The lumped capacitance model for this circuit is shown in Figure 8.5. In this model, each pulling resistance, R_v or R_a, is composed of the line resistance and the driver resistance. The load capacitances, C_a and C_v, consist of the line capacitance and the gate capacitance of the load driven by the line. C_m is the coupling capacitance between the two wires. Most of the papers about modeling cross talk noise published in the earlier years belong to this category (Vittal and Marek-Sadowska, 1997; Pillage and Rohrer, 1990; Cong *et al.*, 2000; Kahng *et al.*, 1999). In deep submicron technology, lumped models are no longer capable of satisfying the accuracy requirements and considering some parameters like the coupling location.

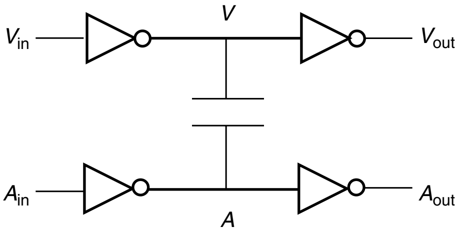

FIGURE 8.4 A Simple Coupling Circuit Structure

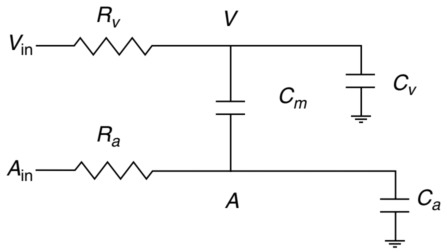

FIGURE 8.5 Capacitive Coupling Model (for the Circuit in Figure 8.4)

8.2.2 Distributed Interconnect Model

Distributed coupled RC(L) tree structure models become necessary even for the early design stages. Many papers addressed this problem (Vittal and Marek-Sadowska, 1999; Davis and Meindl, 2000; Kuhlmann and Sapatnekar, 2001). The distributed π, 3π, and 4π models have been used in (Kahng *et al.*, 1999, 2001; Murat *et al.*, 2002), respectively. We describe the π model in Figure 8.6.

In Figure 8.6, C_{Lv} and C_{La} are the victim and the aggressor load capacitances respectively. R_{dv} and R_{da} are the victim and the aggressor drivers modeled by resistances. C_{c1} and C_{c2} are the coupling capacitance between the two wires distributed to the beginning and the end of the wires. C_{v1}, C_{v2}, C_{a1}, and C_{a2} are the distributed area capacitances for the victim and aggressor wires respectively. In the 4π model found in Becer

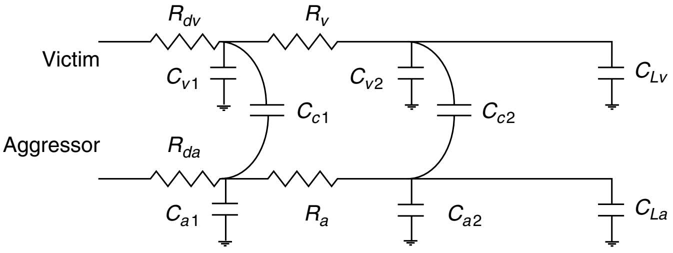

FIGURE 8.6 Interconnect Distributed π Model (for the Configuration in Figure 8.4)

et al. (2002), the users stated that their model is a complete analytical cross talk noise model that incorporates all physical properties including victim and aggressor drivers, distributed RC characteristics of interconnects, and coupling locations in both victim and aggressor lines.

8.2.3 Interconnect Modeling Issues

Some issues need to be considered while modeling the cross talk noise: the **input signal shape**, **number of pins in a net**, **net topology**, and the **driver modeling**. These issues have been discussed in some papers (Sapatnekar, 2000; Vittal and Marek-Sadowska, 1999; Sirichotiyakul *et al.*, 2001).

The nonlinear behavior of the victim driver gate during the transition should be captured (Supamas *et al.*, 2001). The industrial noise analysis tool, ClariNet, has considered this issue. Results on industrial designs were presented to demonstrate the effectiveness of this tool with an 8% error compared to SPICE simulations.

It has been emphasized that the exact functional form used to estimate the capacitance and the delay is not important. The only requirement that the delay model must satisfy is that an increase or decrease in the coupling capacitance should be translated into an increase or reduction in the delay of a net (Sapatnekar, 2000).

Expressions for cross talk amplitude and pulse width in resistive, coactively coupled lines should hold for nets with arbitrary number of pins and topology under any specified input excitation as explained by Vittal and Marek-Sadowska (1999). These authors claim that the magnitude of inductive coupling is small in the presence of good ground return paths close to signal lines. They used their expression in formulations aimed at reducing cross talk. These methods included transistor sizing, wire ordering, wire width optimization, and wire spacing. They failed to get success in some of these formulations. For wire ordering, Vittal and Marek-Sadowska (1997) proposed a new heuristic since they did not report results for this work.

The characteristics that make someone prefer one model over another include the model's operational speed and accuracy. Depending on the design stage, different accuracies and speeds are needed.

8.3 Noise Minimization Techniques

8.3.1 Buffer Insertion

For long interconnects, wire sizing or spacing, explained in following subsections, are not sufficient to limit the interconnect delay. So, buffer insertion is used to trade-off the active device area for reduction of interconnect delays. The additional inserted buffers increase the overall gate delay. Thus, there is an optimal number of repeaters that should be inserted into an RC line to minimize the overall propagation delay (Ismail and Friedman, 2001). This trend is qualitatively illustrated in Figure 8.7. During the routing of global interconnects, macroblocks form useful routing regions that allow wires to go through but forbid buffers to be inserted. They give restrictions on buffer locations. The buffer location restrictions have been taken into consideration and the simultaneous maze routing and buffer insertion problem have been solved in polynomial time (Zhou *et al.*, 2000).

8.3.2 Wire Sizing

It is known that proper wire sizing can effectively reduce the interconnect delay especially in deep submicron or nanometer designs when the wire resistance becomes significant. An optimal wire-sizing algorithm was developed by Cong and Leung (1993) and Cong *et al.* (1993) for a single source RC interconnect tree to minimize the sum of weighted delays from the source to timing-critical sinks under the Elmore delay model. Cong *et al.* (1997) designed an efficient approach to perform global interconnects sizing and spacing (GISS) for multiple nets to minimize interconnect delays with consideration of coupling capacitance as well as area and fringing capacitances. In that paper, they proposed an asymmetric wire-sizing scheme where they could asymmetrically widen or make more narrow the areas above and below the centerline of the original wire. The optimal wire sizing and spacing problem for a single net with fixed surrounding wire segments can be solved by adapting the bottom-up dynamic programming (DP)-based buffer insertion and wire-sizing algorithm proposed by Lillis *et al.* (1996).

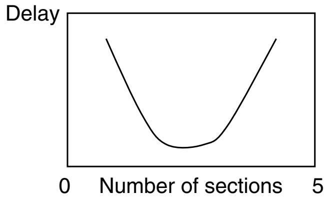

FIGURE 8.7 Relationship Between the Number of Sections of an RC Line and the Total Propagation Delay

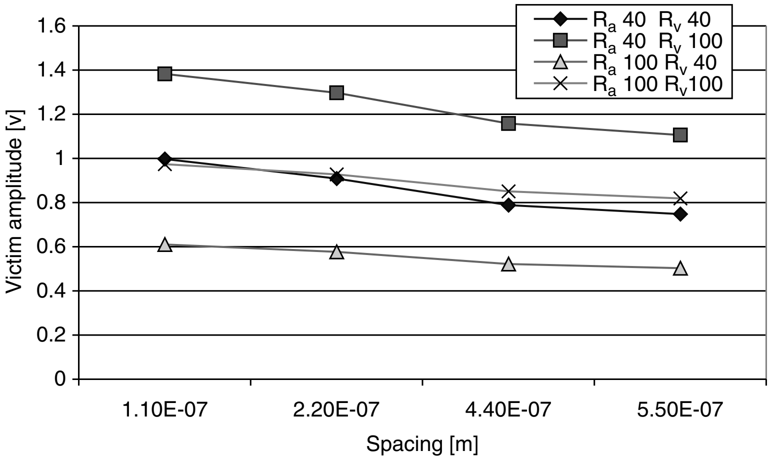

FIGURE 8.8 Victim Amplitude Versus Spacing (Different *Rs*). Adapted from Mohamed *et al.* (2003).

8.3.3 Wire Spacing

Wire spacing can decrease the cross coupling capacitance value effectively (Mohamed *et al.*, 2003). Figure 8.8 shows that as the spacing between wires increases, the peak noise decreases. The noise relatively decreases faster for a small R_a (aggressor driver resistance). Moreover, it is clear that sizing up the victim driver (scaling R_v down) reduces peak noise, where R_v is the victim driver resistance.

For example, the postlayout spacing heuristic in work by Chaudhary *et al.* (1993) proposed a postlayout graph-based spacing algorithm. The framework spaces out wires after detailed routing has been finished. The cross talk effect is based on cross talk voltage glitches because they do not consider the delay. The cross talk effect from driver to sink is simply the superposition of all glitches of wires along the path. The potential disadvantage of this greedy operation is the poor use of space resources around a timing-critical wire.

In Tseng *et al.* (1998), the graph-based optimizer preroutes wires on the global routing grids incrementally in two stages—net order assignment and space relaxation. The timing delay of each critical path is calculated while taking into account interconnect coupling capacitance. The objective is to reduce the delays of critical nets with negative timing slack values by adding extra wire spacing.

8.3.4 Shield Insertion

Shield insertion is another technique for decreasing cross talk. It simply adds a power or a ground line between already existing wires. These power lines act like shields and can isolate between wires. Figure 8.9 shows the effect of adding shields of different sizes on the noise amplitude. As the shield width increases, the noise amplitude decreases. The result is an effective technique specially made to eliminate inductive noise; however, it consumes more area.

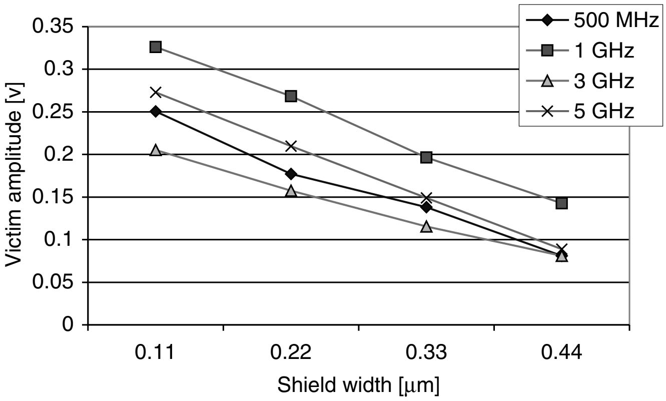

FIGURE 8.9 Noise Amplitude Versus Shield Width at Different Frequencies

The existing net ordering formulations to minimize noise are no longer valid with presence of inductive noise, and shield insertion is needed to minimize inductive noise (He and Lepak, 2000). He and Lepak (2000) formulate two simultaneous shield insertion and net ordering (SINO) problems: (1) the optimal SINO/NF problem to find a min-area SINO solution that is free of capacitive and inductive noise and (2) the optimal SINO/NB problem to find a min-area SINO solution that is free of capacitive noise and is under the given inductive noise bound. They claimed that this work was the first presenting an in-depth study on the simultaneous shield insertion and net ordering problem to minimize both capacitive and inductive noises. The drawbacks of this work are the consideration for having the same wire lengths and the consideration that the appropriate sensitivity matrix is given a priori. In addition, this matrix required an overhead, and He and Lepak (2000) did not mention the complexity or how to build this matrix. They developed four approximate algorithms for solving the SINO/NB problem: greedy-based shield insertion (SI) algorithm, net ordering for minimizing C_x noise followed by SI algorithm (NO+SI algorithm), graph-coloring based SINO algorithm (SINO/GC algorithm), and simulated annealing based SINO algorithm (SINO/SA algorithm). They solved the SINO/NF problem by using the SINO algorithms and setting the noise bound to zero. Note that the SINO/SA always performs the best for any given setting. Lepak *et al.* have extended this work by considering the RLC model.

8.3.5 Network Ordering

It has been shown that signal ordering can effectively reduce the cross talk noise on interconnects. In other words, arranging signals in an order that does not let a wire fight against its neighbor, making a transition in the same direction, can reduce the cross talk noise. For example, two interconnect layout design methodologies for minimizing the cross-coupling capacitance effect in the design of a full-custom data path have been proposed by Yim and Kyung (1999). These are the **control-signal ordering scheme** and the **track assignment algorithm**. Figure 8.10 shows how the control signal for a multiplexer can be ordered to decrease the cross talk effect.

An evolutionary programming approach was used in the track assignment algorithm to minimize the total number of tracks used. Yim and Kyung (1999) proposed an **evolutionary programming-based track assignment** (*EPTA*) algorithm considering both length and switching activity. They showed that the solution quality of EPTA is quite good, and the converging speed is very fast when compared with SA and GA. More than anything else, EPTA does not require an annoying genetic operator design, which makes the implementation of EPTA very easy.

8.4 Interconnect Noise in Early Design Stages

In the current design flow, interconnect optimizations are mainly used in postlayout stages (Chang, 2000). As the global interconnects are largely determined by floor planning, it becomes critical for floor planning engines to be able to handle efficient interconnect planning and optimizations so that the overall timing and design convergence can be achieved. Due to the inherent complexity of the interconnect driven floor planning (IDFP) problem, designers use multistage, adaptive cost functions in IDFP to gradually consider more interconnect optimization, planning, and/or global routing features. Using the adaptive cost functions gives designers flexibility to tune for different design objectives and to trade-off between performance and run time. They use a simulated annealing algorithm to achieve this flow.

The primary goal of Sylvester and Keutzer (2000) was to examine global interconnect effects and determine if there were any significant road blocks that would prevent National Technology Roadmap for Semiconductors (NTRS) performance expectations from being met. Their analysis revealed that due to global RC delays as well as time-of-flight considerations, the global clock would necessarily be slower than the achievable local clock frequency. In addition, they found that cross talk at the global level would not be as significant as at the local level due to the use of large repeaters—their capacitance would dampen the effects of coupling capacitance. Sylvester and Keutzer (2000) proposed a wiring hierarchy that complemented the modular design methodology that they proposed in 1998. This modular methodology proposed the use of 50,000 to 100,000 gate modules of logic to eliminate the impact of interconnect at the local level. These modules are arranged together in isochronous (or locally clocked) regions, which run at a higher clock speed than the global clock. These isochronous regions come together to form the entire design.

Cong *et al.* (2001) presented a multilayer gridless detailed routing system for deep submicrometer physical designs. Their detailed routing system used a hybrid approach consisting of two parts: (1) an efficient variable-width variable-spacing detailed routing engine and (2) a wire-planning algorithm providing high-level guidance as well as rip-up and reroute capabilities. They used a nonuniform grid graph, which has proven to guarantee a gridless connection of the minimum cost in multilayer variable-width and variable-spacing routing problems. They suggested further improving their wire-

planning algorithm and fine-tuning of rip-up and rerouting algorithm.

An integer linear programming (ILP) formulation that yields tight bounds on the quality of the achievable wire-packing solution was formulated by Kay and Rutenbar (2001). The input to cross talk-aware wire packing is composed of a set of wires, a set of variable tracks (per layer), and a cross talk graph XG that determines forbidden wire adjacencies. The output is a legal assignment such that no forbidden adjacencies and no electrical shorts exist, as shown in Figure 8.11. The key technical insight is to model all constraints (both geometric and cross talk conflicts) as cliques in an appropriate conflict graph; these cliques can be extracted quickly from the interval structure of the slice.

Kastner and Sarrafzadeh (2001) developed methods to reduce interconnect delay and noise caused by coupling. The coupling-free routing (CFR) takes a set of nets and tries to find a one-bend coupling-free routing for a subset of nets. A routed net must not be coupled with any other routed net. These authors defined **coupling** as a Boolean variable, which is appropriate when the coupling is greater than some threshold. They developed an exact algorithm for the CFR decision problem via a transformation to 2-satisfiability (2SAT). This algorithm runs in linear time. Kastner and Sarrafzadeh (2001) also presented the implication graph that models the dependencies associated with CFR. Moreover, they developed an algorithm for the maximum coupling-free layout (MAX–CFL) problem. Given a set of nets, the **MAX–CFL** is defined as finding a subset of nets that are coupling-free routable. The subset should have maximum size and/or criticality. This algorithm is the implication algorithm. In addition, Kastner and Sarrafzadeh (2001) presented the coupling capacitance between two wires i and j as follows:

$$C_c(i,\ j) = \frac{f_{ij} \cdot l_{ij}}{d_{ij}} \frac{1}{1 - (w_i + w_j/2d_{ij})},$$

where w_i and w_j are the sizes of wires i and j ($w_i,\ w_j > 0$), f_{ij} is the unit length fringing capacitance between wires i and j, l_{ij} is the overlap length of wires i and j, and d_{ij} is the distance from the center line of wire i to the center of wire j. Because the nets are routed at most one bend, they have minimum wire length. In addition, coupling-free routing minimizes the coupling of the routed nets.

It has been shown that the delay of a wire of length l increases at the rate of $O(l^2)$ without wire sizing, $O(l\sqrt{l})$ with optimal wire sizing, and linearly with proper buffer insertion (Cong and Pan, 1999). The criticality function can easily be changed to incorporate some other functions.

8.5 Case Study Pentium 4

8.5.1 Interconnect Delay and Crosscapacitance Scaling

The interconnect problem has become significant enough to require entire architectural pipe stages in the Pentium IV processor for interconnect communication (Intel, 2001). At the circuit level, widespread use of repeaters has become necessary. To avoid degrading interconnect resistance, the vertical dimension of metals has scaled very weakly compared to the horizontal dimension, leading to extremely high height and width aspect ratios (2-2.2) (see Figure 8.12).

Nowadays, the crosscoupling capacitance between parallel neighboring wires, which can get routed together for long distances, is gaining great importance compared to the self-capacitance wires. The crosscoupling can either lead to a large increase in delay, coupling noise, min delay, or power consumption problems, depending on the switching direction of neighboring wires. Avoiding these delay and noise problems would involve drastically increased wire spacing or extensive shielding. Further, studies on both the Pentium III and Pentium IV processor floor plans have clearly shown that they tend to be interconnect-limited for die area, which increases the penalty for spacing and shielding. Thus, there is a fundamental design trade-off between a simple, robust wiring solution employing extensive spacing and shielding versus an aggressive solution employing short wiring with only judicious shielding leading to high density. The latter requires sophisticated CAD tools, has more risks, but ultimately is much more optimal for a high-volume product. It was therefore the choice for the Intel Pentium IV processor (Intel, 2001).

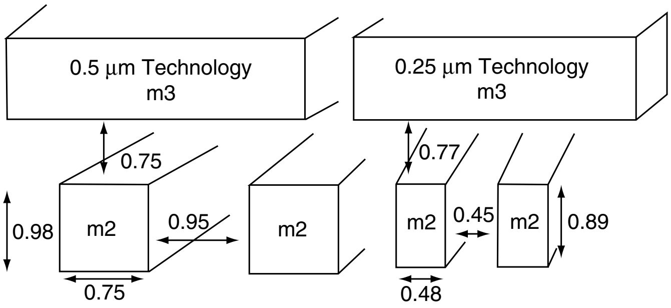

FIGURE 8.12 Wire Aspect Ratio Scaling with Technology. Adapted from Intel (2001).

8.5.2 Wire and Repeater Design Methodology for the Pentium 4 Processor

Delay, noise, slope limits, and gate oxide wear out were all considered by Intel designers when drafting the guidelines for the wire and repeater methodology. Notable features were an increased emphasis on noise robustness and "pushed process" considerations for delay (repeater distance guidelines were made shorter than optimal for delay with the existing process in anticipation of end-of-life process trending when transistors greatly speed up compared to wires). Repeater sizing, rather than best delay optimization for noncoupled wires, was picked to be optimal for noise rejection, for equal rise and fall delays, and for better delay in the presence of coupling. Stringent limitations were put on maximum sizing of repeaters, especially in busses, to reduce collapse of power supply caused by a simultaneously switching bank of repeaters. The methodology and tools allowed Intel developers to use both inverting and noninverting repeaters. Simple length-based design rules were provided for repeaters, and further optimization was possible through internally developed proprietary tools: NoisePad, ROSES, and Visualizer (net routing and timing) analysis. The extensive use of dedicated repeater blocks is evident in the Pentium 4 Processor floor plan. Further, the net length comparison in Figure 8.13 shows that although the Pentium 4 Processor is a much larger chip, it has very few long nets compared to the previous generation of chips, such as the Pentium III Processor. This is even more notable given that the Pentium 4 Processor has more than twice as many full-chip nets as the Pentium III Processor and has architecturally bigger blocks. If we compare the M5 wire segments of the Pentium III and Pentium 4 processors, we note that 90% of the M5 wire segments of the Pentium 4 processor are shorter than 2000 microns, while the same percentage of Pentium III Processor wires are 3500 microns long. These short wires are a key to enabling high-frequency operation.

In the past half century, the world of microelectronic and information techonlogies has experienced a breathtaking and revolutionary evolution—50s semi-conductor, 60s integrated circuits, 70s microprocessor, 80s DSP/FPGA/ASIC processors, 90s multimedia multi-processors, to SoC for ubiquitous computing necessary for the ever-more-connected information world in the 21st century. Subsequently, the field of *digital systems and computer engineering* has also experienced a fast change driven by the devices' technological advances. The performance of digital systems requires integration of system architecture, programming systems, and application. While it is not unusual to have as many as 100 ALU's per chip today, the Moore's law is not directly applicable to performance improvement, which needs also parallelism-friendly software in order to match the hardware speed-up. To this end, chapters related to both computer architecture and sotware programming systems are collected in this section to achieve comprehensive and balanced coverage.

Chapter 1, "Computer Architecture," by Morris Chang, provides an introduction to computer architecture, including microprogramming, memory hierarchy in computer systems, and input and output systems. A computer system consists of processor(s), main memory, clocks, terminals, disks, network interface, and input/output devices. The power of computation can be maximized via a systematic and seamless integration of hardware cores, operating systems, and application softwares. Throughout the 70s, microprogramming computer architecture design was the most dominant approach, and it had a fundamental influence on early development of computing systems. In general, the hierarchy of systems using microprogramming is divided into application softwares, operating systems, machine language, microprogramming, and physical devices. Since the early 80s, the ever-increasing processing power offered by VLSI technology (as governed by the Moore's law) has fundamentally changed the computer design concept. The popularity of reduced instruction set computing (RISC) has virtually eliminated the need for microprogramming. More generally, computer architectures have undergone a rapid change driven by the VLSI, deep-submicron, and nanoscale device technologies.

Chapter 2 is "Multiprocessors," by Peter Y. K. Cheung, G. A. Constantinides, and Wayne Luk. Multiprocessors are categorized by Flynn into SISD (single instruction single data), SIMD (single instruction multiple data), MISD (multiple instruction single data), and MIMD (multiple instruction multiple data) machines. The chapter addresses fundamental issues such as how multiple processors share data, how cache memories on different processors maintain their data correctly, and how multiple processors coordinate with each other. In addition, the following two performance goals of multiprocessor system are explored: (l) increased throughput for independent tasks distributed among a number of processors, and (2) faster execution of a single task on multiple processors. The organization and programming language for the multiprocessor systems vary significantly, depending on the goal.

Chapter 3, "Configurable Computing," by Wayne Luk, Peter Y. K. Cheung, and Nabeel Shirazi, first presents an overview of configurable computing technology and then describes methods for reconfiguration, tools for configurable designs, and the automatic detection of reconfigurable regions. In particular, it covers an efficient approach to exploit run-time reconfigurability. FPGAs have become the favored choice in implementing glue logic, experimental systems, and hardware prototypes due to their clear advantages in user reconfigurability, short turnaround time, and low development costs.

In Chapter 4, "Operating Systems," by Yao-Nan Lien, the hardware core of a basic computer system, which consists of processor(s), memory, and peripheral devices is presented. It is often tedious to write programs that keep track of all these hardware components. The operating system is software, which controls all the computer's resources and provides the base on which the application programs can be written. The operating system puts a layer of software on top of the bare hardware, manages all parts of the system, and presents the user with an interface or virtual machine that is easier to understand and program. The operating system can be viewed as a set of software extensions of primitive hardware, culminating in a virtual machine that serves as a high-level programming environment and manages the flow of work network of computers. Modern operating systems also provide numerous services, such as interprocess communication, file and directory systems, data transfer over networks, and a command language for invoking and controlling programs. In addition to the basic concept on operating systems, the chapter further explores a model operating system as well as two exemplifying operating systems: Unix and MS-DOS.

Chapter 5, "Expert Systems," by Yi Shang, covers four fundamental topics in expert systems—knowledge representation, model- and case-based reasoning, knowledge acquisition, and explanation of solution. An expert system is a computer program that represents and uses knowledge of one or more human experts to provide high-quality performance in a specific domain. Expert systems offer a number of benefits when compared with human experts. They are inexpensive to operate, easy to reproduce and distribute, and can provide permanent documentation of the decision process. Most importantly, expert systems can produce consistent results on the same tasks and handle similar situations consistently.

Two chapters (Chapters 6 and 7) are devoted to emerging topics on multimedia systems. Multimedia data, such as text, audio, images and video, are rapidly evolving as main avenues for the creation, exchange, and storage of information. Rapid advances in VLSI technology have made cost-effective processing of extremely high-volume multimedia data as well as efficient storage and communication over high-bandwidth networks possible. Chapter 6, "Multimedia Systems: Content-Based Indexing and Retrieval," by Faisal Bashir, Shashank Khanvilkar, Ashfaq Khokhar, and Dan Schonfeld, addresses multimedia (image and video) storage and encoding standards (JPEG, MPEG, H.26.X) and explores many multimedia indexing and retrieval techniques. Chapter 7, "Multimedia Networks and Communication," by Shashank Khanvilkar, Faisal Bashir, Dan Schonfeld, and Ashfaq Khokhar, offers comprehesive coverage of many key topics, such as multimedia networks and communication, including multimedia expectations (including real-time characteristics, multicasting support, security, and mobility support, etc.); best-effort internet support for distributed traffic requirements (including service models; integrated and differential services etc.); enhancing the TCP/IP protocol stack to support functional requirements of distributed multimedia applications; and quality of service architecture for third generation cellular systems.

Chapter 8, "Fault Tolerance in Computer Systems from Circuits to Algorithms," by Shantanu Dutt, Federico Rota, and Franco Trovo, starts with a discussion on fundamental issues in fault tolerance and dependability, then it further treats a broad range of fault-detection and fault-tolerance methods with potential applications to field-programmable gate arrays, program control-flow, and processor systems. The ubiquitous use of digital systems in all areas of human endeavor and the decreasing feature sizes of VLSI/ULSI technologies make it important to incorporate fault tolerance mechanisms into modern computer systems.

Chapter 9, "High-Level Petri Nets Extensions, Analysis, and Applications," by Xudong He and Tadao Murata, presents analysis techniques for several extended Petri net models, explores specific system properties, such as performance, reliability, and schedulability, and describes their benefits for many applications in computer science disciplines. Petri nets provide a formal model for concurrent and distributed systems.

1.1 Microprogramming

In 1951, Maurice Wilkes suggested the notion of designing a three-level computer to simplify the hardware. Prior to his suggestion, computers used a two-level approach in which level 1 was for programming (also known as the instruction set architecture [ISA] level) and level 2 was for digital logic. In Wilkes's proposed design, an unchangeable interpreter (the microprogram) was introduced to execute the ISA level program by interpretation. Since microprograms have a smaller instruction set than ISA level programs, the number of hardware components needed was greatly reduced. During the 1970s, the microprogram was the most dominant approach in system design. Nowadays, the popularity of reduced instruction set computing (RISC) has virtually eliminated the need for microprogramming. The basic hierarchy of systems using microprogramming is illustrated in Figure 1.1.

Microprogramming is usually located in read-only memory (ROM), directly controls physical devices, and provides a cleaner interface to the machine language. It is actually an interpreter, fetching the machine language instruction, such as ADD, MOVE, and JUMP, and carrying the instruction out as a series of little steps. To carry out an ADD instruction, for example, the microprogram must determine where the numbers to be added are located, fetch them, add them, and store the result somewhere. The set of instructions that the microprogram interprets defines the machine language, which is not really part of the hard machine at all, but computer manufacturers always describe it in their manuals.

Microprogramming designs the control as a program that implements the machine instructions in terms of simpler microinstructions. Each microinstruction defines the set of data path control signals that must be asserted in a given state. The microprogram is a symbolic representation of the control that will be translated by a program to control logic. In this way, one can choose how many fields a microinstruction should have and what control signals are affected by each field. The format of the microinstruction should be chosen to simplify the representation, making it easier to write and understand the microprogram. For example, it is useful to have one field that controls the ALU and a set of three fields that determine the two sources for the ALU operation as well as the destination of the ALU result. In addition to readability, the microprogram format should make it difficult or impossible to write inconsistent microinstructions. A microinstruction is inconsistent if it requires that a given control signal be set to two different values. To avoid a format that allows inconsistent microinstructions, one can make each field of the microinstruction responsible for specifying a nonoverlapping set of control signals.

Microinstructions are usually placed in a ROM or a programmable logic array (PLA), so one can assign addresses to the microinstructions. The addresses are usually given out sequentially, in the same way that one chooses sequential

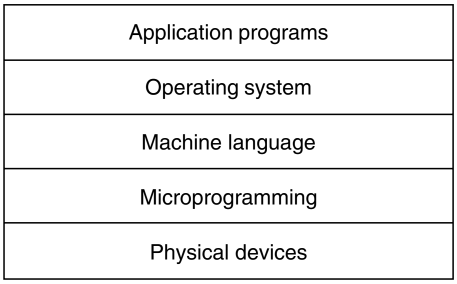

FIGURE 1.1 Basic Hierarchy of Systems Using Microprogramming

numbers for the states in the finite state machine. Three different methods are available to choose the next microinstruction to be executed:

- **Increment the address of the current microinstruction** to obtain the address of the next micro-instruction. This is indicated in the microprogram by putting it in the sequencing field. Because sequential execution is encountered often, many microprogramming systems make this the default and simply leave the entry blank as the default.
- **Branch to the microinstruction** that begins execution of the next instruction. This initial micro-instruction is usually labeled as Fetch and placed in the sequencing field to indicate this action.
- **Choose the next microinstruction** based on control unit input. Choosing the next microinstruction on the basis of some input is called a **dispatch**.

In writing the microprogram, there are two situations in which one may want to leave a field of the microinstruction blank. When a field that controls a functional unit or that causes state to be written (such as the memory field of the ALU destination field) is blank, no control signals should be asserted. When a field only specifies the control of a multiplexor that determines the input to a functional unit, leaving it blank means that one does not care about the input to the functional unit. The easiest way to understand the microprogram is to break in into pieces that deal with each component of instruction execution. The first component of every instruction execution is to fetch the instructions, decode them, and compute both the sequential PC and branch target PC.

1.2 Memory Hierarchy in Computer Systems

Memory is part of the computer used to store information such as instructions and data. Ideally, memory should operate at a speed that is comparable to the CPU so that the CPU can function as close as possible to its maximum speed. Unfortunately, such memory devices are very expensive and only economically feasible in very small systems. For larger systems, the stored information is distributed in a memory hierarchy using different memory devices with various performance and cost. A basic organization of multilevel memory is depicted in Figure 1.2.

As illustrated in Figure 1.2, storage components can be separated by performance into four basic groups: registers, caches, main memory, and secondary memory.

- Registers are small areas of extremely high-speed memory used to store data that will be processed by the CPU. Generally, a register can hold only a few bytes of data, which can be the operands, the results, or the memory addresses that can be accessed in one clock cycle. These registers then form general-purpose register files that can be used by the CPU. In many of today's CPUs, the size of a register file is 32 entries.
- **Caches** are the areas of high-speed memory used to store frequently used data and instructions. Caches allow the CPU to access instructions and data much quicker than if it were to access the data from the main memory. In a nutshell, cache memory works as follows: if the CPU requests a memory access, the memory management unit (MMU) first checks to see if the requested address is in the caches. If the address is in the caches, the data are returned to the CPU (in case of a read request) or updated in the cache (in case of a write request). On the other hand, if the address is not in the cache, the contents of that address (and perhaps its neighbor) must be brought into the cache from the main memory. In today's system, there are often multiple levels of cache memory. For example, Intel's Pentium II uses two levels of cache. In level 1, separate instruction and data caches are used and each with a 16-KB capacity. In level 2, 512 KB of unified

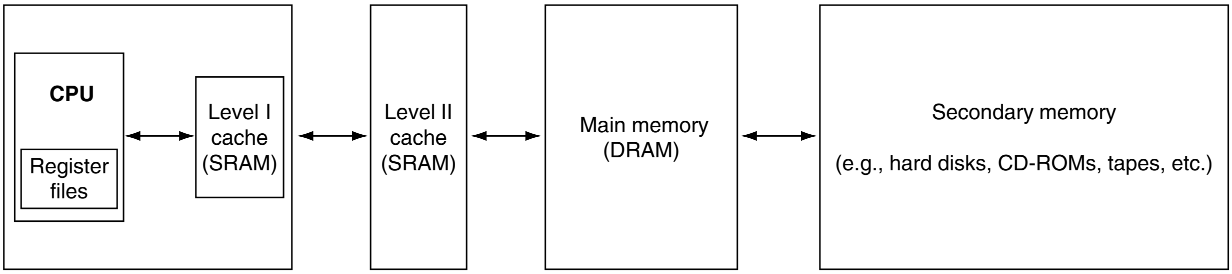

FIGURE 1.2 Basic Organization of Multilevel Memory System

cache is used. Since cache memory is expensive, the cache's capacity is much less than the capacity of main memory (often from 1 to 1000 KB [1 KB is 2^{10} bytes]). On the other hand the common access time of cache memory is only one to three cycles.

- **Main memory** is external memory that is relatively fast and inexpensive. The information stored in the main memory is data and instructions still actively used. The storage capacity of main memory (often from 1 to 1000 MB [1 MB is 2^{20} bytes]) is much larger than that of cache memory. The access time (five or more cycles), however, is also much slower than cache memory.
- **Secondary memory** is much larger in capacity and much slower in access time than main memory. Secondary memory stores information that is not currently used by the CPU. In addition, it also absorbs from the main memory when it is exceedingly used. Examples of secondary memory are a hard disk, a compact disk read-only memory (CD-ROM) disk, a digital video disc (DVD), now called a digital versatile disc, a digital audio tape (DAT), a floppy disk, and a magnetic tape. For hard drives, the typical capacity varies from 0.5 GB to several GB (1 GB is 2^{30} bytes), and the access time is measured in milliseconds. For floppy drives, the capacity varies from one to hundreds of MB (in case of Zip drives and Super drives).

1.2.1 Random-Access Memory

Random-access memory (RAM) allows storage location to be accessed in any order and access time to be fixed regardless of the accessed location. Unlike sequential access memory (e.g., magnetic tape), for which data access can only start from the beginning and the address is searched sequentially, RAM can access any address in a constant time. For example, if the access time of a RAM is stated to be 60 ns, any address location inside that RAM can be accessed within that time. RAM is, therefore, much faster to read from and write to than other storage devices such as hard disks, floppy disks, and magnetic tapes. However, the stored information in RAM is volatile. RAM loses all of its contents as soon as the power to the system is turned off. There are two types of RAM: **static** (SRAM) and **dynamic** (DRAM). It is worth noting that the terms static and dynamic do not refer to mechanical movement in storage device; instead, they refer to the need to refresh the contents. In DRAM, the stored contents have a tendency to decay overtime. Thus, periodic recharging (refreshing) is needed to maintain the content correctness. SRAM, on the other hand, does not require refreshing. A typical refresh rate is 15 ms.

Static RAM

The advantage of **static RAM** SRAM is that it requires no refreshing and often has shorter access time than DRAM. On the other hand, SRAM is more expensive and may require up to four times the size for a given amount of data than DRAM. Moreover, SRAM also consumes more power. SRAM is mainly used in the implementations of level 1 and level 2 caches. Typical capacity of SRAM is from a few kilobytes to 1 MB. In 1998, however, IBM announced the high-performance and high-capacity SRAM that has the capacity of 8 MB and the speed of up to 600 MHz (see Figure 1.3).

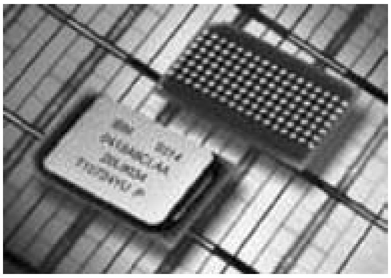

FIGURE 1.3 IBM's High-Performance SRAM

Dynamic RAM

Dynamic RAM (DRAM) possesses a characteristic similar to a capacitor; that is, for every read access, a power refresh is required to maintain the data. In addition, a power refresh is also required every 15 ms just to hold the information. Over the years, DRAM has been mainly used to implement the main memory in most computer systems. Some of the most commonly used DRAMs are given in the following list:

- **Enhanced DRAM** (EDRAM) uses combination of SRAM and DRAM. It is mainly used to implement level II cache memory. In this setup, the data are read first from the SRAM. If data are not found there, the data are then read from the DRAM.
- **Fast page mode DRAM** (FPM DRAM) is the most commonly used DRAM for the personal computer from mid-1980s to the early 1990s.
- **Extended data output** (EDO) DRAM is the leading type of DRAM used in mid-1990s. It is faster than FPM DRAM because it allows the CPU to access data while the refresh cycle is being set up. The typical access time for EDO DRAM is 60 ns. As the CPU speed increases beyond 200 MHz, however, the popularity of EDO DRAM gives way to the faster SDRAM.
- **Synchronized DRAM** (SDRAM) is a generic name for any DRAM that is synchronized with the clock speed optimized for the CPU. SDRAM is faster than EDO DRAM because SDRAM chips can synchronize their operations with the processor clock. Moreover, SDRAM also allows new memory access before the preceeding access is completed. The speed of SDRAM is rated in megahertz instead of the traditional nanoseconds because a comparison can easily be made to the system bus speed. A typical speed of the SDRAM is 66 to 125 MHz.

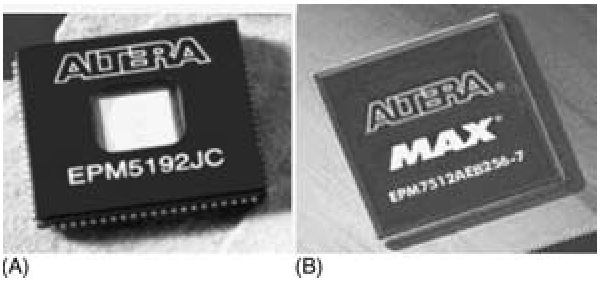

FIGURE 1.5 Illustration of EPROM and EEPROM for Rapid Prototyping. (A) Altera's EPROM-Based Programmable Logic Device (PLD) Family (1988). (B) Altera's EEPROM-Based PLD Family (1992).

- **PC100 SDRAM** is the SDRAM that meets Intel's i440BX specification. The i440BX was designed to use a 100-MHz system bus speed. It is the most commonly used DRAM in personal computer systems (see Figure 1.4).
- **Direct rambus DRAM** (DRDRAM) is a proprietary technology proposed by Rambus in partnership with Intel. It utilizes Rambus DRAM (RDRAM) memory platform. This technology is expected to replace SDRAM as the adopted standard in PCs. In 1999, Rambus reported that its DRDRAM could deliver up to 1.6 GBPS capability. Presently, Rambus DRAM (RDRAM) is used in products ranging from Silicon Graphics workstations to Nintendo-64 video game machines.

1.2.2 Read-Only Memory

Unlike RAM, read-only memory (ROM) cannot have the contents rewritten once they are installed in a system. To read from ROM, the random-addressing method similar to RAM is used. In contrast to RAMs, ROMs have the advantage of being nonvolatile, which means ROMs do not lose their contents when the power to the system is turned off. ROM chips are typically slower than both SRAM and DRAM chips.

One of the first ROM chips was introduced in the late 1960s as masked ROM. This ROM only allowed one-time programming and was used to store unchanged information. Over the years, ROM technology has evolved to include many variations or ROMs. Some of the most commonly used ones are listed in the following list:

- **Erasable programmable ROM** (EPROM) is often used in microcontroller applications. A good example is the basic input output system (BIOS) used to start up the PC. During the start-up process, the EPROM supplies the necessary instructions to the CPU so that the computer's subsystems can be initialized and tested. EPROMs usually have the same organization as the SRAM. EPROMs can be erased by being exposed to ultraviolet light for about 15 min.
- **Electrically erasable programmable ROM** (EEPROM) is user-modifiable ROM that can be erased and reprogrammed repeatedly by applying specific electrical pulses. Unlike for EPROM, an EEPROM chip has to be erased and reprogrammed in its entirety, not selectively. EEPROM also has a limited life span (limited programmability). Moreover, the largest EEPROMs are only 1/64 as large as common EPROMs, and they are only half as fast. At this point, EEPROMs cannot compete with SRAMs and DRAMs because the latter two have much smaller capacity with much less speed and are more expensive. Presently, EEPROMs are mainly used in rapid device prototyping where nonvolatility and easy reprogrammability are crucial. Figure 1.5 illustrates the uses of EPROM and EEPROM technology in high-density programmable logic devices (PLD) for rapid prototyping. Figure 1.5 (A) shows a picture of Altera's MAX 5000 device that is EPROM-based. MAX 5000 family provides logic densities ranging from 600 to 3750 usable gates. This family of devices was launched in 1988. Figure 1.5 (B) shows a picture of Altera's MAX 7000 EEPROM-based device. The MAX 7000 family provides logic densities ranging from 600 to 5000 usable gates. This family of products was launch in 1992.
- **Flash memory** is a more efficient version of EEPROM. Unlike EEPROM, for which the data are byte-erasable and rewritable, flash memory erases and writes data in fixed size block (see Figure 1.6). This effectively improves the performance of flash memory as compared to typical EEPROM. At first, the expectation for flash memory is to replace the hard drive as the adopted mass media storage. This adoption would be a major improvement in mass storage media considering that the access time of flash memory is about 100 ns, whereas the access time of hard disks is in milliseconds. The takeover, however, has not occurred because flash memory is still far too costly to be used as a mass storage device. Presently, flash memory is mainly used in digital photography industry as film for storing digital pictures. The life expectancy of a flash memory is roughly 10,000 erasures.

FIGURE 1.6 Illustration of Flash Memory

1.2.3 Serial-Access Memory

The best way to describe serial-access memory is through an example. Magnetic tapes, hard disk drives, CD-ROM drives, and DVD drives are all serial-access memory devices. To access data on a magnetic tape drive, the tape must be loaded from the beginning. The magnetic tape head is scanned through the tape media until the corresponding location is found and data is accessed. To sum up, the data in serial-access memory must be accessed in a predetermined fashion (in this example, the tape is sequentially scanned from the beginning) using shared read/write devices (e.g., magnetic tape head) for all possible locations on the media. There are three basic mediums to implement serial-access memory devices: **magnetic disk memory**, **magnetic tape memory**, and **optical memory**.

Magnetic Disk Memory

Magnetic disk memory is used to implement hard disks, standard floppy disks, and high-density floppy disks (e.g., Zip drive, Super drive). Hard disks are the most commonly used second memory devices because of their low cost, high speed, and high storage capacity. Hard disk drives are mass storage units that allow read to and write from magnetic media; they consist of one or many thin disks that have magnetic coating, allowing data to be recorded. The recording surface is divided into **concentric tracks**, and each track is divided into segments called **sectors**. The set of tracks at a given radial position is referred to as a **cylinder**. One disk or more are then mount on a spindle and rotate at a constant speed. To access the data, a two-step process is required. First, the read/write head moves across the rotating disk to the locating track. Then the head waits until the right sector is underneath it, and read/write is performed. The descriptions of magnetic disk memory devices are given as follows:

- The **hard disk drive** is the most commonly used mass storage device, as already stated. The size of today's hard drives can vary from 14 inches (used in older mainframe computers) to 1.8 in (used in laptop and portable computers). The most typical size used in a PC is 3.5 in, and the ones used in notebook computers are from 1.8 to 2.5 in. The rotating speed also varies depending on the interface used (discussed more in the bus interface section). For an integrated drive electronics (IDE) interface, the speed varies from 4500 rpm to 7200 rpm. For a small computer systems interface (SCSI), the speed can be as high as 10,800 rpm. The typical capacity varies from one gigabyte to tens of gigabytes (1 GB is 2^{30} bytes).
- The **floppy disk drive**, also known as diskette, is a removable magnetic storage medium that allows recording of data. IBM first introduced it as a 8-in diskette in 1971. In the middle of 1970s, a 5.25 diskette was introduced. Today, the most commonly used floppy disks are 3.5 inches and have the capacity of 800 KB to 2.8 MB (with a standard of 1.44 MB).
- The **high-density floppy disk drive** was first introduced in 1995. High-density floppy disks, while sharing a 3.5-in size with the standard floppy disks, are much faster and have up to one hundred times more capacity than the standard floppy disks. One example is the Zip drive, produced by Iomega. Each Zip disk is capable of storing up to 100 MB of data. Similarly, Imation, a subsidiary of 3 M, also manufactures the Super disk (also known as the LS 120) that can store up to 120 MB of data.
- The **removable hard disk** has been at work in the mainframe computer industry since the 1950s. Back then, the drive mechanism was extremely expensive; therefore, different applications would use different removable disks, during program execution. In the 1980s, removable hard drive was used for backup purposes. The capacity then was 44 MB. Nowadays, removable disks come in various capacities from one gigabyte up to several gigabytes.
- The **redundant array of inexpensive disks** (RAID) was introduced by David Patterson and other researchers at the University of California, Berkeley, in the late 1980s. It is a method where two or more disks are used to store data. Data can be read simultaneously from more than one drive, which improves the performance. Data can also be split among all drives in bits, bytes, or blocks. Typically two or more disks are connected together. A single controller can be used to connect the drives so that they function together as one drive. For extra safety, a second interface controller can be installed to duplex the drives and increase read performance. The major advantages of RAID are improvement in reliability and protection for data in mass storage systems.

Magnetic Tape Memory

The **magnetic-tape memory device** is one of the oldest and cheapest secondary memories. In spite of the popularity of RAM, CD-ROM, and removable hard drives; tape is still used because of its low cost and reliability. In today's systems, tape is mainly used to provide backup data in case of hardware failure to the hard disk system. The major tape formats available for PCs and servers are as follows:

- Quarter-inch cartridges (QIC) are packaged in two formats, 3.5-in mini-cartridges and 5.25-in data-cartridges. Due to its low capacity, QIC is used mainly to back up PCs and small servers.
- Digital linear tape (DLT) was originally developed by Digital Equipment Corporation (DEC) to be used in its midsize systems. Presently, DLT is used to provide backup for midsize local area network (LAN). The current transfer rate of DLT is a 800-KBps backup to tape cartridges that hold up to 40 GB of uncompressed data.
- Digital audio tape (DAT) of 4 mm was originally intended for the recording industry. However, it never caught on, and it was adapted for data storage. It is mainly used to back-up data at work-group level. The transfer rate of DAT is about 1.5 Mbps, and the capacity varies from 4 GB to 24 GB.
- The 8-mm tape was the first high-capacity tape to be widely used in the PC market. The current transfer rate is about 6 Mbps, and the capacity is 20 GB of uncompressed data.

Optical Memory

The popularity of the **optical disk** memory as mass storage media has rapidly grown over the past few years. Optical mediums have much higher recording density than their conventional magnetic counterparts. In 1980, Phillips in partnership with Sony developed the compact disc (CD) that quickly replaced the long-playing record. CDs can be prepared by using high-power infrared laser to burn holes (pits) in a master disk. Once a master disk is made, the successive copies can be made very inexpensively (about 2000 copies for $1.00). To read the disk low-power infrared light is shined through the disk. Since the surface of the CD consists of pits and smooth surfaces (lands), the variations of reflected light are used to translate data into a digital signal. Unlike the hard drive in which the disk is rotated at a constant angular velocity (e.g., 5400 rpm), the CD drive needs to achieve constant linear velocity of 120 cm/sec. This means that the angular velocity when reading on the outside of the disk is 330 rpm, and the velocity when reading the inside is 530 rpm. In 1984, the standard for using CDs to store computer data was precisely defined, and the media was referred to as compact disc read-only memory (CD-ROM). The standard states that CD-ROM is to have physical appearance of CDs. Moreover, it must be optically and mechanically compatible with CDs, which means the manufacturing techniques must be compatible. Since then, there have been many advances in CD-ROM technology, such as creation of the CD-recordable (CD-R), the CD-rewritable (CD-RW), the digital versatile disc (DVD), and the DVD-RAM.

- **CD-ROMs** are the most widely used optical storage. With the capacity of 650 MB, CD-ROMs are ideal for distribution of text, images, and programs in an electronically readable form. Since the mid-1990s, CD-ROMs have become the standard on PC systems.
- **CD-recordable** (CD-R) disks at first glance, appear to be similar to regular CD-ROMs except CD-Rs are either gold or green instead of silver. These green and yellow colors are dye, and they are used to simulate lands and pits. In the initial state, the dye is transparent and allows the laser light to pass through and reflect the inner layer (made out of gold). During the writing stage, the laser power is increased to heat up the dye, which results in a dark spot. During the reading stage, the differences between a dark spot and a transparent spot are interpreted as the differences between pits and lands. Kodak is one of the first manufacturers to produce CD-R disks. One of the first uses of CD-Rs was for Kodak's PhotoCD. CD-Rs are being used for backing up hard disks, and they also make it possible for individuals and small companies to manufacture a small number of CD-ROMs. Unfortunately, this technology also allows many individuals and companies to duplicate CD-ROMs and CDs without any regard for copyright violations.
- **CD-rewritable** (CD-RW) technology allows individuals and companies to write, erase, and rewrite CD-ROMs. Unlike CD-R, CD-RW uses a reflecting alloy that possesses two stable states, crystalline and amorphous. These two states reflect light differently. Inside CD-RW drive, three levels of laser power can be used. At high power, the alloy melts and loses some of its reflectivity (amorphous state). This in effect simulates pits. At medium power, the alloy melts again, but this time returns to its crystalline state and regains its reflectivity (returns lands). At low power, the disk is read but there is no state change. Because CD-RWs still cost considerably more than CD-Rs, they are not as widely used as CD-Rs.
- **Digital versatile disc-ROM** (DVD-ROM) technology is similar to CD technology with only three exceptions. First, the pit size is half of CD's pit size (0.4 mc versus 0.8 mc). Second, the spiral grove for recording is 54% tighter. Last, the laser beam is 17% smaller. With these refinements, the capacity is improved 7-fold. A typical CD-ROM can store 650 MB of data, whereas a DVD-ROM can store 4.7 GB. This translates to the ability to hold up to 133 minutes of high-resolution video, with soundtracks for eight languages and subtitles for additional thirty-two languages. The packaging of DVD-ROM comes in four different formats. The first is single-sided with a single layer, which translates to 4.7 GB. The second is single-sided with a dual layer, which translates to 8.5 GB of storage capacity. The third is double-sided with a single layer, which has the capacity

of 9.4 GB. Finally, a double-sided formate with a dual layer has the capacity of 17 GB.

- **DVD-recordable** (DVD-R) is a write-once system. The original capacity of a single-sided DVD-R disk that has a single-layer was 3.95 GB, which is slightly lower than a single-sided, single-layer DVD-ROM. The capacity has increased to 4.7 GB.
- **DVD-rewritable** (DVD-RAM) is new type of rewritable DVD that provides much greater data storage than today's CD-RW systems. A single-sided, single-layer DVD-RAM has a capacity of 2.6 GB, and a single-sided, single-layer DVD-RAM has a capacity of 5.2 GB. This allows an hour of MPEG-2 video, which is not very practical for home entertainment use when videotapes can have a capacity of up to 5 hr (standard play). This DVD-RAM specification is therefore aimed at the computer market where it can be used to store large amounts of data.

1.3 Bus and Interface

Bus is a set of conductors (wires, PCB tracks, or connections in an integrated circuit) connecting various functional units in a computer. Busses can be either inside or outside the CPU. The outside busses are used to connect the CPU to external memory and peripheral devices. The width of a bus (i.e., the number of parallel connectors) determines the size in bits of the largest data item that it can carry. The bus width and the number of data items per second that it can transmit are factors limiting a computer's performance. Most current microprocessors have 32-bit or 64-bit busses. Some processors have internal busses, which are wider than their external busses (usually twice the width). The width of the internal bus, therefore, affects the speed of all operations and has less effect on the overall system cost than the width of the external bus.

On the other hand, an interface is a communication channel for two or more systems. It can be a hardware connector linking devices or a convention allowing communication between two software systems. There are often some intermediate components between the two systems that connect the interfaces together. For example, two RS-232 interfaces are connected via a serial cable.

When a central processing unit (CPU) sends data to a serial device (receiver) through a RS-232 interface, the data will go through internal busses, external busses, a RS-232 interface, a serial cable, a receiver's RS-232 interface, a receiver's busses, and a receiver's CPU. Normally, a component (e.g., interface card) that is used to transfer signals from busses to some protocol can be recognized by other components or peripheral devices. The interface card will be plugged into an expansion bus slot of a motherboard. Normally, a motherboard has several expansion bus slots allowing components such as a video card, a disk controller, a modern, or a parallel-port card to communicate with the computer. There are three common types of busses: industry standard architecture (ISA), peripheral component interconnect (PCI) local bus, and an accelerated graphics port (AGP). Each (ISA) has its own type of expansion slot and signal definitions. They will be described in the following subsections.

1.3.1 Bus Overview

Bus technology is well-developed in computer systems such as PCs. Most of the busses described here are common in a typical PC-based system. However, some busses such as PCL are also used in Sun Microcomputer systems. In 1982, the first-generation PCs used ISA busses. The ISA bus was an 8-bit bus running at 4.77 MHz on PC XT. Although it was extended to a 16-bit bus with the speed of 8 MHz on PC AT, the low speed led to extended industry standard architecture bus (EISA) design. At the same time, micro channel architecture (MCA) bus was added by IBM to provide users with choices. Newer Intel486TM and Pentium processor-based machines offer ISA/PCI or EISA/PCI. With most vendors now shipping PCI-based machines across their complete product line, it is clear that PCI will be the dominant bus for the future. Furthermore, the transition of corporate PC purchases to Pentium processor-based systems hastens the move to PCI for the adapter interface. This move allows for better response time for PCs, which eliminates the bottlenecks for these high-powered workstations.

ISA expansion slots have existed in PCs for years. Most of the interfaces depending on them such as parallel ports and serial ports, however, have been integrated into motherboards. Moreover, in the PC 99 System Design Guide advocated by Intel and Microsoft, ISA slots have been removed because of their configuration issues.

Terminology

Before introducing bus specification, some terminology needs to be defined so that readers can have better understanding of bus specifications.

- **Auto configurable**: An interface card allows software to identify its requirements and resolve any potential resource conflicts such as IRQ, DMA, I/O address, and BIOS.
- **Bus master support**: This bus master is capable of first-party DMA transfers.
- **Full bus master capability**: This capability allows support of any first-party cycle from any device, including another CPU.
- **Good bus arbitration**: This feature allows fair bus access during conflicts, which means there is no need to back off unless another device needs the bus. This arbitration prevents CPU starvation while allowing a single device to use 100% of the available bandwidth. Other busses let a card use the bus until it decides to release it and attempts

to prevent starvation by having an active card voluntarily release the bus periodically ("bus on time"). This device is to remain off the bus for a period of time ("bus off-time") to give other devices, including the CPU, a chance even if they do not want it.

- **16-Meg addressable**: This limits first-party DMA transfers to the lower 16 Megs of address space. There are various software methods to overcome this problem when more than 16 Megs of main memory are available. This has no effect on the ability of the processor to reach all of the main memory.
- **Backward-compatible with ISA**: This feature allows an ISA card to be placed in the slot of a more advanced bus. It is worth noting that the ISA card does not gain any benefit from being in an advanced slot. Other slots are unaffected.
- **Burst**: This allows the transfer of multiple data items continuously in response to a single request.

Industry Standard Architecture

The **industry standard architecture** (ISA) bus was originally designed for the IBM PC XT with an 8088 (at 4.77 MHz) processor. It is limited to 8 data lines and 20 address lines (1 MB of memory addressing). The PC/AT 80286-based systems maintain the 8-bit PC compatibility and add a 16-bit connector using 16 data lines and 24 address lines. Some features of ISA busses are the following:

- Operating speed of 8 MHz to 8.33 MHz asynchronously
- Maximum throughput of 8 MB ps
- Two CPU cycles used for every read or write
- Bus master support
- Edge-triggered TTL interrupts (IRQs)—no sharing
- Communication with both 8- and 16-bit devices
- DMA capable
- Bus group signals
- 24 address lines
- Low cost

ISA buses are ideal for low- to mid-bandwidth cards, though lack of IRQs can quickly become annoying.

Micro Channel Architecture Bus

The **micro channel architecture** (MCA) **bus** was proprietary and bounded mainly in IBM personal computers. MCA has a better performance than ISA. The data lines and address lines are increased, and the burst data transfer rate can be up to 80 MB/sec. Some of its features are the following:

- Intelligent bus master expansion card support
- 16- or 32-bit data transfers and a 32-bit address bus (4 GB of memory space) support
- CPU clock uncoupled from 10-MHz bus (32-bit data streaming)
- 80 M/s burst, synchronous
- Fully bus master capability
- Good bus arbitration
- Autoconfigurable
- IBM proprietary (not ISA/EISA/VLB compatible)

Extended Industry Standard Architecture Bus

Because MCA was proprietary, the extended industry standard architecture (EISA) was formed to compete with it. EISA gained much more acceptance; MCA has all but disappeared. EISA is an improved version of ISA. It is great for high-bandwidth bus mastering cards, such as SCSI host adapters, but its high cost limits its usefulness for other types of cards. Some of its features are the following:

- Support for intelligent bus master expansion cards
- Support of 8-, 16-, or 32-bit data transfers
- 8–8.33 MHz, synchronous
- Backward-compatible 32-bit address bus (4 GB of memory space)
- Synchronous data transfer protocol
- Cycles synched between CPU, bus master, and DMA
- 33 MB ps data transfer for bursting bus master or DMA
- Automatic configuration of board and expansion cards
- Full bus master capability
- Good bus arbitration
- Sharable IRQs, DMA channels
- Backward compatible with ISA
- Some acceptance outside of the PC architecture
- High cost

Video Electronics Standards Association Local Bus

The **video electronics standards association** (VESA) **local bus** (VLB). VLB is great for video cards, but its lack of a good bus arbiter limits its usefulness for bus mastering cards, and its moderate cost limits its usefulness for low- to mid-bandwidth cards. Since it can coexist with EISA/ISA, a combination of all three types of cards usually works best. Moreover, the VLB has limited electrical integrity at higher speeds. The following list includes some features:

- 32 data bits, 32 address bits
- 25–40 MHz, asynchronous
- Capable of limited bursting (up to 132 MB/sec) in the 386/486 environment
- Bus master capability
- Coexistence with ISA/EISA
- Slot limited to two or three cards typically
- Backward-compatible with ISA
- Moderate cost
- Originally designed to maximize throughput for video graphics
- Memory that adds a local bus for faster access to the processor
- Two types of VL bus

- Type A: no buffering
- Type B: buffering; supports up to three add-in connectors
- Revision 2 adds bus mastering support

Peripheral Component Interconnect Local Bus

The **peripheral component interconnect** (PCI) **local bus** is the newest bus standard accepted by all computer systems such as PC-based systems, Apple's Power Macintosh computers and Workgroup servers, Sun workstations, and PowerPC processor-based computers from IBM and Motorola. The PCI has a high-performance expansion bus architecture that was originally developed by Intel to replace the traditional ISA and EISA busses found in many 80 × 86-based PCs. PCI combines the speed of VLB with the advanced arbitration of EISA. Great for both video cards and bus mastering SCSI/network cards. Some of its features include these:

- 32 data bits (64 bit option), 32 address bits (64-bit option)
- Up to 33 MHz, synchronous
- 132 M/s burst (sustained) (264 M/s with 64-bit option)
- Full bus master capability
- Good bus arbitration
- Slot limited to three or four cards typically
- Autoconfigurable
- Coexistence with ISA/EISA/MCA as well as another PCI bus
- Strong acceptance outside of the PC architecture
- Moderate cost
- Voltage: 3.3 V and 5 V

Accelerated Graphics Port

Because of the large amount of 3-D image processing data, PCI busses limit an animation to be life-like in realism and depth. **Accelerated graphics port** (AGP) technology was invented to accelerate graphics performance by providing a dedicated high-speed port (independent to PCI) for transferring 3-D texture data from system memory to video memory in a graphics controller.

- 32 data bits, 32 address bits (extra 8 lines for sideband addressing)
- Up to 133 MHz
- Up to 1 GBps peak (528 MBps at 66 MHz)
- Slot limited to one card
- Autoconfigurable
- Coexistence with ISA/EISA/MCA as well as another PCI bus
- Voltage: 3.3 V and 1.5 V

1.3.2 Interfaces

Computers communicate with peripherals or each other by using **I/O chips** as interfaces. These chips include universal asynchronous receiver transmitters (UARTs), and parallel input/outputs (PIOs). A video graphics adapter (VGA) interface is used to send signals to a monitor; a parallel port is used to communicate with a printer; and a serial port is used to communicate with a mouse, and so on. First, an interface takes signals from busses according to an *I/O* addresses. For example, a UART chip can read a byte from the data bus and output it in a serial format with parity check. It can be configured as various transmission speeds from 1200 bps to 115,200 bps. Different interfaces have their own specifications and transmission protocols. The following subsections give a brief introduction.

Serial Port and Parallel Port

In general, there are two types of communication ports in a computer: **serial ports** and **parallel ports**. A serial port is an interface through which peripherals can be connected as a communication channel using a serial (bit-stream) protocol. Usually, a serial mouse is connected to COMI (communication port 1). The most common type of serial port is a 25-pin D-type connector carrying RS-232 signals. Smaller connectors (e.g., 9-pin D-type) carrying a subset of RS-232 are often used on personal computers. The serial port is usually connected to an integrated circuit called a UART that handles the conversion between serial and parallel data.

A parallel port is an interface for a computer to communicate peripherals in parallel manner. Data are transferred in or out in parallel, that is, on more than one wire. A parallel port carries 1 bit on each wire, thus multiplying the transfer rate obtainable over a single wire. There will usually be some control signals on the port that indicate when data are ready to be sent or received. The most common type of parallel port is a printer port (e.g., a Centronics port that transfers 8 bits at a time). Disks are also connected via special parallel ports (e.g., SCSI or IDE).

PS/2 Port

A type of port developed by IBM for connecting a mouse or keyboard to a PC is the **PS/2 port**. This port supports a mini-DIN plug containing just six pins. Most PCs have a PS/2 port so that the serial port can be used by another device, such as a modem. The PS/2 port is often called the mouse port. Most laptops have one PS/2 port that is used to hook up a full-sized mouse or keyboard to a laptop. To hook up both a mouse and a keyboard, a PS/2 keyboard and a serial-type mouse are required. The mouse will interface through the laptop's standard serial port.

Integrated Drive Electronics (IDE)

In mid-1980's, the disk controller for a hard drive had integrated with the drive itself. The **integrated drive electronics** (IDE), also called ATA (AT attachment), interface hard drive appeared. However, IDE hard drive has a maximum size limitation (528 MB) due to basic input output system (BIOS) conventions (16 heads, 63 sectors, and 1024 cylinders).

Extended IDE (EIDE) also called ATA-2, drives were later introduced to solve the problem by supporting a second addressing scheme called logical block addressing (LBA) mode. It allows numbering sectors from 0 to 2^24–1 and, consequently, gets beyond the 528-MB limit. The IDE can also control four drives instead of two, has a higher transfer rate, and has the ability to control CD-ROM drives.

AT Attachment Packet Interface (ATAPI)

The enhanced IDE standard functions as an interface for hard drives and PCs. It would be great, however, if other devices such as tape drives and CD-ROMs could be controlled through the same controller. The AT attachment packet interface (ATAPI) is an extension to EIDE that enables the interface to support CD-ROM players and tape drives. Using ATAPI-capable hardware and software drivers, mixing and matching different types of drives on the same EIDE controller, are possible which are both a convenience and savings in hardware costs.

Small Computer System Interface

Small computer system interface (SCSI), standardized in 1986, is a flexible *I/O* bus that has been used in a number of peripherals such as disk drives, CD-ROM drives, tape drives, and scanners. SCSI drives have much higher transfer rates than IDE drives. A SCSI-controlling card plugged into a system expansion slot serves as a host to other SCSI devices. At most, 7 SCSI devices can be linked together to a host (15 for wide SCSI).

There are several versions of SCSI standards: SCSI-1 standard supports transfer rates of up to 3 MBPs, SCSI-2 supports up to 20 MBPs, and SCSI-3 supports up to 40 MBPs. In a chain of SCSI devices, any one can be either an initiator or a target. Normally, the SCSI controller, acting as an initiator, issues commands to other SCSI devices acting as targets. The commands descriptor block (CDB) can be up to 16 bytes and tells the target what to do. These CDB commands are also used to arbitrate the bus when more than two SCSI devices try to use the bus as the same time. This arbitration mechanism improves performance by allowing more than two SCSI devices to be activated at the same time, whereas only one IDE device can be activated at one time. The following are lists of characteristics for different SCSIs:

Major SCSI-1 Characteristics

- Very short bus with only two SCSI connectors or devices
- Single initiator and single target
- Transfer rates of 3 MBPs or less
- No arbitration, no parity, no disconnect
- Single-ended interface
- 6-byte command descriptor block (CDBs)
- 5-MHz bus frequency (transfer rate)

Major SCSI-2 Characteristics

- Higher performance than SCSI-1
- Transfer rates increased to 10 MHz, synchronous mode, routinely using 5 MHz
- Lower overhead, often below 30%
- Single-ended and differential interfaces
- SCSI bus up to 4 bytes wide (32-bit); main use of the 2-byte wide bus, achieving 20-MBPs burst transfer rates
- Diversity of peripheral device types (10 types)
- Greatly improved compatibility
- Improved functionality (e.g., command queuing, disconnect, etc.)
- Improved reliability (e.g., arbitration, parity, error reporting and classification, new commands)

Major SCSI-3 Characteristics

- Much higher performance in respect to burst transfer rates (greater than 40 MBps) and lower overhead
- Distance in kilometers rather than just meters
- Expanded addressability, allowing an almost unlimited number of devices on the same bus
- Universality use of the SCSI system expanded even more
- Higher reliability and robustness of systems
- 20-MHz bus frequency (transfer rate)

Universal Serial Bus

The **universal serial bus** (USB) standard was originally developed by Compaq, Digital Equipment, IBM, Intel, Microsoft, NEC, and Northern Telecom. USB is a two-way serial channel with supports of hot-swapping and a 12-Mbps data transmission rate. It allows up to 127 devices to be connected into a PC through a multilevel tiered star topology using USB hubs. Furthermore, it adopts standard connectors and eliminates add-in interface cards, which results in lower costs for developers and consumers. Features include:

- 12 Mbps (1.5 Mbps for low-speed devices, such as keyboards)
- Up to 127 devices that can be hooked up together
- Cable length less than 5 ms
- Two-way communication channel
- Hot-swapping

IEEE 1394

The **IEEE 1394** is a high-performance serial bus. App developed the bus in early 1990s and called it Fire Wire bus. Sony also markets a similar product under the name i.Link, which is one of many 1394-compliant devices. Because of USB's low speed, it does not provide support for high-speed peripherals, such as digital camcorders and high performance printers. IEEE 1394 can support these high-speed peripherals. IEEE 1394 is the only bus structure that can be used as an internal bus and an external bus in a computer system.

Table 1.1 Illustration of Interface Performance

Bus type	Maximum speed (MBps)
Parallel port (unidirectional)	0.0050–0.015
Serial port (16550 UART)	0.0144
Parallel port (bidirectional)	0.01–0.0375
Serial port (16550/16750 UART)	0.02875–0.0575
USB	12
Parallel port (EPP)	2
SCSI	Regular, 5: wide, 10
ISA (16-bit)	8
SCSI (Fast)	Regular, 10; wide, 20
SCSI (Ultra)	Regular, 20; wide, 40
IEEE 1394a	400
USB 2.0	480
SCSI (Ultra-2)	Regular, 40: wide 80
IEEE 1394b	800
SCSI (Ultra-2)	Regular, 40: wide 80
IEEE 1394a	100
PCI (32-bit)	133
PCI (64-bit)	267
AGP	267
IEEE 1394b	200–400
AGP 2X	533
AGP 4X	1067

The 1394 bus is faster than the USB and most versions of SCSI (it will approach or exceed the speed of PCI in the future). Furthermore, the IEEE 1394 specification is designed to replace the SCSI buses and PCI buses. Features are as follows:

- Up to 400 Mbps (800 Mbps for 1394a and 1394b)
- Up to 63 devices per segment
- Cable length less than 4.5 meters

Table 1.1 illustrates data transfer rates ranking from slowest to fastest.

1.4 Input/Output

Input/output (*I/O*) devices are sometimes called peripheral. They are the parts that link outside world to a computer system. Basically, *I/O* can be divided into three categories: input devices, output devices, and *I/O* devices. The following subsections show a list of input devices, output devices, and *I/O* devices.

1.4.1 Input Devices

- A **bar code reader** is an optical scanning device, usually used to read data of a product such as price tags. Two main technologies are used in reading the tags: charge-coupled devices (CCD) and laser beams. Laser technology offers the advantages of high speed and longer focal lengths, while CCD scanners tend to be more durable since they have no movable parts. CCD scanners are widely used, whereas laser technology is catching up.
- A **digital camera** is similar to a camera except that the image taken is stored in memory instead of film. These image data will usually be uploaded into a computer to be stored in data format.
- **Digitizers/tablets** are drawing tool other than a mouse or a scanner to ease the work of drawing. Whatever is drawn onto the digitizer pad is recorded and displayed onto the video display.
- A **joystick** is usually used to control movement of a cursor or other graphic element for video games and computer graphics.
- A **keyboard** is one of the basic components in a computer system. By definition, it is a set of keys for a user to input data into a computer. American Standard Code for Information Interchange (ASCII) is an encoding system for converting keyboard characters and instructions into the binary number code that the computer understands.
- A **keypad** is a section of a keyboard. It is set up like a calculator to allow users to enter numbers and equations quickly into the computer. Sometimes a keypad is used in embedded systems as the primary input instead of a keyboard to reduce manufacturing cost.
- A **microphone** is a device capable of transforming sound waves into changes in electric currents or voltage. The electric signal is usually interpreted by the computer system through the input port of a sound card.
- A **mouse** is a small handheld device used to control the position of the cursor on the video display. This is the second most important input device other than a keyboard. The movements of a mouse on a desktop correspond to the movements of the cursor on the screen. The most common technology used nowadays is a mechanical mouse due to its reliability and production cost. Other technologies are optical and optomechanical. A mechanical mouse uses a rubber ball to track movements. An optical mouse, on the other hand, uses LED and photo detector to detect changes in gridlines an on the mouse pads an optomechanical mouse combines rubber balls with optical detection that detects rubber ball movements instead of mouse movements. Different manufacturers come up with different designs for a mouse, such as IntelliMouse by Microsoft and NoHands (foot mouse) by Hunter Digital.
- **Scanner** is an electronic device that uses light-sensing equipment to scan paper images (e.g., text, photos, and illustrations) and translate the images into data that the computer can then store, modify, or distribute. Some common data formats are PDF, GIF IPG, TIF and BMP. The most common software interface is called TWAIN. Although TWAIN stands for nothing, some prefer to call it "toolkit without an interesting name". Any software can access the scanner through a TWAIN interface. Software

that supports TWAIN usually has a command option called “Acquire” under their options. Scanners can combine with optical character recognition (OCR) software to convert scanned graphic into text format

- A **touch screen panel** is an input device commonly used in industrial or commercial systems rather than in a personal computer. The information will be directly input into the system by touching the video display. Some of the common technologies used are infrared, resistance, and guided wave.
- A **frackball** is an input device that controls the position of the cursor on the screen, similar to a mouse. The unit is mounted near a keyboard, and moving the ball controls the movement. Most laptop computers come with a trackball because of its small size.
- A **video camera/camcorder** is similar to a video recorder except that the video will be stored in memory instead of film. The video will then be uploaded into a computer.

1.4.2 Output Device

- A **monitor/display** is a video display terminal. It is the most basic output device in a typical computer system. Sometimes this can be an input device if it is modified into a touch screen monitor. Two other common displays are cathode ray tube (CRT) and liquid crystal display (LCD). Other rate technologies are light emitting diode (LED), gas plasma, and other image projection techniques. Most displays use analog signals, thus, they need the video adapter to store them in VRAM, then convert the digital signals to analog signals through DAC. Nowadays, a terminal can display up to 16,777,216 colors or 24-bit long colors. Human beings cannot differentiate this much color, but since it is convenient for programmers to program it in RGB, 1 byte each, it is widely used. For example, colors in HTML are usually expressed in #03F60A using RGB. The sharpness of the display is determined using dots-per-inch (dpi). This depends on the resolution and physical screen size. The screen size’s ratio of width to height (aspect ratio) is usually 4:3.
- A **plotter** is a mechanical drafting device similar but more powerful than printers. It incorporates a moving pen whose horizontal and vertical range in two dimensions is limited only by the size of the bed of the device. It is usually used for floor plans, maps, and blueprints.
- A **printer** is a mechanical device for printing the computer’s output on paper. The three major types of printers are: (1) dot matrix, in which individual letters are composed of a series of tiny ink dots formed by punching a ribbon with the ends of tiny wires; (2) ink jet, which sprays tiny droplets of ink particles onto paper; and (3) laser, which uses a beam of light to reproduce the image of each page before dry toner is applied to the image and transferred to paper. The laser printer is the most popular. The dot matrix is practically obsolete. The resolution of a printer is measured in dots-per-inch. The common resolution of a laser printer ranges from 600 dpi to 1400 dpi.
- A **projector** for a computer system is the same as a traditional slide projector except that it receives input from a computer instead of a slide.
- **Computer speakers** are similar to normal audio speakers except that they obtain the input from a computer sound card instead of from conventional audio devices.

1.4.3 Input and Output Device

- **Disk drives** include CD-ROM drives, DVD-ROM drives, Zipped drives, floppy-disk drives, and hard drives. These drives are used to read and write information. (Refer to Memory Hierarchy in Computer Systems (Section 1.2) for further detail.)
- A **modem** is a device that connects two computers together over a telephone line by converting the computer’s data into an audio signal and vice versa. Modems operate at data rates from 28,800 bps to 57600 bps. Most of them are full duplex although some networks might still need to support half-duplex modems. There is also another device known as cable modem that converts the digital signal into analog, which can be transmitted through coaxial cable.
- **LAN** can be made up of several technologies, such as integrated services digital network (ISDN), fiber optics, twisted pair, and cable.
- **VCRs** can be used as input or output for a computer system through the use of interface cards.
- **Fax machines** are commonly used in offices to send and receive a fax. A fax can be stored in electronic format in a computer.
- **Audio equipment** can be easily connected to a computer system through an interface such as a sound card. Popular audio equipment is MIDI keyboard. MIDI stands for musical instrument digital interface. It stores the information of how the music should be played back instead of all the information about the music, with the help of a wave table in a sound card. Since MIDI skips the storage of actual sound itself, it saves a lot of memory space. However, MIDI might not be accurate without a good wavetable. A wavetable with 32 voices means that the sound card stores 32 voices in its ROM, and MIDI can just call the voices without recording the voices again.

2.1 Introduction

As both the cost and performance of microprocessors continue to improve, it becomes increasingly attractive to build computer systems containing many processors. Performance improvement is one obvious benefit of a multiprocessor system. In the ideal case, a system with N processors can provide N times speedup of compute-bound tasks. Given that the cost of a microprocessor is a small fraction of the total system cost, the cost effectiveness of such an approach is obvious. A different but equally important reason for using multiprocessor systems is for better reliability. The idea here is that even if a single processor fails, the system would continue to work, though at a slower pace. The workload of the failed processor would be automatically taken up by the remaining processors.

Nowadays, multiprocessor systems can be found in many applications. Most file servers and World Wide Web servers are built with machines that can take two or more processors. The data processing industry that requires transaction processing with large databases use, multiprocessor systems as a standard.

There are two ways of looking at how a multiprocessor system improves performance: (1) increased throughput for **independent** tasks distributed among a number of processors and (2) faster execution of a single task on multiple processors. The organization and design of the system differs significantly for the two different goals; some system architectures are discussed in Section 2.2. The programming of the system also depends highly on the architecture and desired functionality, as discussed in Section 2.4.

One common way to categorize all computer systems was originally proposed by Flynn (1972) as shown in the following list:

1. Single instruction, single data (SISD) machines refer to a single processor executing a single instruction stream that operates on data stored in a single memory. All uniprocessor systems belong to this category.
2. Single instruction, multiple data (SIMD) machines allow a single instruction stream to control many processing elements in a lockstep fashion. Each processor has its own data memory so that during each instruction step, many sets of data are processed simultaneously. Both vector processors, such as the CRAY T80, and array processors, such as the Connection Machine (Hillis, 1986), are SIMD machines.
3. Multiple instruction, single data (MISD) machines enable a common sequence of data to be sent to multiple

processors that each operate on data with a different instruction. This type of machine structure is not very useful and has never been implemented in real systems.

4. Multiple instruction, multiple data (MIMD) machines refer to a number of processors executing different instructions on different data streams simultaneously. This is the most common multiprocessor structure; the symmetrical multiprocessor (SMP), clusters, and nonuniform memory access (NUMA) systems are all examples of this category.

In the following sections, we examine the different organization used in multiprocessors. The key issues addressed include:

- How do multiple processors share data?
- How do cache memories on different processors maintain their data correctly?
- How do multiple processors communicate and coordinate with each other?
- How many processors are needed, and what performance improvement can be expected?

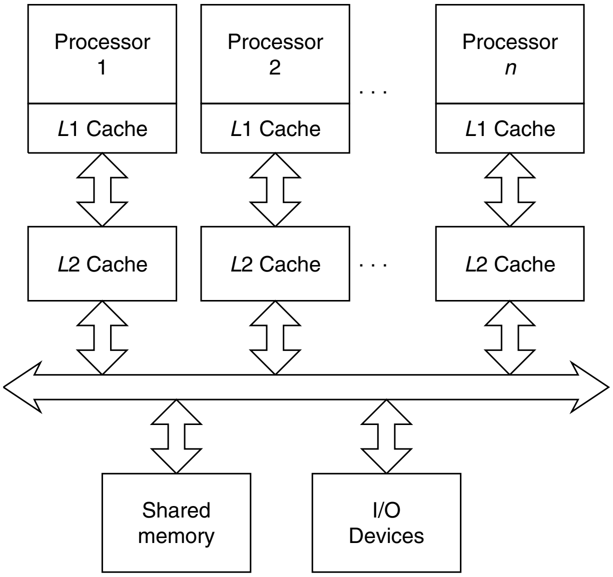

FIGURE 2.1 A Typical SMP Machine

2.2 Architecture of Multiprocessor Systems

2.2.1 Symmetric Multiprocessors

The **symmetric multiprocessor** (SMP) is the most popular form of multiprocessor system available, ranging from low-cost file servers with only two processors to high-performance graphics systems, such as Silicon Graphics's Power Challenge that contains up to 36 processors. In most SMP machines, all processors are connected in a shared backplane. The characteristics of an SMP are the following (Patterson and Hennessy, 1998):

- Two or more similar (or often identical) processors are employed in a stand-alone system.
- All processors share the same memory and *I/O* devices via one or more shared busses with similar access time.
- All processors are capable of performing the same functions.
- The distribution of workload between processors is performed by the operating system in such a way that multiple independent or dependent tasks are shared between processors without any special consideration in the application program.

The distribution workload characteristic is one of the reasons why SMP is widely adopted in commerical products. Most modern operating systems, such as MS-WindowsNT, Linux, and Solaris, support SMP machines. Users no longer need to learn special parallel programming skills to exploit the performance of SMP. Users, however, can also choose to write multithreaded applications to exploit the parallel capability of SMP in a single task.

Figure 2.1 shows a block diagram of a typical SMP machine as would be found in a Pentium-based file server. The common time-shared bus provides the simplest and most cost-effective way to interconnect the processors together. It also, however, limits the number of processors that can be used. Since all memory and *I/O* references pass through the shared bus, the performance of the system is limited by the maximum bandwidth of this bus. One way to alleviate the shared bus bottleneck is the extensive use of cache memory. Most SMP systems have at least two levels of cache memory as shown in Figure 2.1. Typically level 1 cache is on the same chip as the processor, and level 2 cache may or may not be internal to the processor.

Using cache memory in a multiprocessor system introduces the problem of cache coherency: how to guarantee that when a data in a specific cache are altered, this change is reflected in other caches and in main memory. The problem of cache cherency is examined in detail in Section 2.3. Table 2.1 summarizes the key specifications of some SMP systems available in 1999.

2.2.2 Cache Coherent Nonuniform Memory Access

The **cache coherent nonuniform memory access** (CC-NUMA) paradigm, as employed in the Sequent NUMA-Q (Lovett and Clapp, 1996), for example, is a relatively recent idea compared to SMP. CC-NUMA systems strike a balance between the tightly coupled SMP systems and more loosely coupled clusters of communicating computers. The idea behind CC-NUMA systems is that while all processors have access to all portions of the main memory, the memory access time is allowed to vary depending on the part of main memory that is being

Table 2.1 SMP System Specifications

accessed. This allows portions of main memory to be distributed between groups of processors, each group typically arranged in an SMP style or as a uniprocessor. These groups must be able to communicate across a communications network to access nonlocal memory.

The advantage of CC-NUMA over a standard SMP design is that there are several local busses, so each one need not carry all transactions occurring throughout the system. This in turn means that a larger number of processors can be used than in the equivalent SMP design, allowing a greater level of parallelism. The Sequent NUMA-Q system can support over two hundred Pentium II processors. CC-NUMA has a clear advantage over clusters of communicating computers—because the nonlocal memory accesses and cache coherence is maintained automatically, it is a much easier process to port software developed for an SMP to a CC-NUMA system than to a cluster. In addition, the programming paradigm is significantly simpler.

2.3 Cache Coherence

For many years, cache has been used to speed up memory access and overcome bottlenecks in a uniprocessor computer systems. All the reasons for using caches with uniprocessors also exist with multiprocessor systems but exist more acutely. A typical shared-bus SMP system will have its performance severely limited by bus cycle time without using local cache memory.

The existence of caches local to each processor in a multiprocessor system introduces the problem of **cache coherence**. Multiple copies of data could possibly exist in different caches simultaneously due to shared data structures or because of process migration between processors. Each processor must be sure that when it reads a line of memory from its cache, the line has not been previously overwritten in the cache of some other processor or in main memory due to a transaction initiated by another processor. This is the essence of the cache coherence problem for which several techniques have been applied. Techniques to ensure coherence can be divided into **hardware-based** and **software-based approaches**.

Software-based approaches use compiler and operating system techniques to analyze data flow in the processes and act accordingly. Typically, a compiler will mark data as "noncachable" during periods when the data are both shared by multiple processes and being written to at least one process; the compiler marks the data "cachable" during other periods, such as when one process has exclusive use of the data or read-only sharing is in operation (Lilja, 1993). The advantages of using a software approach are clear—by solving the problem at compile-time, it is not necessary to design complex and expensive coherence-preserving hardware. For software with complex control structures, however, it becomes difficult or impossible to analyze which processes have use of which blocks of memory at compile time. The compiler is therefore forced to produce conservative solutions to preserve correctness, leading to significant lost opportunities for caching.

The type of **hardware-based cache coherence approach** used depends heavily on the hardware architecture. For a shared-bus system, it is relatively easy for each cache controller to monitor, or "snoop," on all bus transactions. This is the popular approach used by so-called snoopy protocols such as MESI, to be described in Section 2.3.1. Under other, more general, forms of system architecture, it becomes difficult or wasteful for all cache controllers to monitor all transactions, therefore, another protocol must be adopted. Directory-based protocols that maintain a directory of which parts of main memory are in which caches eliminate the need for a global broadcast mechanism; these protocols are therefore better suited for complex system architectures.

2.3.1 Snoopy Protocols and MESI

Snoopy protocols distribute the responsibility for cache coherence between all cache controllers. Some mechanism must be incorporated so that each cache knows when a line is also in another cache. If this line is subsequently updated, it must inform the other caches that this update has taken place. There are two approaches in snoopy systems: either the write is broadcasted to all caches so that they can update their line accordingly (**write-broadcast**), or the write is simply used to invalidate the lines in the other caches (**write-invalidate**). The MESI protocol is an example of write-invalidate and is used by the Pentium II processor (Shanley, 1998).

MESI caches include two status bits per tag, indicating the state of the corresponding cache line, which can be described by each letter in the MESI abbreviation:

- **M**odified: The line has been modified and is only in this cache.

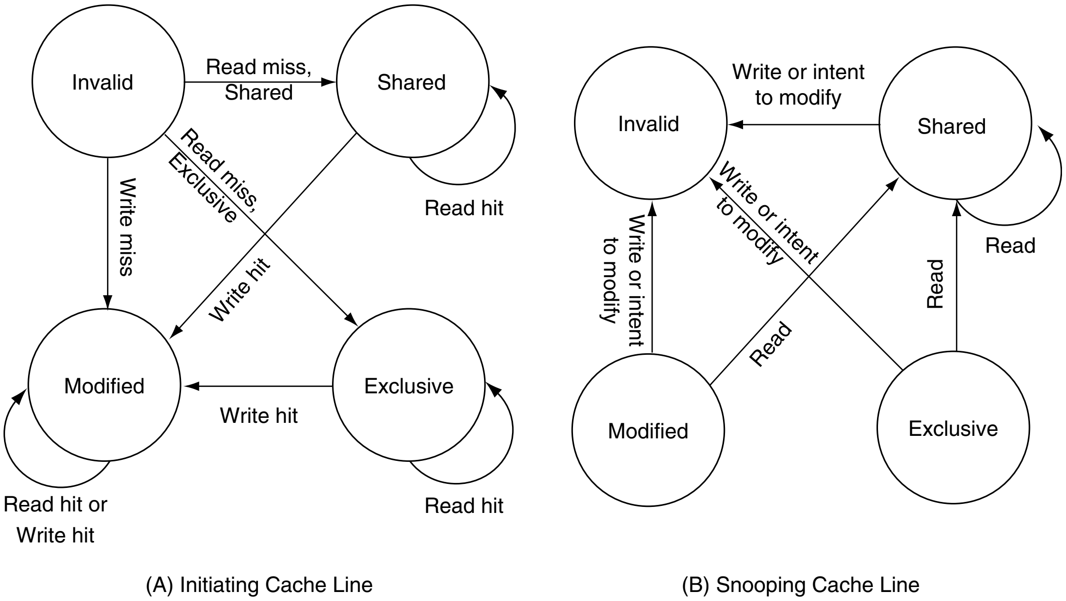

FIGURE 2.2 MESI Protocol State Transition Diagram

- **E**xclusive: The line is "clean" (same as in main-memory) and is only in this cache.
- **S**hared: The line is clean and possibly present in another cache.
- **I**nvalid: The line in the cache does not contain valid data.

The possible states are **read hit**, **read miss**, **write hit**, and **write miss**, as next described; and a state diagram for the MESI-protocol is shown in Figure 2.2 (Stallings, 2000).

1. **Read hit**: On a read hit, the cache controller supplies the data from its cache. No state change occurs.
2. **Read miss**: On a read miss, the cache controller must transfer the relevant line from main memory. A signal is broadcast to all snooping caches that must reply if they have a copy of the cache line.
   - If no signals are returned, the initiating cache controller can set the "exclusive" state.
   - If at least one signal is returned, the initiating cache controller must set the "shared" state.
   - If another cache has an exclusive copy of this line, it too must change the state to shared.
   - If another cache contains a modified copy of the line, this copy is written back to the main memory, and this cache controller must set the shared state before the originating controller can perform the read transfer.
3. **Write hit**: On a write hit to a modified line, the cache controller simply updates the line in the local cache. On a write hit to an exclusive line, the cache controller modifies the line in its local cache, but it must also change the state of the line to "modified." On a write hit to a shared line, the cache controller must inform the other caches so that they can mark their lines as "invalid" (shown as *intent to modify* in the state diagram). After this, the initiating controller can update the line locally and mark it modified.
4. **Write miss**: To write an item of data not in the cache, it is first necessary to read the entire line of memory into the cache. This signals the other caches of the initiating controller's intent to modify.

If another cache contains a modified copy of this line, it is possible that the two modifications are in different positions in the line. It is therefore necessary for the initiating controller to stall while the other cache controller writes its modified line out to main memory before invalidating its line. If no cache has a modified copy of this line, no signals are returned to the initiating processor, which modifies the line in its local cache, marking it modified. If any other caches containing clean copies of this line, their copies are marked invalid.

Some extensions have been proposed to snoopy protocols to reduce the amount of bus traffic generated. In the read-broadcast (Rudolph and Segall, 1984) protocol, a read-miss generated by a cache controller will force an update of that line in every cache. Whether write-invalidate is a better approach than write-broadcast depends on the pattern of data transfer. Karlin *et al.* (1986) proposed a protocol that adaptively decides which approach to take at run time.

2.3.2 Directory-Based Protocols

Directory-based protocols maintain information on which caches contain copies of which memory lines (Agarwal *et al.*, 1988). Most directory-based approaches maintain a single centralized directory, although there have also been proposals to maintain the directory in main memory or to distribute it through each local cache (Stenstrom, 1989).

Maintaining a centralized directory has the least overhead in terms of storage (Stenstrom, 1990), but it suffers from several disadvantages. Every local action that could possibly cause a change in global state must be reported to the controller, causing a bottleneck due to its centralized nature. In addition, a hardware search mechanism must be implemented that allows the controller to search through all duplicates to find which caches have copies of a particular block.

The key advantage of directory schemes is the ability to restrict coherency communications to only those absolutely necessary. There is clearly a trade-off between communication overhead and directory size and complexity. One possibility for exploring the trade-off is to use limited directory schemes (Stenstrom, 1990). In such a scheme, a limit is placed on the number of directory entries pointing to a particular block. The protocol either does not allow more than this number of cache copies of a single line or starts to use broadcasting after this limit has been reached. Another possibility is to use a linked-list style structure in which each cache line points to the next cache to contain a copy of that line. These are known as chained directory schemes, one example being the scalable coherent interface (SFI) as described by IEEE (1989). This approach slows down the coherency communications because they may have to go through several stages of cache controller.

2.4 Software Development and Tools

Two of the goals for multiprocessor software development are the same as those for single-processor systems: (1) the facilities should support correct program development, and (2) the application program should be portable to a wide variety of systems. There is a third goal: performance. The performance goal, however, should satisfy a further requirement of scalability—the speed of the system should increase preferably linearly with the number of processors. This means that the computational load should be optimally distributed among the processors: the task of this optimal distribution is often known as load balancing. While the multiprocessor system architecture usually dictates its scalability, appropriate languages and compilers ensure that the performance potential can be exploited by application programs.

2.4.1 Operating Systems

The two key tasks performed by a multiprocessor operating system are load balancing and failure management (Valiant, 1990), in addition to the tasks required in single-processor operating systems.

For SMP systems, the operating system is required to schedule multiple tasks for execution on multiple processors and to allocate resources to support such execution. The scheduling and resources allocation should take into account the need for load balancing. Since scheduling can be performed by any processor, there should be a mechanism to avoid or resolve conflicts. The same or different parts of the operating system can be executed by many processors, so control information (e.g., operating system tables), storage management (e.g., paging facilities), and synchronization between processors need to be carefully managed to avoid deadlock or invalid operations. Furthermore, the operating system should contribute to failure management—for instance, processor failure should lead to graceful degradation in services and performance.

For cluster systems, load balancing is often achieved by automatically including information about node availability in the scheduling process so that the system can be incrementally scalable. There should be facilities to manage services offered by one or more nodes in the cluster, and such services may also migrate from one node to another.

Failure management in a cluster depends on the cluster method. Two approaches are often adopted: **high-availability clusters** and **fault-tolerant clusters**. A high-availability cluster supports migration of services from failed nodes although partially executed transactions have to be recovered by the application program. A fault-tolerant cluster guarantees service availability by using redundant resources, and there are facilities to complete partially executed transactions.

For CC-NUMA systems, an important task for the operating system is to exploit temporal and spatial locality of data to reduce the need for remote storage access. For instance, spatial locality can be improved by organizing application data into pages to be stored locally to the processor. Another technique is to support page migration: pages in virtual memory can be moved to a node that requires them frequently.

2.4.2 Software Development Methods

This section provides an overview of three methods for parallel programming (Foster, 1995). The first two are based on extending existing sequential languages, C and FORTRAN. The third method, MPI, consists of a library for managing communication in parallel programs and is largely language-independent.

Compositional C++, or CC + +, consists of six new keywords in addition to all of the existing ones in C + + (Chandy and Kesselman, 1993). Each new keyword supports a basic abstraction for parallel programming: specification of sequential code execution in a "processor object", linking together processor objects, specification and synchronization of program threads for concurrent execution on one or more processor objects, control of interleave execution of threads in the same processor object, and transfer of data structure between processor objects. These abstractions provide the means for capturing parallelism, locality, communication, and mapping. CC++ is used particularly for applications involving dynamic task creation, irregular communication and computation patterns, and concurrent composition of objects.

High performance FORTRAN, or HPF, is an example of a data parallel language (Foster, 1995). Parallelism is mainly expressed in terms of array operations: data elements of an array are operated on simultaneously. There are data distribution directives to allow programmer control over data partitioning, agglomeration, and mapping. Communication is inferred by the compiler rather than by the programmer. Although HPF offers a high level of abstraction, not all algorithms can be expressed in the form of a data parallel program. Hence, HPF is especially applicable to those programs easily specified using array operations, such as numerical algorithms based on regular domain decomposition.

Message passing interface (MPI) is a library of standard subroutines for sending and receiving messages and performing collective operations (Foster, 1995). A computation consists of processes created at program initialization. Processes can use point-to-point communication to send messages to one another. A group of processes can perform collectively in global operations, such as summation and broadcast. MPI provides support for program modularity: MPI modules can encapsulate internal communication structures. Such modules can be combined by sequential or parallel composition.

A more recent approach for language-independent parallel software development, called BSP, is covered in the next section.

2.4.3 Software Development: The BSP Approach

The **bulk synchronous parallel** (BSP) programming approach is of interest because it promises the achievement of all the goals mentioned at the beginning of this section: software correctness, portability, and scalable performance (McColl, 1996). The approach is applicable to SMP, cluster, and NUMA architectures. Just as for MPI, libraries exist to support BSP programming in standard sequential languages such as FORTRAN and C. There is also a rigorous theoretical foundation (Valiant, 1990) that allows the development of scalable BSP programs.

The key idea in BSP is to decouple communication from synchronization in the programming model. A parallel system is described as a collection of processors, each with its own local memory, and the processors are connected by a communication network capable of efficient barrier synchronization. A **barrier** is a method to separate two phases of a computation to ensure that messages generated in the two phases are not mixed together.

Execution of a BSP program proceeds in phases called supersteps. Global communication between parallel threads, such as access to memory of remote processors, is only allowed between supersteps but not in a superstep. The application program does not need to concern itself about synchronization, which can be implemented in the hardware or software. The same program can be ported to different systems provided that each supports the BSP programming model.

Since communication and synchronization are decoupled in a BSP program, the programmer does not have to worry about problems such as deadlock, which can occur with synchronous message passing. Debugging a BSP program is also simpler: the barrier at the end of a superstep provides an appropriate break point at which the global state of the parallel computation is well-defined and can be interrogated. Debugging and reasoning about the correctness of a BSP program are hence not much more difficult than for a sequential program. In addition, BSP provides an analytical cost model to assess the performance of parallel algorithms, to facilitate analyzing, and to predict their performance.

Machine-specific libraries for process creation, remote data access, and bulk synchronization have been developed to assist BSP programmers. There are native libraries for IBM's SP2, Cray's T3D, and Silicon Graphics's Power Challenge and other parallel systems. There is also a generic version for any homogeneous parallel Unix machine that has access to PARMACS, PVM, TCP/IP, or System V Shared Memory primitives (Pountain, 1996). These libraries simplify parallel program development: they also facilitate performance estimation for specific parallel machines.

2.4.4 Performance Tools

Performance tools are an essential part of the software tool kit for the development of parallel algorithms. These tools allow software developers to capture empirical data on the execution of their algorithms. These data may then be used to calibrate and validate preconceived mathematical performance models, to compare different algorithms, to investigate the scalability of algorithms with a number of processors, and to identify actual or potential bottlenecks in execution.

The type of data collected by performance tools falls into three categories: **profiles**, **counters and timers**, and **traces** (Foster, 1995). Profiling tools typically use sampling techniques, regularly examining the program counters during execution to determine how much time is spent on different procedures and activities. Profiling is extremely simple to implement and can provide an automatic high-level view of process execution. It is particularly useful for identifying unbalanced loading between processors. In addition, if there are several profiling runs for different processor counts, profiling can be used to determine components that do not scale well under the given algorithm. The disadvantage of using sampling techniques is that they are not always accurate, which is of particular concern if the developer is trying to calibrate timing models. The main problem with simple profiling in a multiprocessor system, however, is that it is unable to reveal the complex interprocessor interactions taking place under the surface.

Counters and timers allow precise information to be made available by inserting extra code to count the number of times a portion of source code has been executed or how long is spent executing it. Counters require manual user insertion of codes or special compiler action. They have the advantage of revealing precise information, unlike sampling techniques; however, timers can be complex, and the presence of the counter or timer may itself interfere with the result that is trying to be measured to some extent.

Traces are detailed logs of program execution. Whenever a meaningful event takes place, such as a message passed between two processes or the entry and exit of a procedure, the event is logged and time-stamped. Analysis tools are then heavily relied upon to extract some meaningful information from these logs or to at least reduce the dimensionality of the data such that visualization tools can be used to explore the information present. The main disadvantage to the use of traces is the huge amount of data that can be created; Foster (1995) gives the example of a 20-byte record on every message on a 128-processor system with messages produced every 10 ms. For this system, a volume of 1 GB of data would be produced per hour. In addition to the storage and postprocessing requirements necessary, logging this much data could itself change performance significantly.

2.5 Recent Advances

Multiprocessor systems are being used successfully today to improve performance in systems running multiple programs concurrently. In addition, multiprocessor systems have shown the ability to improve single-program performance significantly for certain applications containing easily parallelized loops. The extraction of coarse-grained parallelism from a software description and, indeed, the study of languages used to describe parallel software are a flourishing area of research.

With the introduction of the single-chip multiprocessor (Olukotun *et al.*, 1996), the dividing line between research into high-performance system architectures and high-performance processors is becoming blurred. Very coarse-grained programmable logic devices such as Chess (Marshall *et al.*, 1999) or the RAW machines proposed by Waingold *et al.* (1997) can be considered radically different forms of multiprocessor architecture. These approaches eliminate traditional instruction-set interfaces and instead rely heavily on compilation to directly customize the hardware to a particular application. Relying on compilation is possible because the hardware consists of a simple regular array of interchangable processing units. Clearly, this blurs the boundary between compiler research and traditional high-level synthesis, another area under intense investigation (Detton and Wawrzynek, 1999) Extending this approach of exposing the inner architecture of a processor to the compiler even further results in the possibility of more fine-grained reconfigurable computing techniques using field programmable gate arrays (Luk *et al.*,).

2.6 Summary

It is becoming increasingly attractive to build computer systems containing several interacting processors. In general, it is significantly more cost-effective to exploit the parallelism inherent in an algorithm by using multiprocessor approaches than it is to design a single faster uniprocessor.

Multiprocessor architectures have been categorized by the existence of single or multiple instruction and data streams. This chapter has examined multiple-instruction, multiple-data, and MIMD architectures in some detail. The most common form of MIMD multiprocessor arrangement is one of symmetric multiprocessors (SMP). The use of multiprocessors creates the problem of maintaining cache coherence over several levels of cache existing at different places in the computer architecture. This chapter has also presented several cache coherence approaches and the common MESI protocol. In addition, the discussion has surveyed approaches to software design for multiprocessors and some of the more recent problems in multiprocessor design.

3.1 Introduction

Configurable computing, or **reconfigurable computing**, refers to the use of configurable hardware for computing purposes. The root of configurable computing can be traced back to the early 1960s, when the idea of a "restructurable computer" was first proposed by Estrin *et al.* (1963). The recent interest in configurable computing is mainly due to the rapid advance in technology of field-programmable gate arrays (FPGAs), devices containing a collection of programmable elements connected together by a network that may also be programmable by users. In short, FPGAs combine the flexibility of software with a performance approaching that of custom-developed hardware.

This chapter is intended to provide the reader with a flavor of configurable computing and its current and future trends. Configurable computing covers a wide range of topics and is rapidly growing, so our discussion will focus mainly on the promising technology of run-time reconfiguration. Useful reviews of configurable computing and FPGAs include Amano *et al.* (2000), Buell *et al.* (1996), Hauck (1998), Kean (2000), Mangione-Smith (1997), Schaumont (2001), Tessier and Burleson (2001), Trimberger (1994), Villasenor and Hutchings (1998), Villasenor and Mangione-Smith (1997), and Vuillemin *et al.* 1996. Readers who wish to cover further ground are advised to consult some of these resources.

FPGAs have become the favored choice in implementing glue logic, experimental systems, and hardware prototypes because of advantages such as short turnaround time, user reconfigurability, and low development costs. However, there are area and time overheads for providing configurable logic, configurable storage, and configurable routing resources.

Increasingly, designers realize that the key to minimizing the effects of these overheads is to fully exploit the flexibility of FPGAs, especially those that can be rapidly reconfigured at run time. We shall adopt a broad interpretation for the term **run-time reconfigurability**: it includes devices that support only complete reconfiguration by the user and those that can be partially reconfigured at run time.

Run-time reconfiguration has two main benefits. First, it enables multiplexing nonmutually dependent operations in the time domain: circuit area can be reduced by including only the active parts of a circuit at a particular moment in time. If the tasks or the algorithmic steps in an application can be partitioned into smaller ones to fit into available FPGA resources, run-time reconfiguration can be used to swap between the smaller circuits. This technique will enable the implementation of a large virtual circuit in a small physical FPGA.

The second benefit of run-time reconfiguration is to enable design upgrade. The ability to upgrade product features is a fundamental benefit of reconfigurable technology over application-specific integrated circuits; it has the potential to reshape the electronics industry when combined with a "chipless" business model for providing intellectual properties for reconfigurable devices (Kean, 2000). Design upgradability is particularly important for applications where standards evolve quickly or where there is a need to customize designs to unpredictable run-time conditions.

The frequency of reconfiguration is often dependent on the application. For some applications, there is sufficient time between tasks for reconfiguration to take place without affecting performance; for other applications, careful management of reconfiguration is required to minimize the impact of reconfiguration time.

With the development of partially reconfigurable FPGAs, it is possible to reduce the overhead of reconfiguration: the smaller the circuit to be configured, the shorter time it takes. Existing components are replaced by new ones at run time by partially reconfiguring the appropriate parts of the FPGA, while the rest of the FPGA continues to operate. The same principle applies to systems containing multiple FPGAs; computation and configuration can take place concurrently in different devices.

Although incorporating partial reconfiguration into designs is becoming popular, their development is still largely an art involving tedious and error-prone crafting of the circuits at a very low level. Relatively few studies have been reported that concern methods for describing reconfiguration, compilation tools for configurable designs, and the automatic detection of reconfigurable regions. In the next section, we shall outline an approach to exploit run-time reconfigurability. An overview of configurable computing technology, particularly run-time reconfiguration, will be given in Section 3.3, and current and future trends will be covered in Section 3.4. Finally, concluding remarks will be presented in Section 3.5.

3.2 Approach

This section begins with an outline of an approach for design development for reconfigurable hardware (Luk *et al.*, 1999; Shirazi *et al.*, 1998a, 2000). To enable the high-level description of run-time reconfigurable designs, a model has been developed for specifying, visualizing, and optimizing reconfigurable designs (Luk *et al.*, 1999). Such designs can be compiled into hardware by tools that take into account that reconfigurable designs change dynamically with time (Shirazi *et al.*, 2000). Given information regarding the sequence of reconfiguration, the tools select and refine appropriate components in reconfigurable regions.

To ease the development of reconfigurable designs, it is desirable to automate the identification of reconfigurable regions (Shirazi *et al.*, 1998a). This involves the following steps: (1) identification of identical or similar components between two successive designs and (2) placement of such components to minimize reconfiguration time. An example of this process is shown in Figure 3.1. In this design, blocks A, B, and C are present in both design 1 and design 2, while block D is present only in design 1 and block E only in design 2. Given these two designs, the task of a tool is to produce a run-time reconfigurable (RTR) design such that, when reconfiguring from design 1 to design 2, only block D needs to be reconfigured to block E. In other words, the blocks have to be physically aligned to minimize the reconfigurable region covered by blocks D and E; blocks A, B, and C are outside the reconfigurable region and will not be reconfigured.

Run-time management techniques are required to incorporate the necessary components efficiently based on a sequence for reconfiguration. If run-time conditions determine how reconfiguration should be performed, it may not be feasible to produce all the reconfiguration possibilities at compile time. A solution to this problem is to let the hardware manager build the new configuration as required at run time (Shirazi *et al.*, 1998b); various approaches are discussed in Section 3.3.4.

Since pipelining is a common technique to increase the speed of a circuit, it would be advantageous to minimize reconfiguration time of these types of circuits. Further reductions in reconfiguration overhead can be achieved by avoiding latency associated with emptying and refilling the pipeline during reconfiguration. Figure 3.2 describes a technique for overlapping computation and reconfiguration that can be implemented using either existing FPGAs (Luk *et al.*, 1997) or a

Given the pipeline F with stages $f_1, \ldots, f_5$ and the pipeline G with stages $g_1, \ldots, g_5$, the diagram shows how F can be reconfigured into G in five steps. Only one stage of the pipeline is being reconfigured in each step, while the rest of the pipeline continues to operate.

device specially designed to support such overlapping (Schmit *et al.*, 2000).

3.3 Overview

This section presents an overview of important topics in configurable computing, particularly those involving run-time reconfiguration. The topics covered include run-time reconfigurable devices, run-time reconfiguration methods, tools, run-time management, and hardware platforms and applications.

3.3.1 Run-Time Reconfigurable Devices

FPGAs, by definition, are configurable; most of them are also reconfigurable unless they are based on technologies such as Antifuse, that are one-time programmable. Several commercial devices support partial reconfiguration, including the Virtex (Xilinx, 2001) and 6200 (Churcher *et al.*, 1995) devices from Xilinx, the CLAy chip from National Semiconductor (National Semiconductor, 1993), and the AT 40K devices from Ateml (Atmel, 1997). Useful reviews of FPGA architectures are available (Buell *et al.*, 1996; Hauck, 1998; Kean, 2000; Mangione-Smith, 1997; Trumberger, 1994; Villasenor and Hutchings, 1998). Although some devices such as Xilinx 6200 FPGAs are no longer supported commercially, the ideas in the relevant publications may still inspire future advances.

A simple FPGA model is shown in Figure 3.3. In this figure, processing elements, typically containing configurable logic and storage blocks, are represented by squares. The processing elements are connected to configurable switches, represented as circles, that control data flow by establishing the desired connectivity between the busses. Much of the area in an FPGA is usually taken up by the configurable switches and the busses; local and global busses can also be organized hierarchically. The figure demonstrates the regularity found in most FPGAs; practical FPGAs often contain additional resources, such as configurable memory blocks and special-purpose input/output blocks supporting boundary-scan testing (Trimberger, 1994).

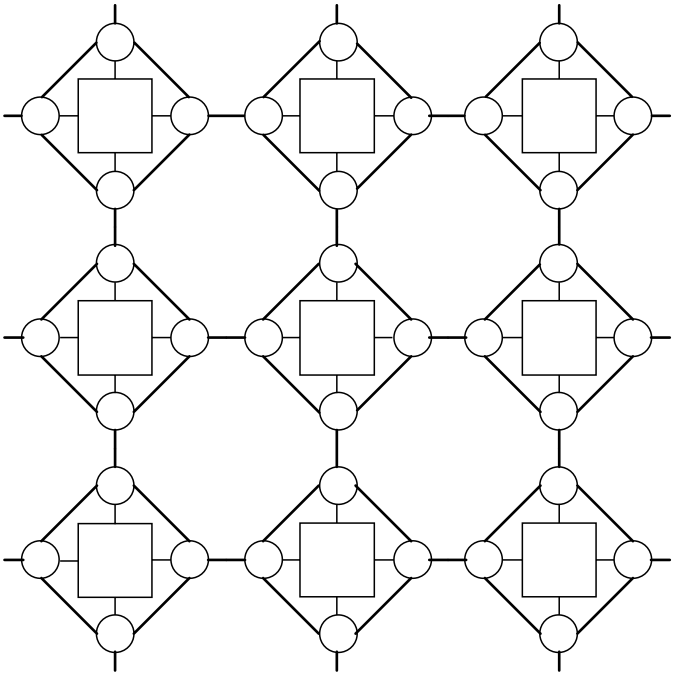

FIGURE 3.3 A Simple Model of an FPGA. Squares represent configurable processing elements, and circles represent configurable switches to control routing.

Many experimental FPGA architectures support run-time reconfiguration. Tau *et al.*, (1995) have come up with an FPGA that stores multiple configurations in memory banks. In a single clock cycle, which is in the order of tens or hundreds of nanoseconds, the chip can replace configuration by another without erasing partially processed data.

A similar FPGA that can perform a context switch in one cycle has been developed by Trimberger *et al.* (1997). The FPGA can store up to eight configurations in on-chip memory.

This FPGA is based on a Xilinx 4000E device and includes extensions for dealing with saving state from one context to another.

The Colt Group led by Athanas is investigating a run-time reconfiguration technique called Wormhole that lends itself to distributed processing (Bittner and Athanas, 1997). The unit of computing is a stream of data that creates custom logic as it moves through the reconfigurable hardware.

Schmit *et al.* (2000) have developed a reconfigurable FPGA targeted toward pipelined designs. Reconfiguration is performed at the level of individual pipeline stages, similar to that described in Figure 3.2. Others have shown that commercial partially reconfigurable FPGAs can also support efficient reconfiguration of pipelined designs (Luk *et al.*, 1997).

There are also configurable devices based on coarse-grain programmable elements (Conquist *et al.*, 1998), multiple-bit arithmetic units (Marshall et al., 1999), and low-power techniques (Rabaey, 1997). Kean (2000) provides an overview of commercial devices available in the year 2000.

3.3.2 Run-Time Reconfiguration Methods

Hutchings and Wirthin (1995) suggested that two types of run-time reconfiguration exist: global and local. During **global reconfiguration**, all the hardware resources are allocated with a new configuration in each configuration step. This method works for nonpartially reconfigurable FPGAs, such as the Xilinx 4000 series. Applications that use the second type of run-time reconfiguration, local reconfiguration, locally or selectively reconfigure subsets of the FPGA during application execution. Since the larger the size of the region to be reconfigured means the longer the reconfiguration time, Hadley and Hutchings (1995) have proposed techniques to minimize the size of the reconfigurable region to reduce reconfiguration time. Others have developed methods and tools that are able to produce designs both locally reconfigurable as well as globally reconfigurable (Shirazi *et al.*, 2000).

To quantify the advantages of run-time reconfigurable designs, Wirthlin and Hutchings (1998) introduced a metric called **functional density** that measures the computational throughput (operations per second) of unit hardware resources. This metric can be used to identify the conditions under which a run-time reconfigured circuit provides higher functional density than its statically configured alternative. Several applications, including neural nets, template matching, and DNA sequence matching, are used to illustrate the superiority of run-time reconfigurable implementations.

Hutchings and Wirthlin (1995) have built a dynamic instruction set computer (DISC) that emulates a reconfigurable microprocessor by using an FPGA and demonstrates the potential of automatic reconfiguration using stored configurations. As a program runs, the FPGA requests a new reconfiguration if the desired instruction is not resident. DISC allows a designer to create and store a large number of circuit configurations and activate them much as a programmer would initiate a call to a software subroutine in a microprocessor. Partial reconfiguration is used to reconfigure FPGA resources with the instruction, thereby minimizing reconfiguration time.

One feature of DISC is that the instructions are interconnected using a fixed bus structure. Luk, Shirazi, and Cheung also proposed methods (1996) and tools (1998, 2000) for run-time reconfigurable designs. An advantage of their approach is that the reconfigurable designs produced are not confined to a specific bus structure.

On DISC 25% to 71% of the execution time is spent reconfiguring. Hauck *et al.* (1999) have studied techniques for reducing reconfiguration time on the Xilinx 6200 by compressing the configuration data stream. They have been able to reduce reconfiguration time 4-fold by using a device specific feature called **wildcarding**. The approach by Shirazi *et al.* (2000) also takes advantage of wildcarding, and they provide an example in which reconfiguration time has been reduced from linear time with respect to size of the component to constant time at best and logarithmic time at worst. More recently, Li and Hauck (2001) described a method for compressing configuration data for Xilinx Virtex FPGAs that exploits the regularity of the frame-based format of configuration data.

The group led by Woods has developed an efficient technique for fast partial reconfiguration for FPGA-based systems (Sezer *et al.*, 1998). They used a library-based approach to achieve a high degree of commonality between designs. The configuration data are stored efficiently in a **configuration data graph** (CDG). A CDG is a database of designs organized according to their shared components. High-speed configuration is also achieved by using **reconfiguration state graphs** (RSGs) that model reconfiguration as state transitions. The tools developed in this thesis generate representations similar to RSGs automatically from a specified reconfiguration sequence. It is also possible to introduce optimization techniques based on compile time information to optimize the RSGs and decrease the amount of configuration data needed (Shirazi *et al.*, 2000).

McKay and Singh (1998) have used partial evaluation techniques to optimize circuits that have slowly changing inputs. They are able to achieve about a 60% increase in clock speed for a parallel multiplier circuit performing just a single level of partial evaluation. Others have also used partial evaluation techniques in compilation tools (Shirazi *et al.*, 2000) and in application development (Shirazi *et al.*, 1998b).

3.3.3 Tools

The introduction of Xilinx Virtex FPGAs (Xilinx, 2001) offered an opportunity for hardware support of partial run-time reconfiguration in large commercial devices. McMillan and Guccione (2000) describes the JRTR tool in the JBits tool suite that provides software support for partial run-time reconfiguration that makes use of the features of the Virtex architecture. The JBits configuration application programming interface (API) provides a set of Java classes to access and manipulate Virtex configuration data.

The JRTR API includes a caching model in which changes to configuration data are tracked, and only the necessary data are written to or read back from the device. The compilation speed is fast, but the user has to lay out components on the devices carefully. Fortunately, there are tools (Shirazi *et al.*, 1998a, 2000) that can be used in combination with the JRTR tool set to automate the development of run-time reconfigurable designs. Such tools should enhance JRTR by automatically finding the reconfigurable regions between subsequent configurations and calculate the difference between configurations, thus minimizing configuration time. It would also be useful to interface hardware compilers (Page and Luk, 1991; Weinhardt and Luk, 2001) to the JRTR tools.

Research on compilation tools for run-time reconfigurable systems, based on the dbC language, is described by Gokhale and Marks (1995). These tools target the National Semiconductor CLAy FPGA (National Semiconductor, 1993) and provide a path for high-level design compilation. Weinhardt and Luk (2001) have extended vectorization and loop transformation techniques used in super-computers for reconfigurable design; Figure 3.4 summarizes the key steps in this framework.

FIGURE 3.4 Design Framework Based on Vectorization Approach. RTR denotes run-time reconfiguration. The dotted line shows possible repetition of some steps that may improve design size and speed.

Promising results have been achieved for mapping loops in a sequential language into reconfigurable hardware.

Page and Luk (1991) describe a hardware compiler for high-level sequential programs augmented with language constructs for parallel operation and communication. This method enables the rapid production of a wide variety of designs, from pipelined video operators to instruction-set processors. The approach is being extended to cover designs involving run-time reconfiguration.

The Trianus system (Gehring and Ludwig, 1996) is an integrated tool set consisting of a layout editor, circuit checker, technology mapper, placer, router, and bit-stream generator and loader for the Xilinx 6200 FPGA. The back ends of the Trianus tool set have been incorporated with the IRIS tools (Woods *et al.*, 1997), allowing designs to be changed at the architectural level in IRIS rather than at the FPGA layout level.

Lysaght and his groups have developed a framework called dynamic circuit switching for specifying, simulating, and debugging reconfigurable designs (Lysaght, 1997; Lysaght and Stockwood, 1996; McGregor *et al.*, 1998; Robinson *et al.*, 1998). Their tools can estimate the reconfiguration time before low-level tools are invoked; this information is used in their compilation process to produce efficient reconfigurable designs.

3.3.4 Run-Time Management

Lysaght and Dunlop (1994) have proposed a self-controlled management technique called **logic caching** that is based on the same principles used by traditional microprocessors. They suggest many improvements to traditional FPGA compilation software to support the development of run-time reconfigurable designs. These include simulation models, automatic design partitioning based on temporal specifications, and support for generating relocatable bit streams. Others have also reported work on temporal partitioning and scheduling of configuration data (Purna and Bhatia, 1999), block-processing based temporal partitioning (Kaul and Vemuri, 2000), identifying and positioning of reconfigurable regions (Shirazi *et al.*, 1998a), and generating relocatable bit streams (Shirazi *et al.*, 1998b).

Bellows and Hutchings (1998) have developed a management technique similar to the method that object-oriented languages use to manage memory. Their management technique is part of their design tool called **JHDL**. A circuit configuration is treated as a distinct object and is downloaded into the FPGA when the constructor of the object is invoked.

The **run-time reconfigurable artificial neural network** developed by Eldridge and Hutchings (1994) uses dynamic reconfiguration to implement three stages of a neural network back-propagation algorithm. Each stage of the algorithm is represented by a circuit module that is swapped in and out of the FPGA hardware as demanded by the application. Only one circuit module is resident on the FPGA at a given time. Some static circuitry is constantly resident which controls data flow and the sequencing of execution of the dynamic modules. Swapping time can be minimized by calculating the difference between the configuration currently resident in the FPGA and the desired new configuration; a tool has been developed for this purpose (Shirazi *et al.*, 2000).

Haug and Rosenstiel (1998) have integrated run-time management techniques into the Linux operating system. Their tools synthesize hardware from user-defined threads in a C program. The operating system's scheduler has been modified to keep track of the configurations in use by the FPGA coprocessor. By incorporating their scheduler into a popular operating system such as Linux, they are one step closer to making run-time reconfiguration a mainstream technology.

Burns *et al.* (1997) have proposed a run-time system for managing the dynamic reconfiguration of FPGAs. The system incorporates operating-system style services that permit high-level operations on circuits, such as circuit transformations and dynamic rerouting of circuits. Shirazi *et al.* (1998b) have also incorporated circuit transformations into their run-time manager.

Brebner (1996) states that the fundamental difference between virtual hardware and virtual memory is that virtual hardware is much more structured. Virtual memory is a collection of independent memory locations and swapping can be done at the single memory location level. In the case of logic circuits, a collection of components operates as a whole; therefore, it is not possible to swap a component unless it is isolated and operates independently from the other components. Brebner defines this type of isolated component as a **swappable logic unit** (SLU). Two different virtual hardware models are defined: **sea of accelerators** and a **parallel harness**. The sea of accelerators model is a collection of SLUs that are independently operating and are accessed via bus-accessible registers. A parallel harness model is a set of SLUs that are cooperating parallel processing elements, interacting with neighbors using perimeter signals, and wiring infrastructure supplied by the operating system. Brebner proposes an operating system to help automate the swapping of SLUs. The swapping of an SLU into an FPGA is broken down into three steps. First, the operating system finds sufficient space to swap the logic into the FPGA by using a two-dimensional recursive bisection technique. If there is not enough available space for the SLU, the operating system removes the least recently used SLUs until enough space is available. Second, the SLU is configured in the FPGA. Third, information about the location of the SLU's *I/O* registers is recorded.

3.3.5 Hardware Platforms and Applications

Luk *et al.* (1998) presented several real-time applications for a hardware platform that includes a daughter board for supplying video data. The architecture of this platform is shown in Figure 3.5. This daughter board is necessary to overcome the

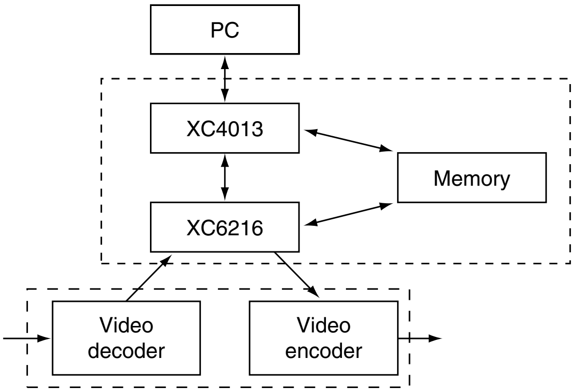

FIGURE 3.5 A Configurable Computing Platform for Video Applications. The upper dashed box contains a commercially available low-cost FPGA board; the lower box contains a video decoder and a video encoder interfaced to the user-programmable FPGA, the XC6216.

I/O bottleneck caused by the PCI bus connecting the platform to a PC host. One use of this platform is in combining real and synthetic video images for augmented reality applications. (Luk et al., 1999).

The FPGA board used in Figure 3.5's hardware platform has been also used to implement an image interpolation engine by Hudson *et al.* (1998). They used run-time reconfiguration to reduce the size of their interpolation engine by four times. To reduce reconfiguration time, they used a tool for incorporating partial reconfiguration into their design (Shirazi *et al.*, 2000).

A further application has been developed for this FPGA board by Singh *et al.* (1998) that involves accelerating Adobe Photoshop computations in a software plug-in framework. As different filters are selected in the application, a new design is downloaded into the platform. The applications implemented include a color to gray scale filter and 1-D and 2-D image convolvers. Partial reconfiguration is not performed when switching between these image processing tasks. By using the same method as Hudson *et al.* (1998), they reduced the time required to reconfigure to a new image processing task. The significance of using this FPGA platform with a mainstream application is that users do not need to know details about the enabling technology to reap its benefits. MacVicar and Singh (1998) have also been able to accelerate the rendering of Bezier curves, a core function in desktop publishing applications.

A different approach to supporting the software plug-in framework was adopted by Haynes *et al.* (2000). They have developed a scalable architecture called Sonic, which consists of multiple modules capable of accommodating different types and sizes of configurable devices, general-purpose processors, and custom-designed circuits. Such modules have a common interface and are connected by high-speed control and data busses. The architecture is particularly effective for video and image processing; the run-time environment includes a multitasking operating system allowing hardware relocation to simplify hardware implementation of plug-in functions.

Although many existing hardware platforms interface to their host through an *I/O* bus such as the PCI bus (Guccione, 2000), the Pilchard (Leong *et al.*, 2001) is unique in interfacing to the host processor through the memory bus. Experiments demonstrate that in read/write benchmarks, the 64-bit Pilchard transfer rates are 6 to 10 times faster than PCI.

Villasenor *et al.* (1996) have implemented an automatic target recognition system using the Xilinx 4000 series FPGAs. Even though the Xilinx 4000 FPGA is not partially reconfigurable, the group was able to achieve an order of magnitude increase in performance over systems built using general purpose processors. In addition, over 75% of the total execution time of their application was spent in reconfiguring the FPGA. This significant reconfiguration overhead can be reduced if a partially reconfigurable FPGA is used.

The **vector dot product**, which involves computing the sum of products of corresponding elements in two vectors, is a common algorithmic kernel in signal processing. Its use ranges from filters and correlators to two-dimensional image transforms, such as the **discrete cosine transform**. Benyamin *et al.* (1999) describes a method for producing optimized reconfigurable hardware implementations of vector dot products. The method is based on a novel representation of common subexpressions in constant data patterns. Whereas traditional techniques such as distributed arithmetic require storage size exponential in the number of vector elements, the storage requirement of the proposed method usually grows linearly with problem size.

Fawcett (1994) describes several applications that have been implemented using reconfigurable logic. He has categorized the applications based on how the FPGAs are reconfigured. These categories are **systems with built-in diagnostics, adaptable systems**, and **multi-purpose hardware**. The examples provided are all implemented using nonpartially reconfigurable FPGAs. By using appropriate tools (2000), designers can retarget these designs on partially reconfigurable FPGAs. For instance, system diagnostics can be performed by partially reconfiguring a portion of the FPGA to perform a boundary scan operation, while the rest of the design continues to operate. An example of an adaptable system that is partially reconfigurable is a network card that changes its back-end functions to support different protocols and that keeps its front-end bus interface functional to service the host's demands.

Other applications involving run-time reconfiguration include data encryption (Dandalis *et al.*, 2000), active networking (Dollas *et al.*, 2001), genomic database search (Lemoine and Merceron, 1995), graph coloring (Rising *et al.*, 1997), continuous speech recognition (Stogiannos *et al.*, 2000), computer graphics (Styles and Luk, 2000), procedural texture mapping (Ye and Lewis, 1999), and solving Boolean satisfiability (Zhong *et al.*, 1998).

3.4 Current and Future Trends

This section discusses various directions of current and future development in configurable computing technology.

3.4.1 Domain-Specific Compilation

Significant productivity gain can be obtained by the use of domain-specific tools. An example is MatLab, a well-known tool for rapid design exploration of digital signal processing applications. Several projects have been undertaken to map MatLab programs, or descriptions in the Simulink block-diagram format, into hardware. Banerjee *et al.* (2001) describe a compiler that maps MatLab programs onto a distributed system containing embedded processors, digital signal processors, and FPGAs. Constantinides *et al.* (2001) present an analytical approach for producing efficient hardware implementations by varying the word length and scaling of each signal in a Simulink block diagram. Hwang *et al.* (2001) demonstrate a visual design flow that addresses issues including the mapping of system parameters, such as sample rates into implementation parameters, and implications of system modeling for testing, such as the test-bench generation. Other domain-specific tools for configurable computing have also been reported: applications include computer graphics, where tools can leverage on the OpenGL interface standard (Styles and Luk, 2000), and image processing, where tools, can build on the Khoros Cantata graphical programming environment (Ong *et al.*, 2001).

The methods and tools described in this subsection are specific to particular application domains. A general approach for producing domain-specific compilers is advocated by Mencer *et al.* (2001). Their approach was based on the use of object-oriented module generators for developing compilers that target domain-specific implementations, such as stream architectures and Boolean satisfiability machines.

3.4.2 Architectural Enhancements

Instead of implementing common operators such as multiplication using fine-grain FPGA resources, it can be more effective to have customized configurable blocks designed specifically for such operators. For instance, Haynes *et al.* (1999) have proposed configurable blocks for efficient multiplication. An array of these blocks are capable of being configured to perform any 8-m by 8-nb signed and unsigned multiplication. The architecture is based on the radix-4 overlapped multiple-bit scanning algorithm. When compared with existing FPGAs for implementing multipliers, this design is shown to be both faster and require fewer transistors.

As another example of architectural enhancement, double buffering techniques can be used for configuration data to support reconfiguration of an FPGA in one clock cycle. This would require only one additional plane of configuration data instead of multiple planes in some context-switchable FPGAs (Tau *et al.*, 1995), hence reducing area and speed overheads. Related ideas on configuration caching algorithms have been explored by Li *et al.* (2000); their algorithms include relocation and defragmentation techniques that allocate and combine configuration data at run time.

3.4.3 Modeling and Optimising Run-Time Reconfiguration

Providing appropriate constructs in hardware description languages is necessary to support run-time reconfiguration. Such constructs are included in the Pebble language (Luk et al., 1997), which can be viewed as a variant of the industrial standard VHDL language. It is also possible to model the reconfiguration mechanism in VHDL (Lysaght and Dunlop, 1994) or in the Circal process algebra (Diessel and Milne, 2000). Currently, most design frameworks require the user to specify the reconfiguration sequence; at compile time, the sequencing information can be extracted and used to guide compilation (Shirazi *et al.*, 2000).

The technique for overlapping configuration and computation (see Section 3.2, Figure 3.2) can be also extended to cover various architectural templates; this extension will enable the reconfiguration of one pipeline to another with a different number of pipeline stages or to change a linear pipeline into a tree-shaped architecture. Frequently, there are multiple ways of reconfiguring designs, and it is important to evaluate the trade-offs involved.

3.4.4 Identification and Mapping of Reconfigurable Regions

Much of current research is focused on automating the optimal partitioning of large circuits into smaller ones to fit into available FPGA resources and the scheduling of the resulting components (Purna and Bhatia, 1999; Kaul and Vemuri, 2000; Liu and Wong, 1999). Run-time reconfiguration can then be performed to swap between the smaller circuits, thus effectively implementing the large circuit in an FPGA, which is physically smaller than the original circuit. If this goal is achieved, circuit designers would not need to worry whether their design fits in the available chip. Multichip partitioning algorithms could be used, however, the partitioning algorithm would need to partition the circuit to maximize the overlap between multiple partitions. Tools for identifying the reconfigurable regions and positioning components (Shirazi, *et al.*, 1998a) can then be applied to maximize physical overlap, thus reducing partial reconfiguration time.

With existing tools, the granularity of the reconfigurable regions is considered to be a logic block (usually the size of a four-input logic gate) or a routing resource. Conceptually, there is no reason why the granularity cannot be expanded to an entire nonreconfigurable FPGA. By doing this, one can develop run-time reconfigurable designs for multi-FPGA systems, such as the Splash 2 platform (Buell *et al.*, 1996) or the Sonic system (Haynes *et al.*, 2000). Although many existing platforms (Guccione, 2000) contain multiple FPGAs that are not partially reconfigurable, the platforms themselves are often partially reconfigurable.

3.4.5 Rapid Compilation and Validation

Fast compilation of configurable computing designs is important. Depending on its complexity, the development cycle of a design often takes a few minutes to many hours. If compilation times for FPGAs were equivalent to today's C++ or Java compilers, productivity would increase tremendously. The JBits tool suite, described in subsection 3.3.3, is capable of rapid compilation provided that users place and route their designs in detail. The JBits tools are being combined with other design tools, such as JHDL (Bellows and Hutchings, 1998) Pebble (Luk and McKeever, 1998) and Lava (Singh and James-Roxby, 2001), so that high-level descriptions can be compiled rapidly into efficient hardware.

The development of intellectual property (IP) cores is another technology that will decrease compilation times. An example is the self-implementing modules (SIMs) methodology (Hwang *et al.*, 2001). A parametrized core is described in SIMs by assigning placement to components in the design; however routing is not specified. Automatic place and route tools are used to route the designs that incorporate SIMs, and these modules are then routed along with user logic. If routing were specified along with placement, compilation times would decrease; however, placement restrictions might be imposed. If at either run time or compile time one of the inputs of the SIM remains constant for a prolonged period, partial evaluation techniques can be used to optimize the SIM. At run time, partial reconfiguration can be used to reconfigure between the constant values. It would be useful to identify automatically the subcomponents of a SIM that remain the same (Shirazi *et al.*, 1998a) when a constant value changes to minimize reconfiguration time.

To speed up the compilation and validation process, Luk et al. (1999) have developed a tool kit for automating the quality assurance of intellectual property cores. Designs can be validated in various ways, including functional simulation, timing analysis, automated theorem proving, and execution on a hardware platform such as the system shown in Figure 3.5. Their work is being extended to cover reconfigurable designs.

3.4.6 Novel Implementation Technology

Faggin (1996) led the design and development of the world's first microprocessor, the Intel 4004. He believes that one day, processors will have some configurable hardware resources incorporated onto the same device. His prediction is being fulfilled by FPGA vendors: Altera, Triscend, and Xilinx are offering devices that contain both reconfigurable logic and a microprocessor. The microprocessor is usually based on an existing architecture from manufacturers such as ARM, MIPS, or IBM to exploit the existing software base. On the research side, the Garp device (Callahan *et al.*, 2000) and the NAPA device (Rupp *et al.*, 1998) are two examples of processor/FPGA hybrid devices.

Perhaps the most radical departure from current silicon technology is to exploit advances in molecular science (Collier *et al.*, 1999) and microfluidic systems (McCaskill and Wagler, 2000) for implementing reconfigurable architectures. If successful, these approaches will have a significant impact on the future of configurable computing.

3.5 Concluding Remarks

Despite the rapid progress made in the last 10 years, many consider configurable computing still in its infancy (Mangione-Smith *et al.*, 1997). As described earlier, there is active research in many aspects of configurable computing: modeling, applications, tools, architectures, platforms, and implementation technology.

In Section 3.1, we explained the two main benefits in configurable computing technology: the ability for time-multiplex resource sharing and ability for hardware upgrades. Many believe that the key to future success of this technology involves techniques and tools that enable designers to gain competitive advantage from these benefits more easily.

We can draw a lesson from history. The invention of virtual memory is a milestone in computing: virtual memory frees programmers from specific machine storage details when developing applications. Run-time reconfiguration can be considered the processing equivalent of virtual memory. Multimillion gate FPGAs are beginning to appear, opening the door to applications that once were never thought to be implementable on FPGAs. The need for more resources, however, will never end. Run-time reconfiguration provides a mechanism for emulating an unlimited amount of gates. For run-time reconfigurable hardware to become as big a success as virtual memory, it needs to be as easy to use as virtual memory—to be completely transparent to the user. By automating run-time reconfiguration, application developers for configurable computing should seldom have to worry about the amount of chip utilization.

The short-term goal in making configurable computing a mainstream technology is to automate the efficient implementation of a configurable design partitioned by hand. The long-term goal is to fully automate the compilation process for specific configurable architectures without compromising design efficiency.

As technology for system-on-a-chip matures, the advantages of configurable computing—the combination of flexibility and performance—can make it increasingly competitive for a wide range of applications.

4.1 Introduction

The operating system of a computer is software, which controls all the computer's resources and provides the base upon which the application programs can be written. Modern operating systems also provide numerous services, such as interprocess communication, file and directory systems, data transfer over networks, and a command language for invoking and controlling programs.

A modern computer system consists of one or more processors, some main memory, clocks, terminals, disks, network interfaces, and other input/output devices. Writing programs that keep track of all these components and use them correctly is an extremely difficult job. The operating system puts a layer of software on top of the bare hardware, manages all parts of the system, and presents the user with an interface or **virtual machine** that is easier to understand and program. Thus, an **operating system** can be defined as a set of software extensions of primitive hardware, culminating in a virtual machine that serves as a high-level programming environment and manages the flow of work in a network of computers.

The virtual machine visible to the user is only the outermost of a series of software layers refining the base hardware. The principle behind the layered architecture is called information hiding—confining the details of managing a class of "objects" in a module that has a friendly interface with its users. With information hiding, designers can protect themselves from extensive reprogramming if the hardware or some part of the software changes: the change affects only the small portion of the software interfacing directly with that system component. By nesting these modules, a hierarchy of levels of abstraction is created so that at any level, users can ignore the details at all lower levels. At the highest level is system users who, ideally, are insulated from everything except what they want to accomplish. Operating systems structured in this way can support diverse environments: programming, game playing, real-time processing, office automation, database, and so on. This situation is shown in Figure 4.1.

At the bottom of the hierarchy is the hardware that may be composed of two or more layers. The lowest layer contains physical devices, such as processors, memory, and disks.

On top of the physical devices, there is a layer of system software that directly controls these devices and provides a cleaner interface to the upper layers of software. These software modules are best known as device drivers in the most popular personal computer systems and are sometimes treated as parts of the operating system. The interface to the device drivers is usually in a primitive format, called **machine language**. The

machine language typically has between 50 and 300 instructions, mostly for moving data around the machine, doing arithmetic, and comparing values. Physical devices are controlled by loading values into special device registers. For example, a disk can be commanded to read by loading the values of the disk address, main memory address, byte count, and direction (read/write) into its registers. A major function of the operating system is to hide all this complexity and give the programmer a more convenient set of instructions to work with.

On top of the operating system is the rest of the system software, such as the command interpreter (shell), compilers, editors, and similar application independent programs. Hundreds of various system programs can be found in the Microsoft Windows 95/98/2000.

Finally, above the system programs come the application programs, which are probably written by the users to solve their particular problems regarding commercial data processing, scientific calculation, and game playing, for example.

4.2 Operating System Concepts

4.2.1 Process

A key concept in all operating systems is the process. A **process** is basically a program in execution. It consists of the executable programs; the program's data and stack; its program counter, stack pointer, and other registers; and all the other information needed to run the program. In a time-sharing system, the operating system periodically decides to stop running one process and starts running another.

When a process is temporarily suspended like this, all information about the process must be explicitly saved during the suspension. The process must be resumed (restarted) later in exactly the same state it was in when it was stopped by restoring the previously saved information. In many time-sharing operating systems, all the information about each process is stored in an operating system table called the **process table**; there is one table for each process currently in existence. Thus, a process consists of its address space, usually called the core image and its process table entry.

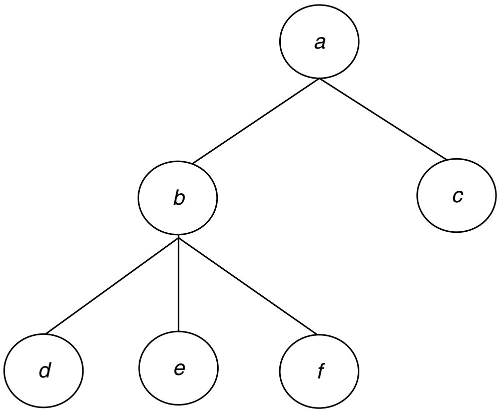

FIGURE 4.2 An Example of Process Tree

A process can be created or terminated by another process using **system calls**, which are extended instructions offered by the operating system. The newly created process is referred to as the **child process** which in turn can create its own child processes. The parent–child relationship among processes forms a process tree structure as shown in Figure 4.2.

Other process system calls are available to request more memory or to release unused memory, wait for a child process to terminate, and overlay its program with a different one.

Operating systems can communicate with a process by sending a signal to the process. The signal causes the process to temporarily suspend whatever it is doing, save its registers on the stack, and start running a special signal handling procedure. Then the signal handler is done, and the running process is resumed. Signals are the software analog of hardware interrupts and can be generated by a variety of causes, such as timers expiring, execution of an illegal instruction, and use of an invalid address. Signals are also used for process-to-process communication, when one process wants to communicate something to another.

In a multiprogramming system, each authorized user is assigned a UID for identification. In addition, each process is assigned a system-wide unique identification, called PID, as well as the UID of its owner for tracking purposes.

4.2.2 Files

Managing various objects, such as information in disks, display monitors, and keyboards, is an important operating system function. To hide peculiarities of these objects, the operating system presents the programmer with a nice, clean abstract model of device-independent files. A file must be opened before it can be read, written, and closed. Therefore, system calls are needed to create, remove, open, read, write, and close files.

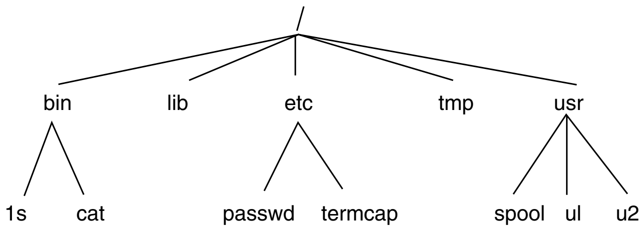

FIGURE 4.3 An Example of Hierarchical File Tree

Most operating systems provide a hierarchical file system for users to manage their files. Files can be grouped together into a directory, which is also a special file and can be grouped into another directory. This model also gives rise to a hierarchical file system, as shown in Figure 4.3.

Every file in the file hierarchy can be specified by its given path name from the top of the hierarchy, the root directory. Such absolute path names consist of the list of directories that must be traversed from the root directory to get to the file, with special symbols such as slashes separating the components. In Figure 4.3, the path for file **passwd** is denoted as **/etc/passwd**. The leading slash indicates that the path is starting from the root directory. As an aside, some systems use a back slash(\) instead of a regular slash(/) as the separator in path names.

At every instant, each process has a current working directory, in which path names not beginning with a slash are looked for. In Figure 4.3, if **etc** is the current directory, then the path name **passwd** denotes the same file as **etc/passwd**. A process can change its working directory by issuing a system call specifying the new working directory.

If several users can access the same computer, the system needs to provide a means for users to protect the privacy of their files. In many systems, a user can specify the type of protection, such as read, write, and execution, against certain groups of users. Before a file can be read or written, it must be opened, at which time the protection is checked. If the access is permitted, the system returns a small integer called a file descriptor or handle to use in subsequent operations. Otherwise, an error code is returned.

Some operating systems such as UNIX and MS-DOS provide a special file abstraction to allow users to perform *I/O* without knowing all details of the hardware. Special files can be read and written in the same way as regular files are read and written. Special files are categorized into two types: **block special files** and **character special files**. Block special files are used to model devices that consist of a collection of randomly addressable blocks, such as disks. By opening a block special file and reading, a program can directly access the desired block on the device without regard to the structure of the file system contained on it.

Character special files are used to model devices that consist of character streams rather than fixed-size randomly addressable blocks. Terminals, line printers, and network interfaces are typical examples of character special files. A program can interact with the user's terminal by reading and writing the corresponding character special file. In UNIX and MS-DOS, when a process is started up, file descriptor 0, called standard input, is normally arranged to refer to the terminal for the purpose of reading. File descriptor 1, called standard output, refers to the terminal for writing. File descriptor 2, called standard error, also refers to the terminal for output but is used only for writing error messages.

In some operating systems, such as UNIX, there is a special concept called **pipe**, which is a pseudo-file that can be used to connect two processes together. When a process wants to send data to another process, it writes on the pipe as though it were an input file for the second process. Thus, communication between processes looks very much like ordinary file reads and writes.

4.2.3 System Calls

In modern operating systems, applications are separated from the operating system itself. The operating system code runs in a privileged processor mode known as **kernel mode** and has access to system data and hardware. Applications run in a nonprivileged processor mode are known as **user mode** and have limited access to system data and hardware by making system calls, which are actually a set of tightly controlled application programming interfaces (APIs).

Corresponding to each system call is a library procedure that user programs can call. This procedure puts the parameters of the system call in a specified place, such as the machine registers; it then issues a TRAP instruction, which is a kind of protected procedure call, to start the operating system. The purpose of the library procedure is to hide the details of the TRAP instruction and make system calls look like ordinary procedure calls.

When the operating system gets control after the TRAP, it examines the parameters to see if they are valid, and if so, performs the work requested. When it is finished, the operating system puts a status code in a register, telling whether it succeeded or failed, and executes a **return from trap** instruction to return control back to the library procedure. The library procedure then returns to the caller in the usual way, returning the status code as a function value. Sometimes additional values are returned in the parameters.

4.2.4 Shell: Command-Based User Interface

A user can interact with the operating system through a special process, **the command interpreter** using a command language. A command language can be either very simple in the early days or as powerful as a regular programming language. Most UNIX systems offer one or more command interpreter with a name called shell or its variations. Unfortunately, the term **shell** may cause some confusion because it is also used by researchers as a generic term to denote the layer of software for users to interact with an operating system. When any user logs in, a shell is started up. The shell has the terminal as standard input and standard output. It starts out by displaying a prompt symbol, such as a dollar sign, indicating that it is waiting to accept a command. For example, if the user types:

```
who,
```

the shell creates a child process and runs the **who** program as the child. The shell is waiting until the child process is terminated. When the child finishes, the shell displays the prompt again and waits for the next command.

UNIX's shell offers a regular programming capability to its users such that its users can request very rich services from the operating system. In addition to the common flow control constructs, shell offers several unique features: *I/O* redirection, pipelining, and background job execution.

A user can specify standard output to be redirected to a file by typing, for example:

```
who > outfile.
```

Similarly, standard input can be redirected from another file, as in:

```
sort < infile > outfile,
```

which invokes the sort program with input taken from file **infile** and output sent to **outfile**.

The output of one program can be used as the input for another program by connecting them with a pipe. Thus, the command:

```
who | wc > /dev/tty 10
```

invokes the **who** program to list all users currently logged in the system and sends the output to **wc** to count the number of entries. The output of **wc** is redirected to a file, **/dev/tty10** which by convention is a special file denoting a terminal.

If a user put an ampersand after a command, the shell does not wait for it to complete. Instead it just gives a prompt immediately. For instance, the command:

```
cc file.c &
```

starts up a compiling job in the background, allowing the user to continue working as the compiler is running.

4.2.5 Graphical User Interface

A graphical user interface (GUI) is another user interface paradigm. A GUI presents the system resources, mostly data files and applications, in graphical objects called icons on the screen and allows users to use a mouse as another input device to express their demands, such as selecting an object, moving an object, and invoking a task. Each task occupies a resizable screen area called a **window** and all objects associated with a task are confined in its window. On the screen, there is a special icon called a **cursor** whose position defines the current focus of the user, and all input given by the user will be delivered to the window where the cursor is located. The user can select any object he or she wants freely by moving the cursor to the top of the object and clicking a button on the mouse. A double click usually means to invoke a task represented by the clicked icon. Because users can intuitively manipulate objects, GUI is also referred to as direct manipulation user interface (DMUI).

4.3 Operating Systems History

Most operatings systems for large mainframes are direct descendants of the third-generation systems, such as Honeywell Multics, IBM VI and VM/370, and CDC Scope. These systems introduced important concepts, such as time sharing, multiprogramming, virtual memory, hierarchical file systems, and device-independent *I/O* (Denning, 1971, 1976).

During the 1960s, many experimental time-sharing systems were constructed to test several new operating systems concepts. These included MIT's Compatible Time Sharing System (CTSS), the University of Cambridge Multiple Access System, IBM TSS/360, and the operating systems for the Manchester University Atlas and the RCA Spectra/70. The most ambitious project of all was Multics (Multiplexed Information and Computing Service) for the General Electric 645 processor (Organick, 1972) Multics simultaneously tested many new concepts such as processes, interprocess communication, segmented virtual memory, hierarchical file system, device independence, *I/O* redirection, a high-level language shell.

Perhaps the most influential current operating system is UNIX, a complete re-engineering of Multics, originally developed at AT&T Bell Laboratories for the DEC PDP computers. Although its size is much smaller than Multics, UNIX retains most of its predecessor's useful characteristics. It also introduces the pipe. The powerful yet simple shell command language together with a large library of utility programs make the UNIX an extremely high productive system for information professionals. Most of UNIX is written in the high-level language C, allowing it to be transported to a wide variety of processors from mainframes to personal computers (Ritchie and Thompson, 1974; Kernighan and Pike, 1984).

Although AT&T developed UNIX, longstanding antitrust provisions prevented AT&T from marketing UNIX or UNIX-based products. Source code was made available to universities for educational purposes. This source code opening policy had a positive effect on the computer industry. It allowed new hardware companies such as SUN, Apollo, and Silicon Graphics to focus on hardware design without having to invest a huge capital in designing operating systems. On the other hand, manufacturers were used to add enhancements and features of their own to differentiate them from other UNIX variants. New versions of UNIX are thus proliferated, resulting in a complex and convoluted history. The most influential two versions, created in the mid-1980s, are AT&T System V and 4.xBSD (Berkeley UNIX) from the Computer Science Department, University of California, Berkeley. Many familiar UNIX features have their origins in academia. Berkeley UNIX was the source of the TCP/IP implementation, sockets, and many common UNIX utilities.

Although compatibility remained a problem among numerous versions, UNIX continued to flourish because it was the only relatively open standards-based operating system not controlled by a single vendor that could be used as an alternative to mainframes.

POSIX is the first serious attempt to reconcile the two flavors of UNIX and was sponsored by the IEEE Standards Board, a highly respected neutral body. The POSIX committee produced a series of standards known as **1003.n-yyyy**, where **1003** is the IEEE POSIX project, **n** denotes the document, and **yyyy** is the year the standard was completed or last amended. It defines a set of library procedures that every conformant UNIX system must supply. There are actually more than 20 standards and draft documents under the POSIX umbrella. The **1003.1–1990** describes interfaces to operating system services at the source-code level. It describes syntax (in the C language) and behavior, not implementation of the interface by the operating system. The **1003.2–1992** describes a programmable shell and related utilities (Walli, 1995).

In the 1980s, a large family of operating systems was developed for personal computers, including MS-DOS, PC-DOS, Apple-DOS, CP/M. Coherent, Xenix, and MINIX. All these systems were of limited function, being initially designed for 8- and 16-bit microprocessor chips with small memories. Processor speeds and memories of personal computers are now sufficient to support full-fledged operating systems such as Linux, FreeBSD, and SUN's Solaris (Torvalds, 1999; Bowman *et al.*, 1999).

With multiprocessors and computer networks in the early 1980s, operating systems began to manage the resources of multiple computers at once. Two early examples are the StarOS and Medusa operating systems for the CM* (pronounced "CM star") machine, a multicomputer consisting of several dozen individual computers linked by a special network (Jones *et al.*, 1979; Ousterhout *et al.*, 1980). Established, single-machine operating systems, such as UNIX and DEC'S VMS, evolved to accommodate networks of computers. Such operating systems typically support standards for accessing files on remote servers from any machine in a network. SUN's Network File System (NFS) was one of the first widely available UNIX-based file systems that provided a single filename space on top of a network of servers and workstations (Sandberg *et al.*, 1985). Carnegie-Mellon's Andrew system provides a UNIX-based network file system that spans more than 5,000 computers around the campus; it allows users to access files without having to know their locations, and it improves performance by caching whole files at individual nodes in the network (Howard *et al.*, 1988).

In addition to a distributed file system, an ideal distributed operating system should give its users an illusion of a single synergistic computer with the collective computing capability extracted from a set of heterogeneous computer systems. The Mach operating system, also developed at Carnegie-Mellon University, is a typical distributed operating system. It handles a variety of distributed system operations, including a uniform file name space, a virtual shared computational memory, and multiprocessing; it is also compatible with UNIX (Accetta *et al.*, 1986; Rashid *et al.*, 1988). Another example is the Amoeba system designed by a team in Vrije Universiteit led by Andrew Tanenbaum (Tanenbaum, 1992).

With massively parallel computers containing thousands of processors, new challenges arise. Operating systems for these machines must support extremely fast synchronization and communication among thousands of processes. Each processor may have its own devices attached, and, hence, the operating system must control thousands of *I/O* channels at once. The concepts of virtual memory and time-sharing must be extended to accommodate massive parallelism. Perhaps the most important challenge is that the programming environment should permit parallel programs to be written with only modest effort beyond what is required for sequential ones (Denning and Tichy, 1990).

As the demand for user mobility increases, a user's need to carry a lightweight handheld personal computer and to be able to access information on the Internet increases as well. Hardware resources, communication bandwidth, and network connectivity available to this type of personal computer are extremely limited so that currently available operating systems running on such machines will not be able to achieve the best performance. Designing a new technology to accommodate this mobile computing environment becomes a new challenge to the operating system research.

The style of contemporary direct manipulation interface evolved largely from a prototype developed at the Xerox Palo Alto Research Center (PARC) in the 1970s. Zerox Star available in 1981 was the first commercial computer system equipped with a GUI. After several failed cases, Apple's Macintosh, introduced in 1984, was a major commercial success. It dominated the GUI personal computer markets for the entire 1980s (Press, 1990). Starting from Windows version 1, version 2, and version 3, Microsoft kept trying to move DOS users away from their command-line interface to a GUI interface and finally achieved its dominant position in the GUI PC market after introducing Windows 95 in 1995. Windows 98 was introduced in 1998 and Windows 2000 was introduced in 2000, as their names imply.

On the UNIX side, the X Window System developed at MIT achieved fairly widespread popularity. Rather than mandate a particular user interface style, X provides primitives to support several policies and styles so that there is no factory standard for any particular interface style. The based system in X is defined by a network protocol so that an application can use windows on any display in a network in a device-independent, network-transparent fashion (Scheifler and Gettys, 1986)

4.4 A Model Operating System

In the hierarchical structure of a model operating system, functions are separated according to their characteristic time scales and their levels of abstraction.

Table 4.1 shows an organization spanning 14 levels. It is not a model of any particular operating system but rather exhibits the relationships among the functions present in most operating systems. Each level encapsulates the system at lower levels into an abstract machine and presents itself to the user, or a program, by a set of objects and the associated operations. A program written at a given level can invoke visible operations at all lower levels, but not operations on higher levels.

4.4.1 Single-Machine Levels 1 through 7

Levels 1 through 7 are called **single-machine levels** because the operating system at these levels deals exclusively with the resources of a single machine. A single machine may contain one or several processors that share a common memory. A multimachine consists of several physically separate computer systems, each of which has its own processor(s) and private memory. There is no shared memory among the separate computers in a multimachine.

The lowest levels include the hardware and firmware of the system. **Level 1** is the electronic circuitry in which objects are such things as registers, gates, and memory cells, and operations are clearing registers, reading memory cells, and other similar items **Level 2** adds the instruction set that can deal with somewhat more abstract entities, such as evaluation stacks and arrays of memory locations. **Level 3** adds the procedure and the operations for call and return. **Level 4** introduces interrupts and a mechanism for invoking special procedures (interrupt-handler routings) when the processor receives an interrupt signal.

The first four levels correspond roughly to the basic machine as it is received from the manufacturer, although there is some interaction with the operating system. For example, interrupts are generated by hardware, but the interrupt-handler routines are part of the operating system.

Level 5 adds primitive processes that are single programs in the course of execution. The information required to represent a primitive process is its state word, which consists of the values of the registers in a processor. This level also provides a context switch operation, which transfers a processor's attention from one process to another by saving the state word of the first and loading the state word of the second. All processes ready to run are queued in a ready list. After a process is switched off its processor, a scheduler in this level selects the next process from the ready list to run. This level also provides semaphores, the special variables used to cause one process to stop and wait until another process has signaled the completion of a task.

Level 6 handles the access to the secondary storage devices. The programs at this level are responsible for operations such as positioning the head of a disk drive and transferring blocks of data. Software at a higher level determines the address of the data on the disk and places requests for data; the requesting process then waits at a semaphore until the transfer has been completed.

Level 7 implements a virtual memory, a scheme that gives the programmer the illusion of having a main memory space large enough to hold the entire program and all its data even if the available real memory is much smaller (Denning, 1970). Software at this level handles the interrupts generated by the hardware when a block of data is addressed that is not in the main memory; this software locates the missing block in the secondary storage, frees space for it in the main storage, and requests

level 6 to read in the missing block. The event is called a **page fault** and the handling process is called **swapping**.

4.4.2 Multi-Machine Levels 8 through 14

From level 8 and those above, the operating system deals with the resources of a larger world, including peripheral devices such as terminals and printers as well as other computers attached to the network. In this world, pipes, files, devices, user processes, and directories can be shared among all the machines.

Level 8 is concerned with communication between processes, which can be arranged through a single mechanism called a **pipe**. A pipe is a one-way channel: data streams in one end and out the other. A request to read items is delayed until items are actually in the pipe. A pipe can connect two processes of the same machine or of different machines equally well. Pipes are implemented in UNIX, MS-DOS, and many other systems.

Level 9 provides services for long-term storage of files. While level 6 deals with disk storage in terms of tracks and sectors, which are the physical units of the hardware, level 9 deals with more abstract entities of variable length. Indeed, a file may be scattered over many noncontiguous tracks and sectors. To be examined or updated, a file's contents must be copied between virtual memory and the secondary storage system. If a file is kept on a different machine, level 9 software can retrieve it by creating a pipe to level 9 on the file's home machine.

Level 10 provides access to external input and output devices, such as printers, plotters, and the keyboards and display screens of terminals. There is a standard interface with all these devices, and a pipe can be used to get access to a device attached to another machine.

Level 11 provides a means of attaching user processes interchangeably to pipes, files, or *I/O* devices. The idea is to make each fundamental operation of levels 8, 9, and 10 (**open**, **close**, **read**, and **write**) look the same so that the author of a program need not be concerned with the differences in these objects.

Level 12 implements user processes, which are virtual machines executing programs. While the level 5 process is primitive and can be completely defined by a state word that records the contents of the registers in a processor, a level 12 user process is a significant extension. It includes one or more primitive processes, a virtual memory containing the program and its workspace, a list of arguments supplied as parameters when the process was started, a list of objects with which the process can communicate, and certain other information about the context in which the process operates.

Level 13 manages a hierarchy of directories that catalogs the hardware and software objects to which access must be controlled throughout the network: pipes, files, devices, user processes, and the directories themselves. The central concept of a directory is a table that matches external names of objects to internal names. An **external name** is a string of characters having some meaning to users; an **internal name** is a binary code used by the system to locate the object. The user designates external names for objects, and the system generates the mapping from external to internal names automatically. A hierarchy arises because a directory can include among its entries the names of subordinate directories.

Level 14 is the shell that separates the user from the rest of the operating system. The shell interprets a high-level command language through which the user gives instructions to the system. Incorporating a listener program, usually called a command interpreter, that responds to a terminal's keyboard, the shell parses each line of input to identify program names and parameters, creates and invokes a user process for each program, and connects those as needed to pipes, files, and devices. Many shells incorporate window managers that allow users to refer to objects by manipulating icons denoting those objects on the display screen and that allow objects to send and receive data from different regions of the display.

4.5 Case 1: UNIX

4.5.1 Introduction to UNIX

UNIX began life as a minicomputer time-sharing system, but is now used on machines ranging from notebook computers to supercomputers. It offers three interfaces: **the shell, the system call library**, and the **system calls** themselves. The shell allows users to type commands for execution. These may be simple commands or more complex shell scripts. Standard input and output may be redirected.

The key concepts in UNIX include the **process**, the **memory mode**, the **file system**, and **I/O**. Processes may fork off subprocesses, leading to a tree of processes. The memory model consists of a text, data, and stack segment for each process. The file system supports regular files, directories, and two kinds of special files. Directories may contain subdirectories, leading to a hierarchical file system. *I/O* is done using character and block special files that are integrated into the file system. Access to UNIX services is achieved via system calls.

Process management in UNIX uses two key data structures, the **process table** and the **user structure**. The former is always in memory, but the latter can be swapped or paged out. Process creation is done by duplicating the process table entry and then the memory image. Scheduling is done using a priority-based algorithm that favors interactive users.

Memory management used to be done by swapping, but it is now done by paging in most UNIX systems. The core map keeps track of the state of each page, and the page daemon uses a clock algorithm to keep enough free pages around.

The file system uses three main tables: the **file descriptor table**, the **open file description table**, and the ***i*-node table**. Each open file has entries in all three of them.

Block device *I/O* uses a buffer cache to reduce the number of disk accesses. An LRU algorithm is used to manage the cache. Character *I/O* can be done in raw or cooked mode, the latter of which is implemented by a line discipline. Line discipline acts like a filter, taking the raw character stream from the terminal driver, processing it, and producing what is called a **cooked character stream**.

4.5.2 Using UNIX

The UNIX Shell

To use UNIX, a user has to log in first by typing user name and password. After a successful login, the login program starts up the command line interpreter, which is most likely a shell variant such as Bourne Shell, Korn Shell, or Berkeley C Shell that has been designed to make it look like C program. A user can choose whatever shell variant he or she likes. The shell initializes itself and then displays a prompt character, often a dollar sign, on the screen and waits for the user to type a command line.

When the user types a command line. The shell extracts the first word from it, assumes it is the name of a program to be run, searches for this program, and runs the program if it finds it. The shell then suspends itself until the program terminates, at which time it tries to read the next command.

Commands may take arguments, which are passed to the called program as a character string. For example, the command line:

```
rm filea fileb
```

invokes the **rm** program to delete the files specified in the arguments **filea** and **fileb**.

With a few exceptions, an argument started with a character(-)denotes an option specified by the user to the command. In the following command:

```
head -20 testfile,
```

the first arguments, **-20**, tells **head** to print the first 20 lines of **testfile** instead of the default number of lines, **10**. The convention of using a dash to denote an option to a command is strongly recommended to reduce the possible confusion to the user. Most UNIX commands accept multiple options and arguments. With a few exceptions, options are often specified before all other arguments.

To make it easy to specify multiple file names, the shell accepts magic characters, sometimes called **wild cards**. An asterisk matches all possible strings, so the following two commands are equivalent:

```
rm file*
rm filea fileb
```

These commands are equivalent if, in the current working directory, only files named **filea** and **fileb** match to **file***. To execute the first command, the shell first expands **file** into **filea fileb** then invokes the **rm** program to delete **filea** and **fileb**. Another wild card is a question mark that matches any one character.

A program like the shell does not have to open the terminal to read from it or write to it. Instead, when it (or any other program) starts up, it automatically has access to a file called **standard input for reading**, a file called **standard output for writing normal output**, and a file called **standard error for writing error messages**. Normally all three default to the terminal, so that reads from standard input come from the keyboard and writes to standard output or standard error go to the screen. Many UNIX programs read from standard input and write to standard output as the default. For example, the command:

```
sort
```

invokes the **sort** program, which reads lines from the terminal (until the user types a CTRL-D, to indicate end of file), sorts them alphabetically, and writes the result to the screen.

It is possible to redirect standard input and standard output, which often is useful. The syntax for redirecting standard input uses a less than sign (<) followed by the input file name. For example, the command:

```
ex File ToBeEdit < exscript
```

invokes **ex** to edit the file **FileToBeEdit** using the editing instructions stored in the file **exscript** as if the editing instructions are given by the user from the keyboard. Similarly, standard output is redirected using a greater than sign. It is permitted to redirect both in the same command. For example, the command:

```
sort < infile > outfile
```

causes **sort** to take its input from the file **infile** and write its output to the file **outfile**. Because standard error has not been redirected, all error messages still go to the screen. A program that reads its input from standard input, does some processing on it, and then writes its output to standard output is called a **filter**.

The UNIX provides pipe capability so that the output of one program can be used as the input for another program by connecting them with a pipe. In the following command:

```
sort < infile | head −30,
```

the vertical bar, called a **pipe symbol**, says to take the output from **sort** and use it as the input to **head**. A collection of commands connected by pipe symbols, called a **pipeline**, may arbitrarily contain many commands. A four-component pipeline is shown by the following two examples. The first one is written as:

```
head −100 infile | cat −n| cut −c1−7
```

and takes the first 100 lines of **infile**, adds line numbers, and removes everything except the first seven characters in each line. This pipeline effectively generates a number sequence from 1 to 100. (Assume the file **infile** has no fewer than 100 lines.) The second one is written as:

```
head -100 infile|cat -n|sort -nr|cut -c8-> outfile
```

and takes the first 100 lines of **infile**, adds line numbers, sorts it in descending numerical order, and finally eliminates line numbers and writes the result into **outfile**. In fact, this example takes the first 100 lines from **infile** and reverses it so that the 100th line becomes the first line and the first line becomes the 100th line in **outfile**. These two examples demonstrate how UNIX provides basic building blocks (numerous filters), each of which does one job, as well as provides a mechanism for them to be put together in almost limitless ways.

UNIX is not only a time-sharing system; it is also a general-purpose multiprogramming system. A single user can run several programs at once, each as a separate process. The shell syntax for running a process in the background is to follow its command with an ampersand (&). Thus, the command:

```
a.out < infile > outfile &
```

runs a user program, **a.out**, from the input file, **infile**, then writes the result to **outfile** but does it in the background. As soon as the command has been typed, the shell displays the prompt and is ready to accept and handle the next command. Pipelines can also run in the background.

It is possible to put a list of shell commands in a file, say **scriptfile** and then start a shell with this file as standard input or as a file argument like following:

```
sh scriptfile
```

The (second) shell just processes them in order, the same as it would with commands typed on the keyboard. Files containing shell commands are called shell scripts. Shell scripts may assign values to shell variables and then read them later. They may also have parameters and use **if, for, while** and **case** constructs. Thus a shell script is really a program written in a shell language.

Files and Directories in UNIX

A UNIX file is a sequence of zero or more bytes containing arbitrary information. No distinction is made between ASCII files, binary files, or any other kinds of files. The meaning of the bits in a file is entirely up to the file's owner. The system does not care.

By convention, many programs expect file names to consist of a base name and an extension separated by a dot (which counts as a character). Thus **prog.c** is typically a C program, **prog.o** is usually a compiled object file, and **a.out** is normally an executable compiled object program. These conventions are not enforced by the operating system.

Files can be protected by assigning each one a 9-bit mode by the owner or the super user, sometimes called the **rights bits**. The first 3 bits refer to the owner's access right to the file. The next 3 bits apply to other members of the owner's group (e.g., department or project). The last 3 bits pertain to everyone else; these 3 bits control reading, writing, and executing the file, respectively. Thus a mode of 640 (octal) means that the owner can read and write the file, other members of the owner's group can read it, and outsiders have no access at all. A mode of 777 (octal) allows everyone to do everything to the file. On the screen, these two example modes are displayed as **rw-r-----** and **rwxrwxrw**, respectively.

Files can be grouped together for convenience in directories. Directories are stored as files and, to a large extent, can be treated like files. They are protected with the same 9 bits as files, except that the 3 **execute bits** grant or deny permission to search the directory rather than execute it.

Directories can contain subdirectories, leading to a hierarchical file system. The root directory is denoted as **/** and usually contains several subdirectories. The **/** character is also used to separate directory names so that the name **/usr/man/sort 1** denotes the file **sort. 1** located in the directory **man**, which itself is in the **/usr** directory. Some of the major directories of the average UNIX file system are shown in Table 4.2.

UNIX Utility Programs

The user interface to UNIX consists not only of the shell but also of a large number of standard utility programs. Roughly speaking, these programs can be divided into six categories:

1. File and directory manipulation commands
2. Filters
3. Compilers and program development tools
4. Text processing
5. System administration
6. Miscellaneous

The POSIX 1003.2 standard specifies the syntax and semantics of just under 100 of these programs, primarily in the first three categories. The idea of standardizing them is to make it possible for anyone to write shell scripts that use these programs and work on all POSIX conformant UNIX systems.

A selection of POSIX utility programs is listed in Table 4.3 along with a short description of each one. All UNIX systems have these and many other programs.

TABLE 4.2 Some Important Directories Found in Most UNIX Systems

Directory	Description
/bin	Frequently used system binaries
/dev	Special drivers for *I/O* devices
/etc	Miscellaneous system administration parameters
/lib	Frequently used libraries
/tmp	Temporary files once stored here
/usr	Contains all user files in this part of the tree
/usr/include	System-provided header files
/usr/man	On-line manuals
/usr/spool	Spooling directories for printers, e-mail, and other daemons

TABLE 4.3 Some Popular UNIX Utility Programs Required by POSIX

Command	Description
awk	A pattern matching language
basename	Strip off prefixes or suffixes from a file name
cat	Link file(s) and write them to standard output
cc	Compile a C program
chmod	Change protection mode for file(s)
comm	Print lines common to two sorted files
cp	Make a copy of a file
cut	Make each column in a document into a separate file
date	Print the date and time
diff	Print all the differences between two files
echo	Print the arguments (used mostly in shell scripts)
find	Find all the files meeting a given condition
grep	Search file(s) for lines containing a given pattern
head	Print the first few lines of file(s)
kill	Send a signal to a process
lp	Print a file on a printer
ls	List files and directories
make	Recompile those parts of a large program that have changed
mkdir	Make a directory
mv	Rename a file or move file(s)
paste	Combine multiple files as columns in a single file
pwd	Print the working directory
rm	Remove file(s)
rmdir	Remove one or more directory
sed	A stream (i.e., noninteractive) editor
stty	Set terminal options such as the characters for line editing
sort	Sort a file consisting of ASCII lines
tail	Print the last few lines of a file
tr	Translate character codes
uniq	Delete consecutive identical lines in a file
wc	Count characters, words, and lines in a file

4.5.3 Linux: An Open Source UNIX Clone for a Personal Computer

Although UNIX has been installed on numerous computer systems ranging from supercomputers to personal computers, it is not suitable for casual personal users for at least two reasons:

1. Its command-based user interface is not friendly enough for casual users.
2. It requires a professional staff for system operation, administration, and maintenance.

The situation did not used to be better for professional personal users either. Not until 1990s was UNIX popular among this type of users for another major reason: there was no standard configuration for the personal computer. Numerous new hardware components, however, are made available on the market everyday. These hardware components are all sold together with necessary system software packages, usually device drivers, so that users can easily **plug-in** these drivers into their operating systems. Although with minimum effort, a casual user can reconfigure the operating system for his or her personal computer, these device drivers usually do not have a version for any UNIX-clone. Furthermore, the companies that sell UNIX-clone for personal computers do not make an operating system source code available, so their users cannot develop required device drivers by themselves. Thus, the popularity of personal computer UNIX is limited by the poor availability of device drivers.

Starting from the early 1990s, a UNIX clone, Linux, was available for free on numerous personal computers with its source code open to the user community. Linux is written from scratch by Linus Torvalds with the assistance of a loosely-knit team of hackers from across the Internet. It aims toward POSIX compliance and has all of the features one would expect of a modern, fully fledged UNIX: true multitasking, virtual memory, shared libraries, TCP/IP networking, and, most importantly, device drivers for most available hardware components.

Linux runs mainly on the IBM-compatible PCs that are equipped with Intel 80386/80486/Pentium CPUs. It requires much less hardware resources than Microsoft Windows. Ports to other architectures are underway. Linux has most standard UNIX utilities including X-Windows and TCP/IP as well as numerous free software that people have compiled or ported from other architecture. There is even a DOS emulator that can run DOS itself and some (but not all) DOS applications. Work has been progressing on an emulator for Microsoft Windows binaries.

The Linux kernel is protected under the GNU General Public License, which basically means that one may freely copy, change, and distribute it, but one may not impose any restrictions on further distribution and must make the source code available to others.

Although Linux popularity has gained great momentum in recent years, it is by no means for casual users because it still requires a certain level of professional skills and some administrative efforts. Professional personal users obtain assistance mainly from various newsgroups on the Internet, especially Usenet. One can look for those newsgroups whose names started with comp.os.linux, comp.unix, and comp.windows.x to obtain more information.

4.6 Case 2: MS-DOS

4.6.1 Introduction to MS-DOS

Microsoft MS-DOS is a single-user operating system for the IBM PC and its successors. It was originally based on CP/M, but many elements from UNIX have been added over the years. Only one process at a time can be active, but a process can create and execute a child process. Doing so, however, suspends the parent until the child is finished.

Memory management in MS-DOS involves four separate regions: **conventional memory** (below 640 K), **upper memory** (between 640 K and 1 M), **high memory** (the 64 K just above 1 M), and **extended memory** (above 1 M). Each of these has different properties and is used in different ways. Ordinary programs are restricted to conventional memory, however, and thus cannot exceed 640 K. Overlays and expanded memory are two of the techniques that are used to get around this limit to some extent.

The MS-DOS file system supports hierarchical directories, absolute and relative path names, and many of the same system calls as the UNIX file system. *I/O* is done using special files, both block and character. It also has the capability to handle primitive shell scripts, called **batch files**.

The implementation of MS-DOS is closely tied to the underlying architecture. MS-DOS makes use of a hardware ROM built into the IBM PC called the basic input output system. (BIOS). The BIOS contains device drivers for the standard devices. Whereas UNIX is self-contained with all device drivers built-in, MS-DOS could just call BIOS procedures to do *I/O*. In addition, users are free to install their own drivers for special devices.

The file system is based on the use of a file allocation table (FAT) for each disk. For each file, a chain of blocks is maintained in the FAT. Directory entries in MS-DOS contain some of the information that in UNIX is in the *I*-nodes.

The character length of file names in MS-DOS has a so-called 8.3 format constraint. Each file can have a name no more than eight characters long with an optional dot extension no more than three characters long. Some examples of valid and invalid file names are listed in Table 4.4.

Although it is not mandatory, file names with certain dot extensions have been associated with certain applications. For example, file names with a **.doc** extension are usually associated with Microsoft word processors, such as MS-Word. The capability of associating file names to applications has been implemented in the Microsoft Windows as a convenient operating system feature. Some examples of such associations are listed in Table 4.5.

Since it was first released along with the IBM PC in August 1981, MS-DOS has kept evolving from version 1.x, 2.x, 3.x, 4.x, up to 5.x with various features added. Its command-based user interface and obsolete programming environment makes it an idiosyncratic and unfriendly operating system for personal computers. In early 1990s, Microsoft developed Windows mouse-driven graphical user interface to replace MS-DOS. Early versions of Windows were executed on the top of MS-DOS so that users had to run MS-DOS first and then invoke Windows to get into a Windows environment. Starting from Windows 95, MS-DOS became a component of Windows so that today's users can start the Windows without running MS-DOS first. After more than 20 years of service, MS-DOS retired from the position of dominant operating system for personal computers although it kept evolving to version 6.x and 7.x.

TABLE 4.4 Examples of Valid and Invalid MS-DOS File Names

Valid file names	Invalid file names
file.txt document.doc hypertxt.htm program.c	file.text mydocument.doc hypertxt.html

TABLE 4.5 Examples of the Association Between Dot File Extensions and Applications

Extensions	Associated applications
.txt	Any plain text viewer (e.g., MS-Notepad)
.doc	MS-Word, MS-Wordpad
.ppt	MS-Powerpoint
.xls	MS-Excel
.wav	MS-MediaPlayer
.mpg	MS-MediaPlayer
.mov	quicktime
.reg	regedit
.zip	pkzip, winzip
.mp3	winamp
.htm	Any HTML viewer (e.g., MS Iexplorer or Netscape Navigator)

4.6.2 Using MS-DOS

Using MS-DOS can be best compared to using a stripped down early version of UNIX. There is a command interpreter or shell (called command.com), a file system, system calls, utility programs, and other features that are often similar to their UNIX counterparts but more primitive.

To use MS-DOS, you just turn on the computer. A few seconds later, the shell prompt appears. Unless the PC hardware itself has a security protection set up, there is no login procedure and no password because MS-DOS is really meant for a personal computer. The underlying assumption is that the machine is used by only one person. For the same reason, files and directories do not have owners, and there are no protection bits. There is also no concept of a superuser. The regular user can do everything.

To run a program, you type its name and arguments into the shell. The shell then forks off a child, passes the arguments to the child, and keeps quiet until the child has finished executing and exists. It is not possible to put an ampersand (**&**) at the end of the command line to start the command off in the background.

Some of the UNIX shell features are also present in MS-DOS, but others are not. The wild card characters * and **?** are present and match all strings and one character, respectively, just as in UNIX. Thus, the command:

```
copy *.c src
```

means copy all files in the current directory ending in **c** to the **src** directory, and the command:

```
del ???
```

means delete from the current directory all files whose names are precisely three characters. Command.com does not distinguish between upper and lower cases. Thus typing:

TABLE 4.6 Some of the MS-DOS Commands Built into the Command.com

MS-DOS Command	UNIX Equivalent	Description
copy	cp	Copy one or more files
date	date	Display or change the current date
del	rm	Remove one or more files
dir	ls	List files and directories
mkdir	mkdir	Create a new directory
rename	mv	Rename a file
rmdir	rmdir	Remove an empty directory
type	cat	Display a file

```
COPY A.TXT B.TXT
```

has exactly the same effect as typing:

```
copy a.txt b.txt.
```

Redirection of standard input and output and filters work the same way as in UNIX and even use the same notation. Pipes are also allowed, but they are implemented differently (using temporary files), which introduces some subtle changes in their behavior. Other features taken from UNIX are shell variables, prompts that can be set by users, and shell scripts.

On the other hand, only one command per line is permitted, there are no background jobs, the use of **[a–z]** for a range is not allowed, and the quoting of strings is not recognized.

Commands in MS-DOS are divided into two categories **internal** and **external**. The are about 40 internal commands that are executed by the shell itself; the external ones are genuine programs, typically in the |**dos** or |**bin** directory. Some of the most common internal commands, along with their UNIX equivalent, are listed in Table 4.6.

Expert Systems

5.1 Overview

An expert is a person who has special skills and knowledge about a restricted domain or field. An **expert system** is a computer program that represents and uses skills and knowledge of one or more human experts to provide high-quality performance in a specific domain.

Expert systems offer a number of benefits when compared with human experts. Expertise embodied in an expert system is permanent, like other software, whereas human expertise is perishable. Expert systems can produce consistent results on the same tasks and handle similar situations consistently, whereas humans can get tired or bored and are influenced by various effects (e.g., their judgment can be easily impacted by new information). Expert systems are inexpensive to operate, easy to reproduce and distribute, and can provide permanent documentation of the decision process. In addition, expert systems may contain knowledge from several human experts, giving them more breadth and robustness than a single expert.

Although expert systems enjoy these advantages, they also have many weaknesses that include lack of common sense knowledge, narrow focus and restricted knowledge, inability to respond creatively to unusual situations, and difficulty in adapting to changing environments.

5.1.1 A Brief History

In 1956, a summer workshop at Dartmouth College attended by ten influential computer scientists marked the birth of artificial intelligence (AI). Following this event, researchers pursued different areas to develop various types of intelligent systems including expert systems.

From the mid- to late 1960s, several important expert systems were developed. At Stanford, Edward Feigenbaum, Joshua Ledergerg, Bruce Buchanan, and Georgia Sutherland developed DENDRAL, the first expert system that interpreted the output of a mass spectrometer for analysis of the structure of organic chemical compounds. At MIT, Joseph Weizenbaum built ELIZA, an interactive dialog expert system, and Joel Moses built MACSYMA, an expert system using symbolic reasoning for solving mathematical problems. During the 1960s, LISP was the dominant programming language used in developing expert systems.

Not many expert systems were built in the 1960s because they were developed from scratch and the development time was long (Clancy and Shortliffe, 1984). This situation changed dramatically following the development of the MYCIN expert system. MYCIN was developed at Stanford University from 1972 to 1980 for diagnosing and treating patients with infectious blood diseases caused by bacteria in the blood and meningitis (Shortliffe, 1976). MYCIN is a rule-based expert system that incorporates approximately 500 rules and uses backward-chaining reasoning, which is discussed in more detail later in this chapter.

During the development of MYCIN, the importance of separating a knowledge base and an inference engine was recognized. Shortly afterwards, EMYCIN (Buchanan and Shortliffe, 1984), the domain-independent version of MYCIN, was produced by removing specific domain knowledge about infectious blood disease. It became the forerunner of expert system shells. The impact of EMYCIN was immediate in the development of subsequent expert systems. For example, PUFF (Aikens *et al*., 1983), a program for analyzing pulmonary problems, was developed based on EMYCIN in about 5 years, a significant improvement over the 20 years required to develop MYCIN.

The value of expert system shells was quickly recognized by the research community and industry. The number of expert systems increased dramatically in the following years. The estimated number of developed expert systems increased from 50 in 1985 to 2200 in 1988 and then to 12,500 in 1992 (Durkin, 1993; Hammond, 1986). The vast majority of them have been developed using a shell, with LISP, PROLOG, and OPS-5 as the other major languages being used. During the past three decades, the field of expert systems has changed from a technology confined to research circles to one being used commercially to aid human decision making in a wide range of applications.

5.1.2 Characteristics and Categories

Compared to conventional computer applications and other AI programs, expert systems have the following distinguished characteristics:

- They deal with complex problems that require a considerable amount of human expertise.
- They encode human knowledge for a specific domain and simulate human reasoning using the knowledge.
- They often solve problems using heuristic or approximate methods, which are not guaranteed to find the best solutions.
- They are able to explain and justify solutions to human users at different knowledge levels.

An expert system is meant to embody the knowledge of human experts in a particular domain so that nonexpert users can use it to solve difficult problems. The knowledge and information handled by the expert system may be inaccurate, fuzzy, or incomplete. Hence, an expert system should be able to reason under approximate and noisy conditions. To improve its performance so that recurring problems can be solved faster and new problems can be solved better, an expert system should learn from its past experience automatically. The learning may be achieved either from previous examples or through analogies between similar problems. In a network environment, an expert system may interact with other systems, such as by obtaining information from a database or by consulting other expert systems. Similar to human experts, an expert system should be able to explain its reasoning process, justify its conclusion, and answer questions about the inference procedure. The explanation ability is also important in the development of the expert system. It enables the designer to validate the encoded knowledge and the reasoning algorithms. Finally, for real-world applications that require real-time response, an expert system should perform well under time and resource constraints.

In the past, expert systems have been built to solve a large range of problems in the fields of engineering, manufacturing, business, medicine, environment, energy, agriculture, telecommunications, government, law, education, and transportation. Generally, they fall into the following broad categories (Waterman, 1986):

- Controlling: Governing the behavior of a complex system
- Designing: Configuring components to meet design objectives and constraints
- Diagnosing: Determining the cause of malfunctions based on observations
- Instructing: Assisting students' learning and understanding of a subject
- Interpretating: Forming high-level conclusions or descriptions from raw data
- Monitoring: Comparing a system's observed behavior to the expected behavior
- Planning: Constructing a sequencing of actions that achieve a set of goals
- Predicting: Projecting probable consequences from given situations
- Scheduling: Assigning resources to a sequence of activities
- Selecting: Identifying the best choice from a list of possibilities
- Simulating: Modeling the behavior of a complex system

Among the large number of developed expert systems, here are some well-known ones:

- DENRAL: A chemical expert system that interprets mass spectra on organic chemical compounds:
- ELIZA: An interactive dialog expert system
- HEARSAY: A speech-understanding expert system
- INTERNIST: One of the largest medical expert systems for internal medicine
- MACSYMA: A symbolic mathematics expert system that solves math problems involving algebra, calculus, and differential equations
- MOLGEN: An object-oriented expert system for planning gene-cloning experiments
- MYCIN: A medical expert system that deals with bacterial infections

- PUFF: A medical diagnostic system for interpreting the results of respiratory tests
- PROSPECTOR: An expert system for predicting potential mineral deposits
- XCON (originally called R1): An expert system used to configure computers that consist of hundreds of modules

5.1.3 Architecture

The architecture of a typical expert system is shown in Figure 5.1. It contains the following major components:

- **A knowledge base** contains specialized knowledge of the problem domain. In a rule-based expert system, the knowledge including facts, concepts, and relationships is represented in the **if . . . then . . .** rule form.
- **An inference engine** performs knowledge processing. It is modeled after the reasoning process of human experts and applies knowledge in the knowledge base as well as information on a given problem for its solution.
- **A working memory** holds the data, goal statements, and intermediate results that make up the current state of the inference process.
- **An explanation subsystem** provides explanations of the reasoning process of the system and justifications for the system's actions and conclusions. Adequate explanation facilitates the acceptance of the system by the user community.
- **A user interface** is the window through which the user interacts with the system. Interface styles include question-and-answer, menu-driven, natural language, graphics interfaces, and online help. An expert system needs to be easy to learn and friendly to use.
- **A knowledge-base editor** is the window through which the knowledge engineer develops the system. It also assists in maintaining and updating the knowledge base.
- **A system interface** links the expert system to external programs and information sources. For example, the expert system may consult other expert systems or obtain information over the Internet.

Among these components, the two most important ones are **knowledge base** and **inference engine**. The knowledge base contains formally encoded domain-specific knowledge of a problem, whereas the inference engine solves problems using various reasoning algorithms. To achieve expert-level performance, expert systems need to access a substantial amount of domain knowledge and to apply the knowledge efficiently through one or several reasoning mechanisms.

The separation of the knowledge base and the inference engine is essential for the success of expert systems. It is very important for a number of reasons: First, knowledge can be represented in a more natural and declarative form that is easier to understand and implement. For example, **if . . . then . . .** rules represent domain knowledge in a more declarative form than embedding the knowledge in problem-solving procedures. Second, developers can focus on creating and organizing high-level knowledge rather than on the detailed implementation. Third, changes made to the knowledge base do not affect the function of inference engine and vice versa. Finally, the same problem-solving techniques employed by the inference engine can be used in a variety of applications.

As a subfield of artificial intelligence (AI), expert system research has strong links with related topics in AI. The four fundamental topics in expert systems are **representing knowledge**, **reasoning using knowledge**, **acquiring knowledge**, and **explaining solutions**. Building a successful expert systems depends on a number of factors, including the nature of the task, the availability of expertise, the amount of knowledge required, and the ability to formally encode the expertise and reason efficiently with it to solve the task.

5.1.4 Languages and Tools

Expert systems have been constructed using various general-purpose programming languages as well as specific tools. LISP and PROLOG have been used widely. OPS-5 has also been

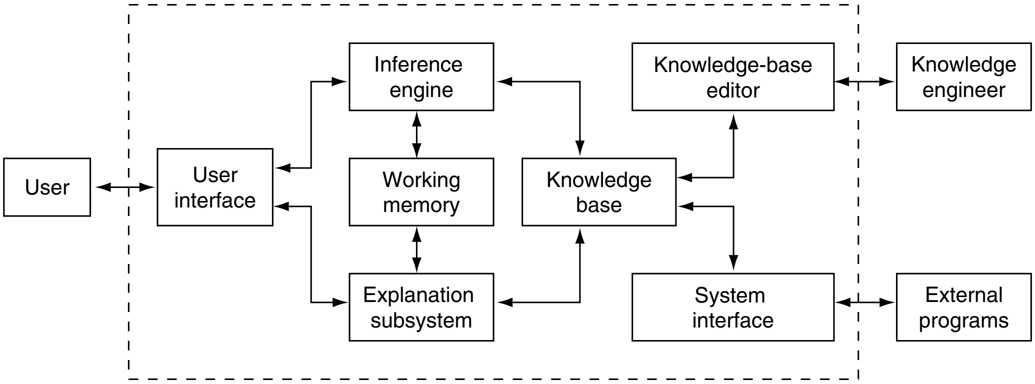

FIGURE 5.1 Architecture of a Typical Expert System

popular among rule-based programmers. OPS is a product of the Instructable Production System Project at CMU in 1975. It was used to create one of the classic expert systems called R1 (later called XCON) to help DEC configure VAX computers. C and C + + have been used in applications when execution speed is of importance. C Language Integrated Production System (CLIPS) is a popular development environment for building rule- and object-based expert systems. CLIPS is written in C for portability and speed. JAVA is relatively new and is gaining popularity in building expert systems mostly due to the desirable attribute of portability on different computer platforms.

Compared to general-purpose programming languages, shells provide better tools for fast design and implementation of expert systems. An expert system **shell** is a programming environment that contains the necessary utilities for both developing and running an expert system. For example, since an expert system shell provides a build-in inference engine, the developer can focus on inputting problem-specific knowledge into the knowledge base. By using expert system shells, the programming skills required to build an expert system become minimal, and the design and implementation time can be greatly reduced.

EMYCIN (Buchanan and Shortliffe, 1984) is an example of shells. The tools it provides include (a) an abbreviated rule language that is easier to read than LISP and more concise than the English subset used by MYCIN; (b) an indexing and grouping scheme for rules; (c) a goal-driven inference engine; (d) a communication interface between the program and the end user; (e) an interface between the system designer and the program, which supports displaying and editing rules, editing knowledge in tables, and running selected rules sets on a problem; and (f) facilities for monitoring the behavior of the program, such as explaining how a conclusion is reached, comparing the results of the current run with correct results and exploring the discrepancies, and reviewing conclusions about a stored library of cases.

General-purpose shells are offered to address a broad range of problems. Many domain-specific tools have also been developed to provide special features to support the development of expert systems for specific domains. The introduction and widespread use of expert system shells promotes the successful applications of expert systems to a wide range of tasks.

5.2 Knowledge Representation

Knowledge representation is a substantial subfield of AI in its own right. Winston defines a **representation** as "a set of syntactic and semantic conventions that make it possible to describe things" (Winston, 1984). The **syntax** of a representation specifies a set of rules for combining symbols to form expressions in the language. The **semantics** of a representation specify the meanings of expressions. In the field of expert systems, knowledge representation is mostly concerned with symbolically coding a large amount of domain knowledge in computer-tractable form such that it can be used to describe the task and the environment unambiguously and to reason with the knowledge efficiently toward certain goals.

Because of the property of unambiguity, mathematical tools are used as the bridges between verbal or mental representation and computer representation of knowledge. These tools include logic, probability theory, fuzzy sets, abstract algebra, and set theories. Major knowledge representation schemes in expert systems include the following:

- **Production rules** are generative rules of intelligent behavior, similar to the grammar rules in automata theory and formal grammars. They encode relationships between facts and concepts as well as associations between data and actions (i.e., the "what to do when" knowledge).
- **Semantic networks and frames** are graphical formalisms for encoding facts, such as objects and events and their properties, and heuristic knowledge for processing information, such as procedures. In these structured representations, nodes stand for concepts and arcs for relationships between them.
- **Logic languages** are derived from mathematical logic; they encode facts and control information in logic formulas.
- **Model-based approaches** use theoretical models to represent knowledge about components and systems.
- **Object-oriented approaches** represent knowledge in terms of interacting objects, which consist of data and procedures.
- **Blackboard architectures** partition domain knowledge into independent knowledge sources and build up solutions on a global data structure, the **blackboard**. The blackboard serves the function of the working memory, but its structure is much more complex.

5.2.1 Rule-Based Expert Systems

Based on predicate logic, probability theory, and fuzzy sets, rule-based expert systems are the most common type of expert systems. Rule-based expert systems use **if-then** rules (or production rules) to represent human expert knowledge, which is often a mix of theoretical knowledge, heuristics derived from experience, and special-purpose rules for dealing with abnormal situations. A production system is an example of rule-based systems: its knowledge base is a rule set, its inference engine is a rule interpreter that decides when to apply which rules, and its working memory contains the data that are examined and modified in the inference process. The rules are triggered by the data, and the rule interpreter controls the selection of the rules and updating of the data.

Generally, the knowledge base of a rule-based expert system consists of a set of rules of the following form:

if **condition**$_1$ and . . . and **condition**$_m$ are true
then **conclusion**$_1$ and . . . and **conclusion**$_n$

Each rule contains one or more conditions and one or more conclusions or actions.

MYCIN is a classical rule-based system. It diagnoses certain infectious diseases, prescribes antimicrobial therapy, and can explain its reasoning (Buchanan and Shortliffe, 1984). In a controlled test, its performance equaled that of specialists. Because medical diagnosis often involves a degree of uncertainty, each MYCIN's rule has associated with it a **certainty factor** (CF), which indicates the extent to which the evidence supports the conclusion (i.e., likelihood). A typical MYCIN rule looks like this:

If **the stain of the organism is gram-positive**, and
the morphology of the organism is coccus, and
the growth conformation of the organism is clumps
then **there is suggestive evidence (0.7) that the**
identity of the organism is staphylococcus.

There are many sources of uncertainty in problem solving. The domain knowledge may be incomplete, error-prone, or approximate. The data may be noisy or unreliable. In the field of expert system, research methods for handling uncertainty include **certainty factor approach, the Bayesian approach, fuzzy logic**, and the **belief theory.**

In the **certainty factor approach** certainty factors are associated with given data, indicating their degree of certainty. Each rule is also associated with a CF representing how strong the conditions of the rule support the conclusions. A certainty factor of a hypothesis h and an evidence e is defined as:

$$CF[h, e] = MB[h, e] - MD[h, e], \tag{5.1}$$

where $MB[h, \ e]$ measures the extent to which e supports h and where $MD[h, \ e]$ measures the extent to which e supports the negation of h. Since $MB[h, e]$ and $MD[h, e]$ have values between zero and one, a CF has a value between -1 and 1. As the CF moves toward 1, the evidence increasingly supports the hypotheses. The CF of the conclusion of a rule is computed as the CF of the rule times the minimum of the CFs of its individual premises. In MYCIN, when several different possible diseases are consistent with available evidences, their certainty factors show how likely each is. When there are multiple possible treatments, their certainty factors show the likelihood that each treatment will work.

The certainty factor approach is simple, easy to understand, and efficient to run; it provides a means of estimating belief that is natural to a domain expert. Its combination methods ensure locality, detachment, and modularity (Stefik, 1995). This means that adding or deleting rules does not require rebuilding the entire certainty model.

A more general approach than the certainty factor approach is the **Bayesian approach** based on conditional probabilities. The certainty factor approach is simple because it ignores prior probabilities that are difficult to estimate. It makes a strong assumption, however, that all rules are independent. At the heart of the Bayesian approach is the **Bayes' rule**. The Bayes' rule (also known as Bayes' law or Bayes' theorem) is the following equation:

$$P(Y|X) = \frac{P(X|Y)P(Y)}{P(X)}, \tag{5.2}$$

where $P(A)$ represents the unconditional or prior probability that A is true and where $P(A|B)$ represents the conditional or posterior probability A given that all we know is B. This simple equation underlies modern AI systems for probabilistic inference. The limitations of the Bayesian approach resides in the assumptions that the evidences are independent, prior probabilities are known, and the sets of hypotheses are both inclusive and exhaustive.

Fuzzy logic is also widely used to deal with uncertainty. Probability theory represents uncertainty based on frequency of occurrence, whereas fuzzy logic sets represent imprecision as a graded membership function with a value between zero and one. Fuzzy logic has been applied in various types of expert systems, including rule-based systems, to handle uncertainties. In fuzzy rule-based expert systems, knowledge is represented in fuzzy rules and fuzzy sets. Fuzzy rules are **if-then** statements that contain fuzzy variables. These rules are processed based on the mathematical principles of fuzzy logic.

Belief theory is yet another alternative approach. **Dempster-Shafer theory of evidence** performs reasoning under uncertainty in a structured space of hypotheses. It provides a means for computing a belief function over the hypothesis space and a way for combining belief function derived from different pieces of evidence. This approach is based on better mathematical foundations than the CF approach and is more general than the Bayesian and CF approaches (Durkin, 1993).

5.2.2 Model-Based Systems

Expert systems relying on heuristic rules have a number of limitations. They fail when a problem does not match the heuristics or when the heuristics are applied in inappropriate situations. The **model-based approach** attempts to address these problems by solving problems based on theoretical models of the components and systems. They are less dependent on expert opinion and experience and have higher flexibility and scope for expansion. The downsides are the cost and complexity of building models and the resulting programs that may be large and cumbersome (Stern and Luger, 1997).

The central concept of a model-based system is a model, a description of a device, or a system using an appropriate modeling language. The model specifies the structure, functions, and behaviors of the devices for the purposes of analysis, prediction, diagnosis, and other such procedures. The causal and structural information in the model may be represented using a number of data structures, such as rules and objects. For example, in using objects to represent the component structure in a model, the fields of an object represent a component's state, and the methods define its functionality. A model-based system reasons based on the model.

The types of models employed in model-based systems can be categorized as follows:

- **Declarative versus procedural**: Declarative models describe relationships between entities. They are very general, but can lead to complex and inefficient reasoning algorithms. Procedural models are more appropriate when the knowledge contains a strong element of directionality. They tend to be highly specialized to a certain task or situation and can efficiently derive outputs for inputs.
- **Quantitative versus qualitative**: Quantitative models are numerical models (e.g., the algebraic or differential equation-based models in traditional engineering disciplines). In qualitative models, variables take on qualitative values like *low* and *normal* instead of numerical values. The representation is usually based on fuzzy sets and belief networks. The advantage of qualitative models is that they map the domain knowledge in a more natural way and better reflect a human point of view.
- **Certain versus uncertain**: When the knowledge is inaccurate, incomplete, or ambiguous, the model should still be able to represent and process the knowledge. The major techniques for dealing with uncertainty are probability theory and fuzzy theory.
- **Static versus dynamic**: Static models represent steady-state or equilibrium behaviors of systems, whereas dynamic models represent behaviors in transient states.
- **Continuous versus discontinuous**: In continuous models, behavior trajectories evolve smoothly through adjacent states. Discrete models present discrete state transitions, jumping from one state to another with different properties.

The following simple examples of device and circuit analysis from Davis and Hamscher (1992) illustrate the concept of models. To represent an adder shown in Figure 5.2(A), the model encodes the knowledge that captures the functionality of the adder. It consists of three expressions that represent the relationships between values on the terminals: (1) if we know the values at A and B, then the value at C is $A + B$; (2) if we know the values at A and C, then the value at B is $C - A$; and (3) if we know the values at B and C, then the value at A is $C - B$.

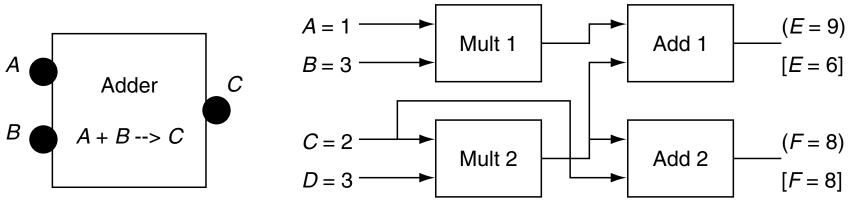
Using this kind of model in fault diagnosis, consider the circuit of two multipliers and two adders shown in Figure 5.2(B). The input values are given at A through D, and the output values are given at E and F with the expected output values in parentheses and the actual ones in brackets. The task is to determine which device is faulty from the fact that we expect 9 at E and instead get 6. Let's assume that only a single device is faulty. Since the value at E depends on Add-1, Mult-1, and Mult-2, one of them must have a fault. Since we get a correct value at F, Mult-2 must be correct. Thus, the fault lies in either Mult-1 or Add-1. Additional tests may be applied to the fewer devices left to identify the faulty one.

5.3 Reasoning

Some reasoning strategies are general, whereas others are specific to particular knowledge representation schemes. Goal-driven and data-driven strategies are general reasoning strategies. In data-driven reasoning, from the conditions that are known to be true, we reason forward to establish new conclusions. In contrast, in goal-driven reasoning, we reason backward from a goal state toward the conditions necessary to make it true. In addition, representation-specific reasoning methods have been developed for the various types of expert systems, including rule-based systems, frame-based systems, logic systems, model-based systems, object-oriented systems, fuzzy logic systems, blackboard systems, and many others.

5.3.1 Forward and Backward Chaining in Rule-Based Systems

In a rule-based system, the inference engine usually goes through a simple recognize-assert cycle. The control scheme is called forward chaining for data-driven reasoning, and backward chaining for goal-driven reasoning. The basic idea of forward chaining is when the premises of a rule (the **if** portion) are satisfied by the data, the expert system asserts the



(A) Behavior Description of an Adder (B) A Circuit with a Faulty Device

FIGURE 5.2 Examples of Device and Circuit Analysis

conclusions of the rule (the **then** portion) as true. A **forward-chaining reasoning system** starts by placing initial data in its working memory. Then the system goes through a cycle of matching the premises of rules with the facts in the working memory, selecting one rule, and placing its conclusion in the working memory. This inference process is useful in searching for a goal or an interpretation, given a set of data. For example, XCON is a forward-chaining rule-based system (McDermott, 1982) that contains several thousand rules for designing configurations of computer components for individual customers. It was one of the first clear commercial successes of expert systems. Its underlying technology has been implemented in the general-purpose language OPS-5.

In a **backward-chaining reasoning system** the goal is initially placed in the working memory. The system matches rule conclusions with the goal, selects one rule, and places its premises in the working memory. The process iterates, with these premises becoming new goals to match against rule conclusions. Thus, the system works backward from the original goal until all the subgoals in the working memory are known to be true. Subgoals may also be solved by asking the user for information. For example, MYCIN's inference engine uses a backward-chaining control strategy. From its goal of finding significant disease-causing organisms, MYCIN uses its rules to reason backward to the data available. Once it finds such organisms, it attempts to select a therapy to treat the disease(s). Since it was designed as a consultant for physicians, MYCIN was given the ability to explain both its reasoning and its knowledge (Buchanan and Shortliffe, 1984).

Given a fixed reasoning method, the process of searching through alternative solutions can be affected through the structuring and ordering of the rules in implementations. For example, in production systems, a rule of the form "**if *p* and *q* and *r* then *s***" may be interpreted in backward chaining as a procedure of four steps: **to do s**, **first do *p***, **then do *q***, **then do *r*.** Although the procedural interpretation of rules reduces the advantages of declarative representation, it can be used to reflect more efficient heuristic solution strategies. For instance, the premises of a rule may be ordered so that the one that is most likely to fail or is easiest to be satisfied will be tried first.

To illustrate forward and backward chaining, consider a simple example with the following rules in the knowledge base:

```
Rule 1: if a and b, then c
Rule 2: if c and d, then p (s1)
Rule 3: if not d and not e, then p (s2) or p (s3)
Rule 4: if not d and e, then p (s4)
```

The symbols *a* to *e* and *s*1 to *s*4 represents objects, and *p* represents a property of objects.

To perform backward-chaining reasoning, the top-level goal, *p*(*X*), is placed in the working memory as shown in Figure 5.3(A), where *X* is a variable that can match with any object. The conclusions of three rules (rules 2, 3, and 4) match with the expression in the working memory. If we solve conflicts in favor of the lower-numbered rule, then rule 2 will be selected and fire. This causes *X* to be bound to *s*1 and the two premises of rule 2 to be placed in the working memory as in Figure 5.3(B). Then, since the conclusion of rule 1 matches with a fact in the working memory, we then fire rule 1 and place its promises in the working memory as in Figure 5.3(C). At this point, there are three entries in the working memory (*a, b, d*) that do not match with any rule conclusion. The expert system will query the user directly about these subgoals. If the user confirms them as true, the expert system will have successfully determined the causes for the top-level goal *p*(*X*).

The control of the previous backward-chaining process performs a depth-first search, in which each new subgoal is searched exhaustively first before moving onto old subgoals. Other search strategies, such as breadth-first search, can also be applied.

Given the same set of rules, forward chaining can also be applied to derive new conclusions from given data. For example, the algorithm of forward chaining with breadth-first search is as follows: Compare the content of the working memory with the premises of each rule in the rule base using the ordering of the rules. If the data in the working memory match a rule's premises, the conclusion is placed in the working memory, and the control moves to the next rule. Once all rules have been considered, the control starts again from the beginning of the rule sets.

5.3.2 Model-Based Reasoning

Model-based reasoning contains a diverse set of approaches and a collection of loosely connected techniques, with most applications in the areas of monitoring, control, and diagnosis. For diagnosis applications, model-based reasoning usually consists of the following elements: (a) simulate and predict the normal behavior of the system, (b) record dependencies between internal model components and predicted observations, (c) upon detection of abnormal observations, use the dependencies to identify conflicting model assumptions, and (d) in the presence of multiple candidates, apply a measurement strategy to reduce the number of candidates.

Among the various types of models, qualitative models have been the focus of model-based reasoning in AI. They are useful in the situations where the quantitative models are impossible to develop due to lack of knowledge or are prohibitively computationally expensive. They may also correspond to the common sense knowledge better than abstract mathematical models. The major approaches in building qualitative models and related reasoning systems are the following:

- **Constraint-based approach**: A physical system is modeled by a set of qualitative mathematical constraints between the variables that comprise the model (Kuipers, 1986).
- **Component-based approach**: A model represents the topological structure of the target system, consisting of components, connections, and materials that flow through connections (deKleer and Brown, 1984). The behavior of each component is described by a set of local properties (i.e., relationships between inputs, internal states, and outputs).
- **Process-based approach**: A system is modeled based on component models and system topology, similar to the component-based approach. The difference is that the process-based approach uses *processes* to model physical interactions and to define the dynamic characteristics of the target system (Davis and Hamscher, 1992).

5.3.3 Case-Based Reasoning

Knowledge acquisition is a very difficult process in building expert systems. **Case-based reasoning** (CBR) systems simplifies the process by using a collection of past problem solutions (cases) to address new problems (Kolodner, 1993). The basic idea underlining this approach is "what was true yesterday is likely to be true today."

Past cases are either collected from human experts or from previous successes or failures of the system. A case usually contains three components: **problem description**, **solution to the problem**, and **outcome of the solution**. A description of the problem contains all descriptive information necessary for solving the problem. The description of the solution allows the reuse of a previous solution without starting from scratch once a similar case arrives. The outcome description contains explanations of what was carried out, whether it was a success or failure, the repair strategy in the case of failure, and how to avoid the failure. Cases can be represented in many different forms such as rules, logic formulas, frames, and database records. To be successful, it is important for a CBR system to have a sufficiently large collection of cases to reason from and to have a domain that is well understood.

CBR systems select and reason from appropriate past cases to build general rules and are able to learn from experiences because success and failure of previous attempts are retained. The major steps in case-based reasoning are as follows:

1. A new problem is analyzed and represented in the form such that the system can retrieve relevant past cases from its memory. A past case is appropriate if it has the potential to provide a solution to the new problem. Typically, heuristics are used to choose cases similar to the new problem based on certain similarity measures.
2. A retrieved case is modified so that it is applicable to the new problem. Analytic methods or heuristic methods are applied to transform the stored solution into operations suitable to the new problem.
3. In applying the transformed case to the new problem, an initial solution is proposed, tested, and evaluated. If it does not perform well, an explanation of the result is generated.
4. The new case is saved into the case collection with a record of its success or failure for future use. The system goes through an incremental learning process as new cases are added.

To retrieve relevant cases, one technique is to assign indexes (or labels) to all cases. Indexes represent an interpretation of a situation and determine under what conditions a case can be used to make useful inferences (Kolodner, 1993). Assigning indexes is problem dependent, requiring a good understanding of the problem domain. Another technique is to compute the relevance of a case based on similarity measures. For example, in nearest-neighbor matching, each corresponding feature of a new case and a retrieved case is compared by looking at the field type and values. Each feature gets a similarity score, and the weighted sum of the feature scores is the overall similarity score of the two cases.

To apply a retrieved case to the new problem, the previous solution may need to be modified to fit the current problem. There are two general types of modification: **structural** and **derivational**. In structural modification, simple changes, such as substituting values or adjusting and interpolating numerical numbers, are made to the retrieved solution to make it work for the new problem. In derivational modification, procedures that generated the previous solutions are run again to generate a new solution to the new case.

To illustrate how case-based reasoning works, let's look at CHEF, a CBR system that creates cooking recipes (Hammond, 1986). The input to CHEF is a list of goals that specify different types, tastes, and textures of dishes. The output is a recipe that satisfies these constraints. For example, the input may be "create a crisp pork dish; include broccoli; use stir-fry method." CHEF looks in its case base for a recipe that makes a similar meal and then adapts it to solve the new problem. If it already has a recipe for pork with cabbage, it may copy the recipe and substitute broccoli for cabbage. However, broccoli may not remain crisp if cooked like cabbage. Thus, the way of stir-frying may be modified, for example, by using rules from other cases involving crisp broccoli.

CBR has been applied to a variety of applications, including diagnosis, classification, interpretation, instruction, planning, and scheduling. One example is Support Management Automated Reasoning Technology (SMART) of Compaq (Acorn and Walden, 1992), which provides quality technical support by using previous cases to resolve new ones instead of trying to diagnose a new problem from scratch. Another system, CARES (Ong *et al.*, 1997), employs CBR to predict the recurrence of colorectal cancer.

Hybrid systems combining CBR with rule-based reasoning and model-based reasoning have also been developed. In combining CBR and rule-based reasoning, rules may be used to capture broad trends and general strategies in the problem domain, whereas cases are used to support exceptions and explain and justify rules. In combining CBR and model-based reasoning, model-based reasoning is good at handling well-understood components under normal situations, whereas CBR covers the part of the domain that does not have a good model or theory. In addition, by incorporating domain knowledge into CBR, past cases can be more efficiently organized, searched, retrieved, and better adapted to the new cases.

5.4 Knowledge Acquisition

Knowledge acquisition refers to the process of extracting, structuring, and organizing domain knowledge from domain experts into a program. A **knowledge engineer** is an expert in AI language and knowledge representation who investigates a particular problem domain, determines important concepts, and creates correct and efficient representations of the objects and relations in the domain.

Capturing domain knowledge of a problem domain is the first step in building an expert system. In general, the knowledge acquisition process through a knowledge engineer can be divided into four phases:

1. **Planning**: The goal is to understand the problem domain, identify domain experts, analyze various knowledge acquisition techniques, and design proper procedures.
2. **Knowledge extraction**: The goal is to extract knowledge from experts by applying various knowledge acquisition techniques.
3. **Knowledge analysis**: The outputs from the knowledge extraction phase, such as concepts and heuristics, are analyzed and represented in formal forms, including heuristic rules, frames, objects and relations, semantic networks, classification schemes, neural networks, and fuzzy logic sets. These representations are used in implementing a prototype expert system.
4. **Knowledge verification**: The prototype expert system containing the formal representation of the heuristics and concepts is verified by the experts. If the knowledge base is incomplete or insufficient to solve the problem, alternative knowledge acquisition techniques may be applied, and additional knowledge acquisition process may be conducted.

Many knowledge acquisition techniques and tools have been developed with various strengths and limitations. Commonly used techniques include interviewing, protocol analysis, repertory grid analysis, and observation.

Interviewing is a technique used for eliciting knowledge from domain experts and design requirements. The basic form involves free-form or unstructured question–answer sessions between the domain expert and the knowledge engineer. The major problem of this approach results from the inability of domain experts to explicitly describe their reasoning process and the biases involved in human reasoning. A more effective form of interviewing is called **structured interviewing**, which is goal-oriented and directed by a series of clearly stated goals. Here, experts either fill out a set of carefully designed questionnaire cards or answer questions carefully designed based on an established domain model of the problem-solving process. This technique reduces the interpretation problem inherent in the unstructured interviewing as well as the distortion caused by domain expert subjectivity.

As an example, let's look at the interviewing process used in constructing GTE's COMPASS system (Prerau, 1990). COMPASS is an expert system that examines error messages derived from a telephone switch's self-test routines and suggests running of additional tests or replacing a particular component. The interviewing process in building COMPASS has an elicit–document–test cycle as follows:

1. Elicit knowledge from an expert.
2. Document the elicited knowledge in rules and procedures.
3. Test the new knowledge using a set of data:
   (a) Have the expert analyze a new set of data.
   (b) Analyze the same set of data using the documented knowledge.
   (c) Compare the two results.
   (d) If the results differ, find the rules or procedures that lead to the discrepancy and return to step 1 to elicit more knowledge to resolve the problem.

Protocol analysis is another technique of data analysis originated in clinical psychology. In this approach, an expert is asked to talk about his or her thinking process while solving a given problem. The difference from interviewing is that experts find it much easier to talk about specific problem instances than to talk in abstract terms. The problem-solving process being described is then analyzed to produce a structured model of the expert's knowledge, including objects of significance, important attributes of the objects, relationships among the objects, and inferences drawn from the relationships. The advantage of protocol analysis is the accurate description of the specific actions and rationales as the expert solves the problem.

Repertory grid analysis investigates the expert's mental model of the problem domain. First, the expert is asked to identify the objects in the problem domain and the traits that differentiate them. Then, a rating grid is formed by rating the objects according to the traits.

Observation involves observing how an expert solves a problem. It enables the expert to continuously work on a problem without being interrupted while the knowledge is obtained. A major limitation of this technique is that the underlying reasoning process of an expert may not be revealed in his or her actions.

Knowledge acquisition is a difficult and time-consuming task that often becomes the bottleneck in expert system development (Hayes-Roth *et al.*, 1983). Various techniques have been developed to automate the process by using domain-tailored environments containing well-defined domain knowledge and specific problem-solving methods (Rothenfluh *et al.*, 1996). For example, OPAL is a program that expedites knowledge elicitation for the expert system ONCOCIN (Shortliffe *et al.*, 1981) that constructs treatment plans for cancer patients. OPAL uses a model of the cancer domain to acquire knowledge directly from an expert. OPAL's domain model has four main aspects: **entities and relationships**, **domain actions**, **domain predicate**, and **procedural knowledge**. Based on its domain knowledge, OPAL can acquire more knowledge from a human expert and translate it into executable code, such as production rules and finite state tables. Following OPAL, more general-purpose systems called PROTEGE and PROTEGE-II were developed (Musen, 1989). PROTEGE-II contains tools for creating domain ontology and generating OPAL-like knowledge acquisition programs for particular applications PROTEGE-II is a general tool developed by abstraction from a successful application, similar to the process from MYCIN to EMYCIN.

Another example of automated knowledge acquisition is the SALT system (Marcus and McDermott, 1989) associated with an expert system called Vertical Transportation (VT) for designing custom-design elevator systems. SALT assumes a propose-and-revise strategy in the knowledge acquisition process. Domain knowledge is seen as performing one of three roles: (1) proposing an extension to the current design, (2) identifying constraints upon design extension, and (3) repairing constraint violation. SALT automatically acquires these kinds of knowledge by interacting with an expert and then compiles the knowledge into production rules to generate a domain-specific knowledge base. SALT retains the original knowledge in a declarative form as a dependency network, which can be updated and recompiled as necessary.

To build a knowledge base, the knowledge can be either captured through knowledge engineers or be generated automatically by machine learning techniques. For example, rules in rule-based expert systems may be obtained through a knowledge acquisition process involving domain experts and knowledge engineers or may be generated automatically from examples using decision-tree learning algorithms. Case-based reasoning is another example of automated knowledge extraction in which the expert system searches its collection of past cases, finds the ones that are similar to the new problem, and applies the corresponding solutions to the new one. The whole process is fully automatic. An expert system of this type can be built quickly and maintained easily by adding and deleting cases. Automatic knowledge generation is especially good when a large set of examples exist or when no domain expert exists.

In addition to generating knowledge automatically, machine learning methods have also been used to improve the performance of the inference engines by learning the importance of individual rules and better control in reasoning.

5.5 Explanation

Providing explanations that clarify the decision-making process and justify recommendations is an integral component of an expert system. It is one of the primary user requirements (Dhaliwal and Benbasat, 1996; Ye and Johnson, 1995). The explanation facility may be used by different users for different reasons in different contexts. For example, novice users can use the facility to find more about the knowledge being applied to solve a particular problem. Advanced users access it to make sure that the system's knowledge and reasoning process is appropriate. Decision makers use the explanation facility because it aids them in formulating problems and models for analysis. The context may be problem solving by end users, knowledge-base debugging by knowledge engineers, or expert system validation by domain experts and/or knowledge engineers. Although explanations are commonly used by end-users, they also play a significant role in the development of expert systems by offering enhanced debugging and validation abilities. Most current expert system development shells and environments include explanation tools.

The knowledge required for providing explanations may be derived from the knowledge base or may be separate from the knowledge used in solving problems. Depending on the type of problem-solving tasks, explanations may be presented to the users in different ways, such feed-forward and feedback.

Feed-forward explanations focus on the input cues, are not case-specific, and are presented prior to an assessment being performed, whereas feedback explanations focus on the outcome, explain a particular case-specific outcome, and are presented subsequent to the assessment.

The major types of explanations include why, how, what, what-if, and strategic explanations. The **why** explanations provide justification knowledge of the underlying reasons for an action based on causal models. The **how** explanations provide reasoning trace knowledge of the inference process. The **why** and **how** explanations were first introduced in MYCIN. They remain the core of most explanation facilities in current expert system applications and development shells. The **what** explanations provide knowledge about the object definitions or decision variables used by the system. The **what-if** explanations provide direct and explicit information about the sensitivity of decision variables. The **strategic** explanations provide information about the problem-solving strategy and metaknowledge.

In MYCIN, the explanation module is invoked at the end of every consultation. To explain the result, the module retrieves the list of rules that were successfully applied, along with the conclusions drawn. It allows the user to interrogate the system about the conclusions. Inquiries generally fall into two types: why a particular question was put and how a particular conclusion was reached. MYCIN keeps track of the goal–subgoal structure of the computation and uses it to answer a why question by citing the related rules together with other conditions. To answer a how question, MYCIN maintains a record of the decisions it made and cites the rules that it applied as well as the degree of certainty of the decision.

Multimedia Systems: Content-Based Indexing and Retrieval

6.1 Introduction

Multimedia data, such as text, audio, images and video, are rapidly evolving as main avenues for the creation, exchange, and storage of information in the modern era. Primarily, this evolution is attributed to rapid advances in the three major technologies that determine the data's growth: VLSI technology that is producing greater processing power, broadband networks (e.g., ISDN, ATM, etc.) that are providing much higher bandwidth for many practical applications, and multimedia compression standards (e.g., JPEG, H.263, MPEG, MP3, etc.) that enable efficient storage and communication. The combination of these three advances is spurring the creation and processing of increasingly high-volume multimedia data, along with efficient compression and transmission over high-bandwidth networks. This current trend toward the removal of any conceivable bottleneck for those using multimedia data, from advanced research organizations to home users, has led to the explosive growth of visual information available in the form of digital libraries and online multimedia archives. According to a press release by Google Inc. in December 2001, the search engine offers access to over 3 billion Web documents and its Image search comprises more that 330 million images. Alta Vista Inc. has been serving around 25 million search queries per day in more than 25 languages, with its multimedia search featuring over 45 million images, videos, and audio clips.

This explosive growth of multimedia data accessible to users poses a whole new set of challenges relating to data storage and retrieval. The current technology of text-based indexing and retrieval implemented for relational databases does not provide practical solutions for this problem of managing huge multimedia repositories. Most of the commercially available multimedia indexing and search systems index the media based on keyword annotations and use standard text-based indexing and retrieval mechanisms to store and retrieve multimedia data. There are often many limitations with this method of keyword-based indexing and retrieval, especially in the context of multimedia databases. First, it is often difficult to describe with human languages the content of a multimedia object (e.g., an image having complicated texture patterns). Second, a manual annotation of text phrases for a large database is prohibitively laborious in terms of time and effort. Third, since users may have different interests in the same multimedia object, it is difficult to describe it with a complete set of keywords. Finally, even if all relevant object characteristics are annotated, difficulty may still arise due to the use of different indexing languages or vocabularies by different users. As recently as the 1990s, these major drawbacks of searching visual media based on textual annotations were recognized as unavoidable, and this prompted a surging increase in interest in content-based solutions (Goodrum, 2000). In content-based retrieval, manual annotation of visual media is avoided, and indexing and retrieval are instead performed on the basis of media content itself. There have been extensive studies on the design of automatic **content-based indexing and retrieval** (CBIR) systems. For visual media, these contents may include color, shape, texture, and motion. For audio/speech data, contents may include phonemes, pitch, rhythm, and cepstral coefficients. Studies of human visual perception indicate that there exists a gradient of sophistication in human perception, ranging from seemingly primitive inferences (e.g., shapes, textures, and colors), to complex notions of structures (e.g., chairs, buildings, and affordances), and to cognitive processes (e.g., recognition of emotions and feelings). Given the multidisciplinary nature of the techniques for modeling, indexing, and retrieval of multimedia data, efforts from many different communities of engineering, computer science, and psychology have merged in the advancement of CBIR systems. But the field is still in its infancy and calls for more coherent efforts to make practical CBIR systems a reality. In particular, robust techniques are needed to develop semantically rich models to represent data, computationally efficient methods to compress, index, retrieve, and browse the information; and semantic visual interfaces integrating the above components into viable multimedia systems.

This chapter reviews the state-of-the-art research in the area of multimedia systems. Section 6.2 reviews storage and coding techniques for different media types. Section 6.3 studies fundamental issues related to the representation of multimedia data and discusses salient indexing and retrieval approaches introduced in the literature. For the sake of compactness and focus, this chapter reviews only CBIR techniques for visual data (i.e., for images and videos); the review of systems for audio data readers are referred to Foote (1999).

6.2 Multimedia Storage and Encoding

Raw multimedia data require vast amount of storage, and, therefore, they are usually stored in a compressed format. Slow storage devices (e.g., CD-ROMs and hard disk drives) do not support playback/display of uncompressed multimedia data (especially of video and audio) in real-time. The term **compression** refers to removal of **redundancy** from data. The more redundancy in the data is reduced, the higher the **compression ratio** is achieved. The method by which redundancy is eliminated to increase data compression is known as **source coding**. In essence, the same (or nearly the same) information is represented using fewer data bits. There are several other reasons behind the popularity of compression techniques and standards for multimedia data:

- Compression extends the playing time of a storage device. With compression, more data can be stored in the same storage space.
- Compression allows miniaturization of hardware system components. With less data to store, the same playing time is obtained with less hardware.
- Tolerances of system design can be relaxed. With less data to record, storage density can be reduced, making equipment that is more resistant to adverse environments and that requires less maintenance.
- For a given bandwidth, compression allows faster information transmission.
- For a given bandwidth, compression allows a better-quality signal transmission.

The previous bulleted list explains the reasons that compression technologies have helped the development of compressed domain-based modern communication systems and compact and rugged consumer products. Although compression in general is a useful technology, and, in the case of multimedia data, an essential one, it should be used with caution because it comes with some drawbacks as well. By definition, compression removes redundancy from signals. Redundancy is, however, essential in making data resistant to errors. As a result, compressed data is more sensitive to errors than uncompressed data. Thus, transmission systems using compressed data must incorporate more powerful error-correction strategies. Most of the text-compression techniques, such as the Lampel-Ziv-Welch codes, are very sensitive to bit errors: an error in the transmission of the code table value results in bit errors every time the table location is accessed. This phenomenon is known as **error propagation**. Other variable-length coding techniques, such as Huffman coding, are also sensitive to bit errors. In real-time multimedia applications, such as audio and video communications, some error concealment must be used in case of errors.

The applications of multimedia compression are limitless. The **International Standards Organization** ISO has provided standards that are appropriate for a wide range of possible compression products. The video encoding standards by ISO, developed by Motion Pictures Expert Group (MPEG), embrace video pictures from the tiny screen of a videophone to the high-definition images needed for electronic cinema. Audio coding stretches from speech-grade monochannel to multichannel surround sound. Data compression techniques are classified as **lossless** and **lossy** coding. In lossless coding, the data from the decoder is identical bit-for-bit with the original source data. Lossless coding generally provides limited compression ratios. Higher compression is possible only with lossy coding in which data from the decoder is not identical to the original source data and between them minor differences exist. Lossy coding is not suitable for most applications using text data but is used extensively for multimedia data compression as it allows much greater compression ratios. Successful lossy codes are those in which the errors are imperceptible to a human viewer or listener. Thus, lossy codes must be based on an understanding of psychoacoustic and psychovisual perceptions and are often called **perceptive codes**. The following subsections provide a very brief overview of some of the multimedia compression standards. Subsection 6.2.1 presents image encoding standards, and subsection 6.2.2 discusses several video encoding standards.

6.2.1 Image Encoding Standards

As noted earlier, the task of compression schemes is to reduce the redundancy present in raw multimedia data representation. Images contain three forms of redundancy:

- **Coding redundancy**: Consider the case of an 8-bit per pixel image (i.e., each pixel in the image is represented with an 8-bit value ranging between 0 to 255, depending on the local luminosity level in that particular area of the image). Because the gray scale value of some of the pixels may be small (around zero for a darker pixel), representing those pixels with the same number of bits for the ones with a higher pixel value (brighter pixels) is not a good coding scheme. In addition, some of the gray scale values in the image may be occurring more often than others. A more realistic approach would be to assign shorter codes to the more frequent data. Instead of using fixed-length codes as above, the **variable length coding** schemes (e.g., Shannon-Fano, Huffman, arithmetic, etc.) would be used in which the smaller and more frequently occurring gray scale values get shorter codes. If the gray levels of an image are encoded in such a way that uses more code symbols than absolutely necessary to represent each gray level, the resulting image is said to contain the coding redundancy.
- **Interpixel redundancy**: For the case of image data, redundancy will always be present if only the coding redundancy is explored and however rigorously it is minimized by using state-of-the-art variable length coding techniques. The reason for this is that images are typically composed of objects that have a regular and somewhat predictable morphology and reflectance and the pixel values are highly correlated. The value of any pixel can be reasonably predicted from the value of its neighbors; the information carried by each individual pixel is relatively small. To exploit this property of the images, it is often necessary to convert the visual information of the image into somewhat nonvisual format that better reflects the correlation between the pixels. The most effective technique in this regard is to transform the image into frequency domain by taking the discrete fourier transform (DFT), discrete cosine transform (DCT) or any other such transform.
- **Psychovisual redundancy**: This type of redundancy arises from the fact that a human eye's response is not equally sensitive to all the visual information. The information that has less relative importance to the eye is said to be psychovisually redundant. Human perception of the visual information does not involve the quantitative analysis of every pixel; rather, the eye searches for some recognizable groupings to be interpreted as distinguished features in the image. This is the reason that the direct current (dc) component of a small section of the image, which indicates the average luminosity level of that particular section of the image, contains more visually important information than a high frequency alternating current (ac) component, which has the information regarding the difference between luminosity levels of some successive pixels. Psychovisual redundancy can be eliminated by throwing away some of the redundant information. Since the elimination of psychovisually redundant data results in a loss of quantitative information and is an irreversible process, it results in lossy data compression. How coarse or how fine to quantize the data depends on what quality and/or what compression ratio is required at the output. This stage acts as the tuning tap in the whole image compression model. On the same grounds, the human eye's response to color information is not as sharp as it is for the luminosity information. More color information is psychovisually redundant than the gray scale information simply because the eye cannot perceive finer details of colors, whereas it can for gray scale values.

The following paragraphs outline the details of one very popular image compression standard, JPEG, that is a result of a collaborative effort between ITU-T and ISO.

JPEG: Digital Compression and Coding of Continuous-Tone Still Images

The Joint Photographic Experts Group (JPEG) standard is used for compression of continuous-tone still images (ISO 10918-1, 1994). This compression standard is based on the Huffman and run-length encoding of the quantized DCT coefficients of image blocks. The widespread use of the JPEG standard is motivated by the fact that it consistently produces compression ratios in excess of 20:1. The compression algorithm can be operated on both gray scale as well as multichannel color images. The color data, if in psychovisually redundant RGB format, is first converted to a more "compression-friendly" color model like YCbCr or YUV. The image is first broken down into blocks of size 8 × 8 called **data units**. After that, depending on color model and decimation scheme for chrominance channels involved, **minimum code units** (MCUs) are formed. A minimum code unit is the smallest unit that is processed for DCT, quantization, and variable-length encoding subsequently. One example for the case of the YUV 4:1:1 color model (each of chrominance component being half in width and half in length) is shown in Figure 6.1. Here the MCU consists of four data units from the Y component and one each from the U and V components.

FIGURE 6.1 Minimum Code Unit

Each of the data units in an MCU is then processed separately. First a two-dimensional (2-D) DCT operation is performed that changes the energy distribution of the original image and concentrates more information in low frequencies. The DCT coefficients are then quantized to reduce the magnitude of coefficients to be encoded and to reduce some of the smaller ones to zero. The specs contain two separate quantization tables for luminance (Y) and for chrominance (U and V). The quantized coefficients are then prepared for symbol encoding. This is done by arranging them in a zigzag sequence as shown in the Figure 6.2, with lowest frequencies first and the highest frequencies last, to keep the scores of zero-valued coefficients at the tail of the variable-length bit stream to be encoded in the next phase. The assumption is that low-frequency components tend to occur with higher magnitude, while the high-frequency ones occur with lower magnitudes; placing the high frequency components at the end of the sequence to be encoded is more likely to generate a longer run of zeros yielding a good overall compression ratio.

As far as the symbol encoding is concerned, the standard specifies the use of either Huffman or arithmetic encoding. Realizing the fact that image data applications are computation intensive and performing the Huffman encoding for each block of 8 × 8 pixels might not be practical in most situations, the specs provide standard Huffman encoding tables for luminance (Y) and for chrominance (U and V) data. The experimentally proven code tables based on the average statistics of a large number of video images with 8 bits per pixel depth yield satisfactory results in most practical situations. For the dc encoding, the difference of each block's dc coefficient with the previous one is encoded. This code is then output in two successive bunches: one for the size of this code and the succeeding one for the most significant bits of the exact code. Since ac coefficients normally contain many zeros scattered between nonzero coefficients, the technique to encode ac coefficients takes into account the run of zeros between current and upcoming ac coefficients.

A direct extension of the JPEG standard to video compression known as motion JPEG (MJPEG) is obtained by the JPEG encoding of each individual picture in a video sequence. This approach is used when random access to each picture is essential, such as in video editing applications. The MJPEG compressed video yields data rates in the range of 8 to 10 Mbps.

6.2.2 Video Encoding Standards

Video data can be thought of as a sequential collection of images. The statistical analysis of video indicates that there is a strong correlation between successive picture frames as well as in the picture elements themselves. Theoretically,

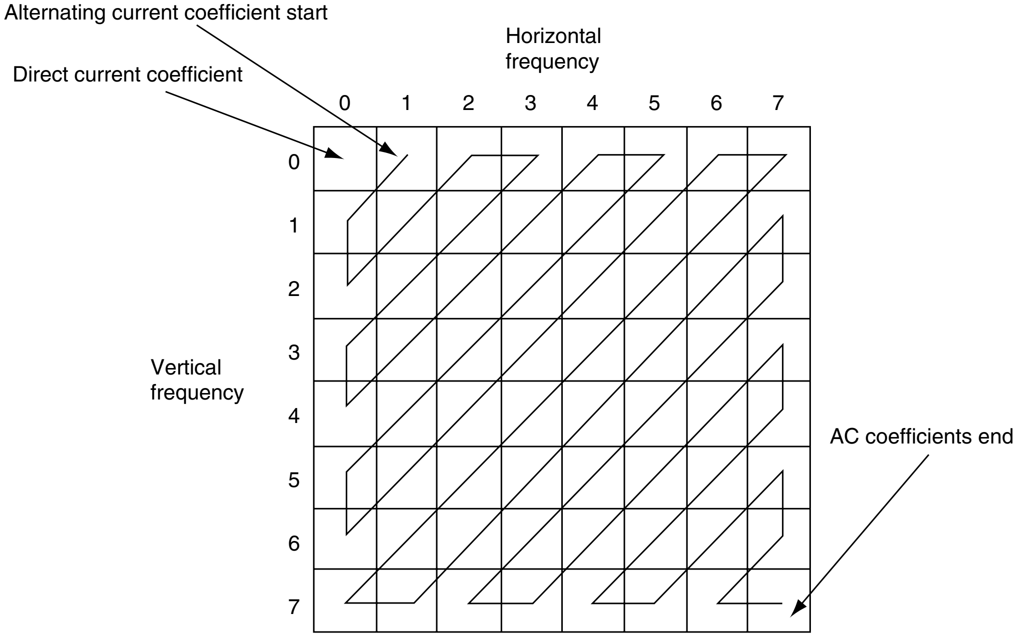

FIGURE 6.2 Zigzag Ordering of the Quantized DCT Coefficients

decorrelation of the temporal information can lead to bandwidth reduction without greatly affecting the video quality. As shown in the previous section, spatial correlation between image pixels is exploited to achieve still image compression. Such a coding technique is called **intraframe coding**. If temporal correlation is exploited as well, this is called **interframe coding**.

Interframe coding is the main coding principal that is used in all standard video codecs. First, a theoretical discussion of temporal redundancy reduction is given and then some of the popular video compression standards are explored in more detail.

Temporal redundancy is removed by using the differences between successive images. For static parts of the image sequence, temporal differences will be close to zero and, hence, are not coded. Those parts that change between frames, either due to illumination variation or motion of objects, result in significant image error that needs to be coded. Image changes due to motion can be significantly reduced if the motion of the object can be estimated and the difference can be taken on a motion-compensated image. To carry out **motion compensation**, the amount and direction of moving objects has to be estimated first. This is called **motion estimation**. The commonly used motion estimation technique in all the standard video codecs is the **block matching algorithm** (BMA). In a typical BMA, a frame is divided into square blocks of N^2 pixels. Then, for a maximum motion displacement of w pixels per frame, the current block of pixels is matched against a corresponding block at the same coordinates but in a previous frame in the square window of width $N + 2w$. The best match on the basis of a matching criterion yields the displacement. Various measures such as cross correlation function (CCF), mean squared error (MSE) and mean absolute error (MAE) can be used in the matching criteria. In practical coders, MSE and MAE are more often used since it is believed that CCF does not give good motion tracking, especially when the displacement is not quite large. MSE and MAE are defined as:

$$MSE(i, j) = \frac{1}{N^2}\sum_{m=1}^{N}\sum_{n=1}^{N}(f(m, n) - g(m+i, n+j))^2, \; -w \le i, j \le w.$$
$$MAE(i, j) = \frac{1}{N^2}\sum_{m=1}^{N}\sum_{n=1}^{N}|f(m, n) - g(m+i, n+j)|, \; -w \le i, j \le w. \tag{6.1}$$

The $f(m,n)$ variable represents the current block of N^2 pixels at coordinates (m, n), and $g(m+i, n+j)$ represents the corresponding block in the previous frame at new coordinates $(m+i, n+j)$. Motion estimation is one of the most computationally intensive parts of video compression standards, and some fast algorithms for this have been reported. One such algorithm is three-step Search, which is the recommended method for H.261 codecs (to be explained subsequently). It computes motion displacements up to 6 pixels per frame. In this method, all eight positions surrounding the initial location with a step size of $w/2$ are searched first. At each minimum position, the search step size is halved and the next eight positions are searched. The process is outlined in Figure 6.3. This method, for w set as 6 pixels per frame, searches 25 positions to locate the best match.

Motion Picture Expert Group

The motion picture expert group (MPEG) provides a collection of motion picture compression standards developed by the IEC. Its goal is to introduce standards for movie storage and communication applications. These standards include audio compression representation, video compression representation, and system representation. The following subsection briefly outlines the details of three video compression standards developed by MPEG.

MPEG-1: Coding of Moving Pictures for Digital Storage Media

The goal of MPEG-1 was to produce VCR NTSC (352 × 240) quality video compression to be stored on CD-ROM (CD-I and CD-Video formats) using a data rate of 1.2 Mbps. This approach is based on the arrangement of frame sequences into a group of pictures (GOP) consisting of four types of pictures: I-picture (intra), P-picture (predictive), B-picture (bidirectional), and D-picture (dc). I-pictures are intraframe JPEG-encoded pictures that are inserted at the beginning of the GOP. The P- and B-pictures are interframe motion-compensated JPEG-encoded macroblock difference pictures that are interspersed throughout the GOP.[1] The system level of MPEG-1 provides for the integration and synchronization of the audio and video streams. This is accomplished by multiplexing and including time stamps in both the audio and video streams from a 90-KHz system clock (ISO/IEC, 1991).

[1] MPEG-1 restricts the GOP to sequences of 15 frames in progressive mode.

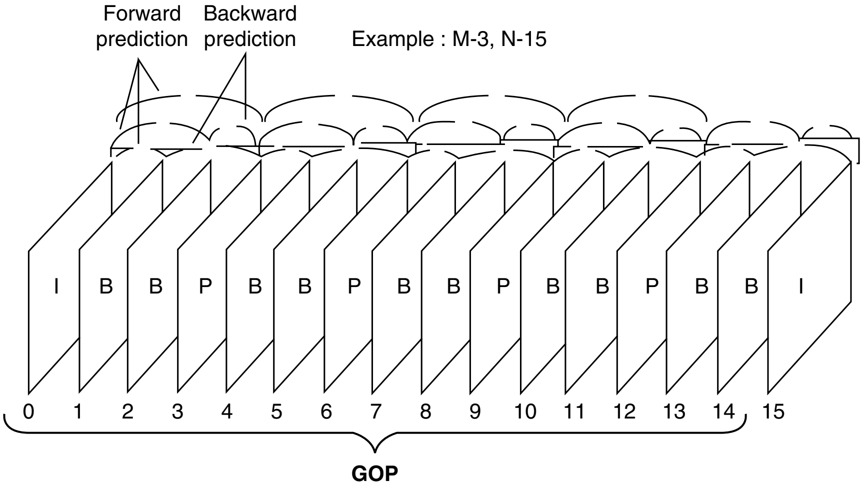

FIGURE 6.4 A Typical MPEG-1 GOP

In MPEG-1, due to the existence of several picture types, GOP is the highest level of hierarchy. The first coded picture in a GOP is an I-picture. It is followed by an arrangement for P- and B-pictures, as shown in Figure 6.4. GOP length is normally defined as the distance *N* between I-pictures. The distance between anchor I/P to P-pictures is represented by *M*. The GOP can be any length, but there has to be one I-picture in each GOP. Applications requiring random access, fast-forward play, or fast and reverse play may use short GOPs. GOP may also start at scene cuts; otherwise, motion compensation is not effective. Each picture is further divided into a group of macroblocks, called **slices**. The reason for defining slices is to reset the variable length code to prevent channel error propagation into the picture. Slices can have different sizes in a picture, and the division in one picture need not be the same as in any other picture. The slices can begin and end at any macroblock in a picture, but the first slice has to begin at the top left corner of the picture, and the end of last slice must be the bottom right macroblock of the picture. Each slice starts with a **slice start code** and is followed by a code that defines its position as well as a code that sets the quantization step size. Slices are divided into **macroblocks** of size 16 × 16, which are further divided into **blocks** of size 8 × 8 as in JPEG.

The encoding process for the MPEG-1 encoder is as follows. For a given macroblock, the coding mode is first chosen. This depends on the picture type, the effectiveness of motion-compensated prediction in that local region, and the nature of the signal in the block. Next, depending on the coding mode, a motion-compensated prediction of the contents of the block based on past and/or future reference pictures is formed. This prediction is subtracted from the actual data in the current macroblock to form an error signal. After that, this error signal is divided into 8 × 8 blocks, and a DCT is performed on each block. The resulting 2-D 8 × 8 block of DCT coefficients is quantized and scanned in zigzag order to convert it into a 1-D string of quantized coefficients like in JPEG. Finally, the side information for the macroblock, including the type, block-pattern and motion vectors, and DCT coefficients are coded. A unique feature of the MPEG-1 standard is the introduction of B-pictures that have access to both past and future anchor points. They can either use past frame, called **forward motion estimation** or the future frame, called **backward motion estimation**, as shown in Figure 6.5.

Such an option increases motion compensation efficiency especially when there are occluded objects in the scene. From the two forward and backward motion vectors, the encoder has a choice of choosing either any of the two or a weighted average of the two, where weights are inversely proportional to the distance of the B-picture with its anchor position.

MPEG-2: Coding of High-Quality Moving Pictures (MPEG-2)

The MPEG-1 standard was targeted for coding of audio and video for storage, in which the media error rate is negligible. Hence, MPEG-1 bitstream was not designed to be robust to bit errors. In addition, MPEG-1 was aimed at software-oriented image processing, where large and variable length packets could reduce the software overhead. The MPEG-2 standard,

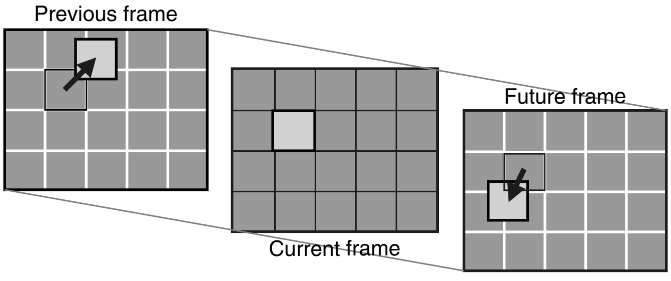

FIGURE 6.5 Motion Estimation in B-Pictures

on the other hand, is more generic for a variety of audio–visual coding applications. It has to have the error resilience for broadcasting and ATM networks. The aim of MPEG-2 is to produce broadcast-quality video compression and support higher resolutions including high definition television (HDTV).[2] MPEG-2 supports four resolution levels: low (352 × 240), main (720 × 480), high-1440 (1440 × 1152), and high (1920 × 1080) (ISO/IEC, 1994). The MPEG-2 compressed video data rates are in the range of 3 to 100 Mbps.[3] Although the principles used to encode MPEG-2 are very similar to MPEG-1, they provide much greater flexibility by offering several profiles that differ in the presence or absence of B-pictures, chrominance resolution, and coded stream scalability.[4] MPEG-2 supports both progressive and interlaced modes.[5] Significant improvements have also been introduced in the MPEG-2 system level. The MPEG-2 systems layer is responsible for the integration and synchronization of the elementary streams (ES): audio and video streams as well as an unlimited number of data and control streams that can be used for various applications such as subtitles in multiple languages. This is accomplished by first packetizing the ES, thus forming the packetized elementary streams (PES). These PES contain timestamps from a system clock for synchronization. The PES are subsequently multiplexed to form a single output stream for transmission in one of two modes: program stream (PS) and transport stream (TS). The PS is provided for error-free environments, such as storage in a CD-ROM. They are used for multiplexing PES that share a common time base, using long variable-length packets.[6] The TS is designed for noisy environments, such as communication over ATM networks. This mode permits multiplexing streams (PES and PS), which do not necessarily share a common time-base, using fixed-length (188 bytes) packets.

In the MPEG-2 standard, pictures can be interlaced, whereas in MPEG-1, the pictures are progressive only. The dimensions of the units of blocks used for motion estimation/compensation can change. Because the number of lines per field is half the number of lines per frame in the interlaced pictures, for motion estimation it might be appropriate to choose blocks of 16 × 8 (i.e., 16 pixels over 8 lines) with equal horizontal and vertical resolutions. The second major difference between the two is **scalability**. The scalable modes of MPEG-2 video encoders are intended to offer interoperability among different services or to accommodate the varying capabilities of different receivers and networks upon which a single service may operate. MPEG-2 also has a choice of a different DCT coefficient scanning mode **alternate scan** as well as a zigzag scan.

MPEG-4: Content-Based Video Coding

The intention of MPEG-4 was to provide low bandwidth video compression at a data rate of 64 Kbps that can be transmitted over a single N-ISDN B channel. This goal has evolved to the development of flexible, scalable, extendable, and interactive compression streams that can be used with any communication network for universal accessibility (e.g., Internet and wireless networks). MPEG-4 is a genuine multimedia compression standard that supports audio and video as well as synthetic and animated images, text, graphics, texture, and speech synthesis (ISO/IEC, 1998). The foundation of MPEG-4 is on the hierarchical representation and composition of audio–visual objects (AVO). MPEG-4 provides a standard for the configuration, communication, and instantiation of object classes: The configuration phase determines the classes of objects required for processing the AVO by the decoder. The communication phase supplements existing classes of objects in the decoder. Finally, the instantiation phase sends the class descriptions to the decoder. A video object at a given point in time is a video object plane (VOP). Each VOP is encoded separately according to its shape, motion, and texture. The shape encoding of a VOP provides a pixel map or a bitmap of the object's shape. The motion and texture encoding of a VOP can be obtained in a manner similar to that used in MPEG-2. A multiplexer is used to integrate and synchronize the VOP data and composition information—position, orientation, and depth—as well as other data associated with the AVOs in a specified bitstream. MPEG-4 provides universal accessibility supported by error robustness and resilience, especially in noisy environments at very low data rates (less than 64 Kbps): bit stream resynchronization, data recovery, and error concealment. These features are particularly important in mobile multimedia communication networks.

H.26X: Video Compression Standards

The H.26X provides a collection of video compression standards developed by the ITU-T. The main focus of this effort is to present standards for videoconferencing applications compatible with the H.310 and H.32X communication network standards. These communication network standards include video compression representation, audio compression representation, multiplexing standards, control standards, and system standards. The H.26X and MPEG standards are very similar with relatively minor differences due to the particular requirements of the intended applications.

H.261: Coding for Video Conferencing

The H.261 standard has been proposed for video communications over ISDN at data rates of p × 64 Kbps. It relies on

[2] The HDTV Grand Alliance standard adopted the MPEG-2 video compression and transport stream standards in 1996.

[3] The HDTV Grand Alliance standard video data rate is approximately 18.4 Mbps.

[4] The MPEG-2 video compression standard, however, does not support D-pictures.

intraframe and interframe coding for which integer–pixel accuracy motion estimation is required for intermode coding (H. 261, 1990).

H.263 Video Coding for Low Bit-Rate Communications

The H.263 standard is aimed at video communications over POTS and wireless networks at very low data rates (as low as 18 to 64 Kbps). Improvements in this standard result from the incorporation of such features as half-pixel motion estimation, overlapping and variable blocks sizes, bidirectional temporal prediction,[7] and improved variable-length coding options (H. 263, 1995).

H.26L: Video Communications over Wireless Networks

The H.26L standard is designed for video communications over wireless networks at low data rates. It provides features such as fractional pixel resolution and adaptive rectangular block sizes.

6.3 Multimedia Indexing and Retrieval

As discussed in the previous sections, multimedia data poses its distinct challenges for modeling and representation. The huge amount of multimedia information now available makes it all the more important to organize these multimedia repositories in a structured and coherent way to make it more accessible to a large number of users. This section explores the problem of storing multimedia information in a structured form (indexing) and searching the multimedia repositories in an efficient manner (retrieval). Subsection 6.3.1 outlines an image indexing and retrieval paradigm. The subsection first discusses the motivation for using content-based indexing and retrieval for images and then explores several different issues and research directions in this field. Subsection 6.3.2 highlights similar problems in the area of video indexing and retrieval. As with any other emerging field going through intellectual and technical exploration, the domain of content-based access to multimedia repositories causes a number of research issues to surface; these issues cannot be summarized in a single concise presentation. One such issue is query language design for multimedia databases. The interested reader can refer to Catarci *et al.* (1995), Hibino and Rundensteiner (1995), Kaushik and Rundensteiner (1998), and Zhang *et al.* (1997).

6.3.1 Image Indexing and Retrieval

Because of the tremendous growth of visual information available in the form of images, effective management of image archives and storage systems is of great significance and an extremely challenging task indeed. For example, a remote sensing satellite, which generates seven band images including three visible and four infrared spectrum regions, produces around 5000 images per week. Each single spectral image, which corresponds to a 170 km × 185 km of the earth's region, requires 200 mB of storage. The amount of data originated from satellite systems is already reaching a terabyte level per day. Storing, indexing, and retrieving such a huge amount of data by their contents is a very challenging task. Generally speaking, data representation and feature-based content modeling are two basic components required by the management of any multimedia database. As far as the image database is concerned, data representation focuses on image storage, whereas feature-based content modeling is related to image indexing and retrieval. Depending on the background of the research teams, different levels of abstractions have been assumed to model the data. As shown in Figure 6.6, these abstractions can be classified into three categories based on the gradient model of human visual perception. This figure, also captures the mutual interaction of some disciplines of engineering, computer science, and cognitive sciences.

Level 1 represents systems that model raw image data using features such as color histogram, shape, and texture descriptors. This model can be used to serve the queries like "find pictures with dominant red color on a white background." Content-based image indexing and retrieval (CBIR) systems based on these models operate directly on the data, employing techniques from the signal processing domain. Level 2 consists of derived or logical features involving some degree of statistical and logical inference about the identity of objects depicted by visual media. An example query at this level can be "find pictures of Eiffel Tower." Using these models, systems normally operate on low-level feature representation, though they can also use image data directly. Level 3 deals with semantic abstractions involving a significant amount of high-level reasoning about the meaning and purpose of the objects or scenes depicted. An example of a query at this level can be "find pictures of laughing children." As indicated at level 3 of the figure, the artificial intelligence (AI) community has had the leading role in this effort. Systems at this level can take semantic representation based on input generated at level 2.

The following subsections explore some of the major building blocks of CBIR-systems.

Low-Level Feature-Based Indexing

Low-level visual feature extraction to describe image content is at the heart of CBIR systems. The features to be extracted can be categorized into general features and domain-specific features. The latter ones may include human faces, fingerprints, and human skin. Feature extraction in the former context, such as from databases that contain images of wide ranging content with images that do not portray any specific topic or theme and come from various sources, is a very challenging job. One possible approach is to perform segmentation first

[7] Bidirectional temporal prediction, denoted as a PB-picture, is obtained by coding two pictures as a group and avoiding the reordering necessary in the decoding of B-pictures.

and then extract visual features from segmented objects. Unconstrained segmentation of an object from the background, however, is often not possible because there generally is no particular object in the image. Therefore, segmentation in such a case is of very limited use as a stage preceding feature extraction. The images thus need to be described as a whole unit, and one should devise feature extraction schemes that do not require segmentation. This restriction excludes a vast number of well-known feature extraction techniques from low-level feature-based representation: all boundary-based methods and many area-based methods. Basic pixel-value-based statistics, possibly combined with edge detection techniques, that reflect the properties of human visual system in discriminating between image patches can be used. Invariance to specific transforms is an issue of interest in feature extraction as well. Feature extraction methods that are global in their nature or perform averaging over the whole image area are often inherently translation invariant. Other types of invariances (e.g., invariance to scaling, rotation, and occlusion) can be obtained with some feature extraction schemes by using proper transformations. Because of the perception subjectivity, there does not exist a single best representation for a given feature. For any given feature, there exist multiple representations that characterize the feature from different perspectives. The main features used in CBIR systems can be categorized into three groups: color features, texture features, and shape features. The following subsections review the importance and implementation of each feature in the context of image content description.

Color

Color is one of the most widely used low-level features in the context of indexing and retrieval based on image content. It is relatively robust to background complication and independent of image size and orientation. Typically, the color of an image is represented through a color model. A color model is specified in terms of a 3-D coordinate system and a subspace in that system where each color is represented by a single point. The more commonly used color models are RGB (red, green, and blue), HSV (hue, saturation, and value), and YIQ (luminance and chrominance). Thus, the color content is characterized by three channels from a color model. One representation of color content of the image is made by using a color histogram. The histogram of a single channel of an image with values in the range $[0, L-1]$ is a discrete function $p(i) = n_i/n$, where i is the value of the pixel in current channel, n_i is the number of pixels in the image with value i, n is the total number of pixels in the image, and $i = 0, 1, 2, \ldots, L-1$. For a three-channel image, there will be three such histograms. The histograms are normally divided into bins in an effort to coarsely represent the content and reduce dimensionality of a subsequent matching phase. A feature vector is then formed by linking the three channel histograms into one vector. For image retrieval, the histogram of a query image is then matched against the histogram of all images in the database using a similarity metric. One similarity metric that can be used in this context is **histogram intersection**. The intersection of histograms h and g is given by:

$$d(h, g) = \frac{\sum_{m=0}^{M-1} \min(h[m], g[m])}{\min\left(\sum_{m0=0}^{M-1} h[m0], \sum_{m1=0}^{M-1} g[m1]\right)}. \tag{6.2}$$

In this metric, colors not present in the user's query image do not contribute to the intersection. Another similarity metric between histograms h and g of two images is **histogram quadratic distance**, which is given by:

$$d(h, g) = \sum_{m0=0}^{M-1} \sum_{m1=0}^{M-1} (h[m0] - g[m0]) a_{m0,m1} \cdot (h[m1] - g[m1]). \tag{6.3}$$

where $a_{m0,m1}$ is the crosscorrelation between histogram bins based on the perceptual similarity of the colors $m0$ and $m1$. One appropriate value for the crosscorrelation is given by:

$$a_{m0,m1} = 1 - d_{m0,m1}, \tag{6.4}$$

where $d_{m0,m1}$ is the distance between colors $m0$ and $m1$ normalized with respect to the maximum distance. **Color moments** have also been applied in image retrieval. The mathematical foundation of this approach is that any color distribution can be characterized by its moments. Furthermore, since most of the information is concentrated in the low-order moments, only the first moment (mean) and the second and third central moments (variance and skewness) can be used for robust and compact color content representation. Weighted Euclidean distance is then used to compute color similarity. To facilitate fast search over large-scale image collections, **color sets** have also been used as approximations to color histograms. The color model used is HSV, and the histograms are further quantized into bins. A color set is defined as a selection of the colors from quantized color space. Because color set feature vectors are binary, a binary search tree is contructed to allow fast search (Smith and Chang, 1996a).

One major drawback of color histogram-based approaches is the lack of explicit spatial information. Specifically, based on global color based representation, it is hard to distinguish between a red car on white background and a bunch of red balloons with a white background. This problem is addressed by Khokhar *et al.* (2000). They have used encoded quadtree spatial data structure to preserve the structural information in the color image. Based on a perceptually uniform color space CIELab*, each image is quantized into k bins to represent k different color groups. A color layout corresponding to pixels of each color in the whole image is formed for each bin and is represented by the corresponding encoded quadtree. This encoded quadtree-based representation not only keeps the spatial information intact but also results in a system that is highly scalable in terms of query search time.

Texture

An image can be considered as a mosaic of regions with different appearances, and the image features associated with these regions can be used for search and retrieval. Although no formal definition of **texture** exists, intuitively this descriptor provides measures of properties such as smoothness, coarseness, and regularity. These properties can generally not be attributed to the presence of any particular color or intensity. Texture corresponds to repetition of basic texture elements called **texels**. A texel consists of several pixels and can be periodic, quasiperiodic, or random in nature. Texture is an innate property of virtually all surfaces, including such elements as clouds, trees, bricks, hair, and fabric. It contains important information about the structural arrangement of surfaces and their relationship to the surrounding environment. The three principal approaches used in practice to describe the texture of a region are statistical, structural, and spectral. **Statistical approaches** yield characterization of textures as smooth, coarse, grainy, and so on. **Structural techniques** deal with the arrangement of image primitives, such as description of texture based on regularly spaced parallel lines. **Spectral techniques** are based on properties of Fourier spectrum and are used primarily to detect global periodicity in an image by identifying high-energy, narrow peaks in the spectrum (Gonzalez, 1992) Haralick *et al.* (1973) proposed the co-occurrence matrix representation of texture feature. This method of texture description is based on the repeated occurrence of some gray-level configuration in the texture; this configuration varies rapidly with distance in fine textures and slowly in coarse textures. This approach explores the gray-level spatial dependence of texture. It first constructs a co-occurrence matrix based on the orientation and distance between image pixels and then extracts meaningful statistics from the matrix as texture representation. Motivated by the psychological studies in human visual perception of texture, Tamura *et al.* (1978) have proposed the texture representation from a different angle. They developed computational approximations to the visual texture properties found to be important in psychology studies. The six visual texture properties are **coarseness, contrast, directionality, linelikeness, regularity**, **and roughness**. One major distinction between the Tamura texture representation and co-occurrence matrix representation is that all the texture properties in Tamura representation are visually meaningful, whereas some of the texture properties used in the co-occurrence matrix representation may not. This characteristic makes Tamura texture representation very attractive in image retrieval because it can provide a friendlier user interface.

The use of texture feature requires texture segmentation, which remains a challenging and computationally intensive task. In addition, texture-based techniques lack robust texture models and correlation with human perception.

Shape

Shape is an important criterion for matching objects based on their profile and physical structure. In image retrieval applications, shape features can be classified into **global** and **local** features. Global features are the properties derived from the entire shape, such as roundness, circularity, central moments, and eccentricity. Local features are those derived by partial processing of a shape, including size and orientation of consecutive boundary segments, points of curvature, corners, and turning angle. Another categorization of shape representation is **boundary-based** and **region-based**. The former uses only the outer boundary of the shape, while the latter uses the entire shape of the region. Fourier descriptors and moment invariants are the most widely used shape representation schemes. The main idea of a Fourier descriptor is to use the Fourier transformed boundary as the shape feature. Moment invariant technique uses region-based moments, which are invariant to transformations, as the shape features. Hu *et al.* (1962) proposed a set of seven invariant moments derived from second and third moments. This set of moments is invariant to translation, rotation, and scale changes. Finite element method (FEM) (Pentland *et al.,* 1996) has also been used as shape representation tool. FEM defines a stiffness matrix that describes how each point on the object is connected to other points. The eigenvectors of the stiffness matrix are called modes and span a feature space. All the shapes are first mapped into this space, and similarity is then computed based on the eigenvalues. Along the similar lines of Fourier descriptors, Arkin *et al.* (1991) developed a Turning function-based approach for comparing both convex and concave polygons.

Spatial Versus Compressed Domain Processing

Given the huge storage requirements of nontextual data, the vast volumes of images are normally stored in compressed form. One approach in CBIR systems is to first decompress the images and transform them into the format used by the system. The default color format used by majority of the CBIR systems is RGB, which is very redundant and unsuitable for storage but very easy to process and use for display. Once the raw image data has been extracted after decompression, any of the content modeling techniques can be applied to yield a representation of the image content for indexing. This process of decompressing the image before content representation poses an overhead in the most likely scenario of more and more image content being stored in compressed form due to the success of image coding standards like JPEG and JPEG-2000. A better approach toward this issue in many of the modern systems is to process compressed domain images as a first class and default medium (i.e., compressed images should be operated upon directly). Since compressed domain representation either has all (if it is a lossless coding scheme) or most of the important (if it is a lossy scheme, depending on the quantization setting in the encoder) image information intact, indexing based on image content can be performed from minimal decoding of compressed images.

Discrete cosine transform (DCT) is at the heart of the JPEG still-image compression standard and many of the video compression standards, like MPEG-1, MPEG-2, and H.261. Shen and Sethi (1996) have used DCT coefficients of encoded blocks to mark areas of interest in the image. This distinction can be used to give more preference to these areas when processing the image for content representation. Locations of areas of interest are those parts of the image that show sufficiently large intensity changes. This is achieved by computing the variance of pixels in a rectangular window around the current pixel. In the DCT domain, this translates to computing the ac energy according to the relationship:

$$E = \sum_{u=0}^{7} \sum_{v=0}^{7} F_{uv}^{2} \quad (u, v) \neq (0, 0), \tag{6.5}$$

where F_{uv} stands for ac coefficients in the block and where the encoded block is 8×8 as in image/video coding standards. Shen and Sethi (1996) also propose fast coarse-edge detection techniques using DCT coefficients. A comparison of their approach with edge detection techniques in spatial domain speaks in favor of DCT coefficients based-edge detection because a coarse representation of edges is quite sufficient for content description purposes.

Because image coding and indexing are quite overlapping processes in terms of storage and searching, one approach is to unify the two problems in a single framework. There has been a recent shift in trends in terms of transformation used for frequency domain processing, from DCT to discrete wavelet transform (DWT) because of DWT's time frequency and multiresolution analysis nature. DWT has been incorporated in modern image and video compression standards like JPEG-2000 and MPEG-4. One such system that uses DWT for compression and indexing of images is proposed in Liang *et al.* (1999). The wavelet-based image encoding techniques depend on successive approximate quantization (SAQ) of wavelet coefficients in different subbands from wavelet decomposition. The image indexing from DWT encoded image is mainly based on significant coefficients in each subband. Significant coefficients in each sub band are recognized as the ones whose magnitude is greater than a certain threshold, which is different at each decomposition level. The initial threshold is chosen to be half the maximum magnitude at first decomposition level, whereas successive thresholds are given by dividing the threshold at a previous decomposition level by 2. During the coding process, a binary map called significant map is maintained so the coder knows the location of significant as well as insignificant coefficients. To index texture, a two-bin histogram of a wavelet coefficient at each sub band is formed with the count of significant and insignificant wavelet coefficients in the two bins. For color content representation, YUV color space is used. A nonuniform histogram of 12 bins containing count of significant coefficients given each of the 12 thresholds is computed for each color channel. This way, three 12-bin histograms are computed for luminance (Y) and chrominance (U and V) channels. For each of the histograms, first-, second-, and third-order moments (mean, variance, and skewness) are computed and used as indexing features for color.

Segmentation

Most of the existing techniques in current CBIR systems depend heavily on a low-level feature-based description of image content. Most existing approaches represent images based only on their composition with little regard to spatial organization of the low-level features. On the other hand, users of the CBIR systems often would like to find images containing particular objects ("things"). This gap between low-level description of the image content and the object images represent can be filled by performing segmentation on images to be indexed. Segmentation subdivides an image into its constituent parts or objects. Segmentation algorithms for monochrome images generally are based on one of two basic properties of gray-level values: **discontinuity** and **similarity**. In the first category, the approach is to partition an image based on abrupt changes in gray level. The principal areas of interest in this category are detection of isolated points and detection of lines and edges in an image. The principal approaches in the second category are based on thresholding, region growing, and region splitting and merging. The Blob-World system proposed by Carson *et al.* (1997) is based on segmentation using the expectation–maximization algorithm on combined color and texture features. It represents the image as a small set of localized coherent regions in color and texture spaces. After segmenting the image into small regions, a description of each region's color, texture, and spatial characteristics is produced. Each image may be visualized by an ensemble of 2-D ellipses or "blobs," each of which possesses a number of attributes. The number of blobs in an image is not very overwhelming to facilitate fast image retrieval applications and is typically less than ten. Each blob represents a region on the image that is roughly homogeneous with respect to color or texture. A blob is described by its dominant color, mean texture descriptors, spatial centroid, and scatter matrix. The exact retrieval process is then performed on the blobs in a query image. On similar lines but in domain-specific context, Iqbal and Aggarwal (1999) apply perceptual grouping to develop a CBIR system for images containing buildings. In their work, semantic interrelationships between different primitive image features are exploited by perceptual grouping to detect presence of man-made structures. Perceptual grouping uses concepts as grouping by proximity, similarity, continuation, closure, and symmetry to organize primitive image features into meaningful higher level image relations. The approach is based on the observation that the presence of a man-made structure in an image will generate a large number of significant edges, junctions, parallel lines, and groups in comparison with an image of predominantly nonbuilding objects. These structures are generated by the presence of corners, windows, doors, and boundaries of the buildings, for example. The features they extract from an image are hierarchical in nature and include **line segments**, **longer linear lines**, **L junctions**, **U junctions**, **parallel lines**, **parallel groups**, and **significant parallel groups**.

Most of the segmentation methods discussed in image processing and analysis literature are automatic. A major advantage of this type of segmentation algorithms is that it can extract boundaries from a large number of images without occupying the user's time and effort. However, in an unconstrained domain, for nonpreconditioned images, which is the case with image CBIR systems, the automatic segmentation is not always reliable. What an algorithm can segment in this case is only regions and not objects. To obtain high-level objects, human assistance is almost always needed for reliable segmentation.

High-Dimensionality and Dimension Reduction

It is obvious from the discussion thus far that content-based image retrieval is a high-dimensional feature vector-matching problem. To make the systems truly scalable to large size image collections, two factors should be considered. First, the dimensionality of the feature space needs to be reduced to achieve the embedded dimension. Second, efficient and scalable multidimensional indexing techniques need to be adapted to index the reduced but still high-dimensional feature space. In the context of dimensionality reduction, a transformation of the original data set using the Karhunen-Loeve transform (KLT) can be used. KLT features data-dependent basis functions obtained from a given data set and achieves the theoretical ideal in terms of compressing the data set. An approximation to KLT given by principal component analysis (PCA) gives a very practical solution to the computationally intensive process of KLT. PCA, introduced by Pearson in 1901 and developed independently by Hotelling in 1933, is probably the oldest and best known of the techniques of multivariate analysis. The central idea of PCA is to reduce the dimensionality of a data set in which there are a large number of interrelated variables while retaining as much as possible of the variation present in the data set. This reduction is achieved by transforming to a new set of variables, the principal components (PCs), that are uncorrelated and ordered so the first few retain most of the variation present in *all* of the original variables. Computation of the principal components reduces to the solution of an eigenvalue–eigenvector problem for a positive–semidefinite symmetric matrix. Given that x is a vector of p random variables, the first step in a PCA evaluation is to look for a linear function $\alpha_1^{'}x$ of the elements of x that have maximum variance, where α_1 is a vector of p constants $\alpha_{11}, \alpha_{12} \ldots \alpha_{1_p}$. Next, look for a linear function $\alpha_2^{'}x$, uncorrelated with $\alpha_1^{'}x$, which has maximum variance and so on. The kth derived variable $\alpha_k^{'}x$ is the kth PC. Up to p PCs can be found, but in general most of the variation in x can be accounted for by m PCs, where $m \ll p$. If the vector x has known covariance matrix Σ, then the kth PC is given by an orthonormal linear transformation of x as $y_k = \alpha_k^{'}x$, where α_k is an eigenvector of Σ corresponding to its kth largest eigenvalue λ_k. Consider an orthogonal matrix Φ_q with α_k as the kth column and containing $q \ll p$ columns corresponding to q PCs; it can be shown that for the transformation $y = \Phi_q x$, the determinant of covariance matrix for transformed data set y, det (Σ_y) is maximized. The statistical importance of this property follows because the determinant of a covariance matrix, which is called the **generalized variance** can be used as a single measure of spread for a multivariate random variable. The square root of the generalized variance for a multivariate normal distribution is proportional to the *volume* in p-dimensional space, which encloses a fixed proportion of the probability distribution of x. For a multivariate normal x, the first q PCs are therefore q linear functions of x whose joint probability distribution has contours of fixed probability that enclose the maximum volume (Joliffe, 1986). If the data vector x is normalized by its variance and autocorrelation matrix instead of covariance matrix is used, then above mentioned optimality property and derivation of PCs still hold. For the efficient computation of PCs, at least in context of PCA rather than general eigenvalue problems, singular value decomposition (SVD) has been termed as the best approach available (Chambers, 1997).

Even after the dimension of the data set has been reduced, the data set is still almost always fairly high-dimensional. There have been contributions from three major research communities in this direction: computational geometry, database management, and pattern recognition. The history of multidimensional indexing techniques can be tracked back to middle 1970s when cell methods, quadtree and k-d tree were first introduced. However, their performance was far from satisfactory. Pushed by the then urgent demand of spatial indexing from GIS and CAD systems, Guttman proposed the R-tree indexing structure in 1984. Some good reviews of various indexing techniques in the context of image retrieval can be found in (White and Jain, 1996). Khokhar *et al.* (1999) have dealt with the feature vector formation and its efficient indexing as one problem and suggest a solution in which query response time is relatively independent of the database size. They exploited energy compaction properties of the vector wavelets and designed suitable data structures for fast indexing and retrieval mechanisms.

Relevance Feedback

The problem of content-based image retrieval is different than the conventional computer vision-based pattern recognition task. The fundamental difference between the two is that in the latter, we **are looking for exact match for the object to be searched with as small and as accurate a retrieved list as possible**. But in the former, the goal is to extract as many "similar" objects as possible, the notion of similarity being very loose as compared to the notion of exact match. Moreover, the human user is the indispensable part in the former. Early literature and CBIR systems emphasized fully automatic operation. This approach did not take into account the fact that the ultimate end user of the CBIR system is human, and the image is inherently a subjective medium (i.e., the perception of image content is very subjective, and the same content can be interpreted differently by users having different search criteria). This human perception subjectivity has different levels to it: one user might be more interested in a different dominant feature of the image than the other, or two users might be interested in the same feature (e.g., texture), but the perception of a specific texture might be different for the two users. Recent drive is oriented more toward how humans perceive image content and how to integrate such a "human model" into the image retrieval systems. Rui *et al.* (1998) have reported a formal model of a CBIR system with relevance feedback integrated into it. They first initialized a retrieval system with uniformly distributed weights for each feature. Then user's information need is distributed among all the features. The similarity is then computed on the basis of weights by user's input, and retrieval results are displayed to the user. The user marks each retrieved result as **highly relevant, relevant, no-opinion, irrelevant**, and **highly irrelevant** according to his or her information needs and perception subjectivity. The system updates its weights and goes back into the loop.

CBIR Systems: Query By Image Content

The field of content-based indexing and retrieval has been an active area of research for the past few decades. The research effort that has gone into development of techniques for this problem has led to some very successful systems currently available as commercial products as well as other research systems available for the academic community. Some of these CBIR systems include Virage (Bach *et al.*, 1996), Netra (Ma and Manjunath, 1997), PhotoBook (Pentland *et al.*, 1996), VisualSeek (Smith and Chang, 1996b), WebSeek (Smith and Chang, 1997), MARS (Mehrotra *et al.*, 1997), and BlobWorld (Carson *et al.*, 1997). A comparative study of many of the CBIR systems can be found in (Venters and Cooper, 2000). This section, for illustrative purposes, reviews one example of a commercial CBIR system known as Query By Image Content (QBIC).

QBIC is the first commercial content-based image retrieval system. Developed by IBM Almaden Research Centre, it is an open framework technology that can be used for both static and dynamic image retrieval. QBIC has undergone several iterations since it was first reported (Niblack *et al.*, 1998). QBIC allows users to graphically pose and refine queries based on multiple visual properties, including color, shape, and texture. QBIC supports several query types: simple, multifeature, and multipass. A simple query involves only one feature. For example, identifying images that have a color distribution similar to the query image can involve a complex query with more than one feature, which can take the form of a multifeature or a multi-pass query. For identifying images that have similar color and texture features, a multifeature query would be possible and involve the system searching through the different types of feature data in the database to identify similar images. All feature classes would have equal weightings during the search, and all feature tables would be searched in parallel. In contrast, with a multipass query, the output of an initial search would be used as the basis for the next search. The system would reorganize the search results from a previous pass based on the "feature distances" in the current pass. For example, a user could identify images that have a similar color distribution and then reorder the results based on color composition. With multifeature and multipass queries, users can weight features to specify their relative importance. QBIC technology has been incorporated into several IBM software products, including DB2 Image Extender and Digital Library. QBIC supports several matching features, including color, shape, and texture. The global color function computes the average RGB colors in the entire image for both the dominant color and the variation of color throughout the entire image. Similarity is based on the three average color values. The local color function computes the color distribution for both the dominant color and the variation for each image in a predetermined 256 color space. Image similarity is based on the similarity of the color distribution. The shape function analyzes images for combinations of area, circularity, eccentricity, and major axis orientation. All shapes are assumed to be nonoccluded planar shapes, allowing each shape to be represented as a binary image. The texture function analyzes areas for global coarseness, contrast, and directionality features.

6.3.2 Video Indexing and Retrieval

When compared with content-based image indexing and retrieval, which has been an active area of research since the 1970s, the field of content-based access to video repositories is still gaining due attention. As discussed at the beginning of subsection 6.3.1, human visual perception displays a gradient of sophistication, ranging from seemingly primitive inferences (e.g., shapes, textures, and colors) to complex notions of structures (e.g., chairs, trees, and affordances) to cognitive processes (e.g., recognition of emotions and feelings). Given the multidisciplinary nature of the techniques for modeling, indexing, and retrieving visual data, efforts from many different communities have merged in the advancement of content-based video indexing and retrieval (CBVIR) systems. Depending on the background of the research teams, different levels of abstractions have been assumed to model the data. As shown in Figure 6.7, we classify these abstractions into three categories based on the gradient model of human visual perception specifically in the context of CBVIR systems. In this figure, we also capture the mutual interaction of some of the disciplines of engineering, computer science, and cognitive sciences.

Level 1 represents systems that model raw video data using features such as color histogram, shape and texture descriptors, or trajectory of objects. This model can be used to serve a query like "shots of object with dominant red color moving from left corner to right." CBVIR systems based on these models operate directly on the data, employing techniques from signal processing domain. Level 2 consists of derived or logical features involving some degree of statistical and logical inference about the identity of objects depicted by visual media. An example query at this level can be "shots of Sears Tower." Using these models, systems normally operate on low-level feature representation, though they can also use video data directly. Level 3 deals with semantic abstractions involving a significant amount of high-level reasoning about the meaning and purpose of the objects or scenes depicted. An example of a query at this level can be "shots depicting human suffering or sorrow." As indicated at level 3 of the figure, the AI community has had the leading role in this effort. Systems at this level can take semantic representation based on input generated at level 2.

Despite the diversity in modeling and application of CBVIR systems, most systems usually rely on similar video processing modules. The following subsections explore some of the broad classes of modules typically used in a content-based video indexing and retrieval system.

Temporal Segmentation

Video data can be viewed hierarchically. At the lowest level, video data is made up of **frames**; a collection of frames that result from single camera operation depicting one event is called a **shot**, and a complete unit of narration that consists of a series of shots or a single shot taking place in a single location and dealing with a single action defines a **scene** (Monaco, 1977). CBVIR systems rely on the visual content at distinct hierarchical levels of the video data. Although the basic representation of raw video is provided in terms of a sequence of frames, the detection of distinct shots and scenes is a complex task.

Transitions or boundaries between shots can be abrupt (cut) or they can be gradual (fade, dissolve, and wipe). Traditional temporal segmentation techniques have focused on cut detec-

tion, but there has been increasing research activity on gradual shot boundary detection as well. Most of the existing techniques reported in the literature detect shot boundary by extracting some form of feature for each frame in the video sequence, then evaluating a similarity measure on features extracted from successive pairs of frames in the video sequence, and finally declaring the detection of a shot boundary if the features difference conveyed by the similarity measure exceeds a threshold. One such approach is presented in (Naphade *et al.*, 1998a) in which two difference metrics, histogram distance metric (HDM) and spatial distance metric (SDM), are computed for every frame pair. HDM is defined in terms of three-channel linearized histograms computed for successive frame pair f_i and f_{i+1} as follows:

$$D_h(f_i, f_{i+1}) = \frac{1}{M \times N} \sum_{j=1}^{256x3} |H_i(j) - H_{i+1}(j)|, \qquad (6.6)$$

where H_i represents the histogram of frame f_i and $M \times N$ is the dimension of each frame. For each histogram, 256 uniform quantization levels for each channel are considered. SDM is defined in terms of the difference in intensity levels between successive frames at each pixel location. Let $I_{i,j}(f_k)$ denote the intensity of a pixel at location (i,j) in the frame f_k, and then the spatial distance operator is defined as:

$$d_{i,j}(f_k, f_{k+1}) = \begin{cases} 1 \cdots, |I_{i,j}(f_k) - I_{i,j}(f_{k+1})| > \varepsilon. \\ 0 \cdots, \mathit{otherwise}. \end{cases} \qquad (6.7)$$

SDM is then computed as follows:

$$D_s(f_k, f_{k+1}) = \frac{1}{M \times N} \sum_{i=1}^{M} \sum_{j=1}^{N} d_{i,j}(f_k, f_{k+1}). \qquad (6.8)$$

These two distances are then treated as a 2-D feature vector, and an unsupervised *K*-means clustering algorithm is used to group shot boundaries into one cluster. For a review of major conventional shot boundary detection techniques, refer to Borecsky and Rowe (1996), which also provides a comparison between five different techniques based on pixel difference from raw data, DCT coefficients difference, and motion-compensated difference. Due to the huge amount of data to be processed in the case of full-frame pixel difference-based methods as well as data's susceptibility to intensity differences caused by motion, illumination changes, and noise, many novel techniques (beyond the scope of the review presented in Borecsky and Rowe, 1996), have been proposed in both the compressed as well as uncompressed domain. We shall now present a brief overview of some of the recent advances in shot detection.

Porter *et al.* (2000) proposed a frequency domain correlation approach. This approach relies on motion estimation information obtained by use of template matching; that is, for each 32 × 32 block in a given frame, the best matching block in a corresponding neighborhood in the next frame is sought by calculating the normalized crosscorrelation in the frequency domain as:

$$\rho(\varepsilon) = \frac{F^{-1}\left\{\hat{x}_1(\bar{\omega}) \times \overset{*}{\hat{x}}_2(\bar{\omega})\right\}}{\sqrt{\int |\hat{x}_1(\bar{\omega})|^2 d\bar{\omega} \cdot \int |\hat{x}_2(\bar{\omega})|^2 d\bar{\omega}}}, \quad (6.9)$$

where ε and $\bar{\omega}$ are the spatial and frequency coordinate vectors, respectively, $\hat{x}_i(\bar{\omega})$ denotes the Fourier transform of frame $x_i(\varepsilon)$, F^{-1} denotes the inverse Fourier transform operation, and * is the complex conjugate. Next, the mean and standard deviation of the correlation peaks for each block in the whole image are calculated, and the peaks beyond one standard deviation away from the mean are discarded, thus making the technique more robust to sudden local changes in a small portion of the frame. An average mean is then computed from this pruned data. This average match measure is compared to the average match of the previous pair, and a shot boundary is declared if there is a significant decrease in this similarity match feature.

A novel approach proposed by Liu and Chen (2002) argues that at the shot boundary, the contents of new shot differ from contents of the whole previous shot instead of just the previous frame. They proposed a generic and recursive principal component analysis-based approach that can be built on any feature extracted from frames in a shot and that generates a model of the shot trained from features in previous frames. Features from the current frame are extracted, and a shot boundary is declared if the features from the current frame do not match the existing model by projecting the current feature onto the existing eigenspace.

In an effort to cut back on the huge amount of data available for processing and to emphasize the fact that in video shots, while objects may appear or disappear, the background stays much the same and follows the camera motion in one shot, Oh *et al.* (2000) have proposed a background tracking (BGT) approach. A strip along the top, left, and right borders of the frame, covering around 20% of frame area, is taken as a fixed background area (FBA). A signature 1-D vector called transformed background area (TBA) formed from the Gaussian pyramid representation of the FBA is computed. Background tracking is achieved by a 1-D correlation matching between two TBAs obtained from successive frames. Shot detection is declared if the background tracking fails as characterized by a decrease in the correlation matching parameter. This approach has been reported to detect and classify both abrupt and gradual scene changes.

Observing the fact that single features cannot be used accurately in a wide variety of situations, Chen *et al.* (2004) have proposed to construct a high-dimensional feature vector called generalized trace (GT) by extracting a set of features from each dc frame. For each frame, GT contains the number of intracoded as well as forward- and backward-predicted macroblocks; a histogram intersection of current and previous frames for Y, U, and V color components; and a standard deviation of Y, U, and V components for the current frame. GT is then used in a binary regression tree to determine the probability that each frame is a shot boundary. These probabilities are used to determine the frames that most likely correspond to the shot boundary.

Hanjalic (2002) has put together a nice analysis of the shot boundary detection problem itself, identifying major issues that need to be considered and creating a conceptual solution to the problem in the form of a statistical detector based on minimization of average detection–error probability. The thresholds used in their system are defined at the lower level modules of the detector system. The decision making about the presence of a shot boundary is left solely to a parameter-free detector, where all of the indications coming from different low-level modules are combined and evaluated.

Lelescu and Schonfeld (2000, 2003) presented a scene change detection method using stochastic sequential analysis theory. The dc data from each frame are processed using PCA to generate a very low-dimensional feature vector Y_k corresponding to each frame. These feature vectors are assumed to form an independant identically distributed (*i.i.d*) sequence of multidimensional random vectors having Gaussian distribution. Scene change is then modeled as change in the mean parameter of this distribution. Scene change detection is formulated as a hypothesis testing problem, and the solution is provided in terms of a threshold on a generalized likelihood ratio. Scene change is declared at frame k when the maximum value of the sufficient statistic g_k evaluated over frame interval j to k exceeds the threshold:

$$g_k = \max_{1 \le j \le k} \left\{ \frac{k - j + 1}{2} (X_j^k)^2 \right\}. \quad (6.10)$$

Here X_j^k is defined as:

$$X_j^k = \left[(\bar{Y}_j^k - \Theta_0)^T \Sigma^{-1} (\bar{Y}_j^k - \Theta_0) \right]^{1/2}. \quad (6.11)$$

In this expression, $\bar{Y}_j^k$ is the mean of feature vectors Y in the current frame interval j to k, and Θ_0 is the mean of Y in an initial training set frame interval consisting of M frames. This approach, which is free from human fine-tuning, has been reported to perform equally well for both abrupt and gradual scene changes.

Video Summarization

Once a video clip has been segmented into atomic units based on visual content coherence, the next step is to compactly represent the individual units. This task is the major block in summarizing video content using a table of contents approach. This step also facilitates efficient matching between two shots at query time for content-based retrieval. Most existing systems represent video content by using one representative frame from the shot called a **keyframe**. Keyframe-based representation has been recognized as an important research issue in content-based video abstraction. The simplest approach for this problem is to use the first frame of each shot as a keyframe (Nagasaka and Tanaka, 1992). Although the approach is simple, it is limited because each shot is allotted only one frame for its representation irrespective of the complexity of the shot content. In addition, the choice of the first frame over other frames in the shot is arbitrary. To have more flexibility in keyframe-based representation of a video shot, Zhang *et al.* (1997) proposed to use multiple frames to represent each shot. They used criteria such as color content change and zoom-in type of effects in shot content to decide on the keyframes for each shot. A technique for shot content representation and similarity measure using subshot extraction and representation is presented in Lin *et al.* (2001). This approach uses two content descriptors, dominant color histogram (DCH) and spatial structure histogram (SSH), to measure content variation and to represent subshots. The quantized hue, saturation, and value (HSV) color histogram are First Computed for each frame. Next, the dominant local maxima positions in each frame's histogram are identified and tracked throughout the shot. After tracking, only the colors with longer durations are retained as dominant colors of the shot. Histogram bins are finally weighted by the duration of each bin in the whole shot. SSH is computed based on spatial information of color blobs. For each blob, histograms are computed for the area, position, and deviation.

Delp *et al.* (2001) represented a shot using a tree structure called a **shot tree**. This tree is formed by an agglomerative clustering technique performed on individual frames in a shot. Starting at the lowest level with each frame representing a cluster, the algorithm iteratively combines the two most similar frames at a particular level into one cluster at the next higher level. The process continues until a single cluster represented by one frame for the whole shot is obtained. This approach unifies the problem of scene content representation for both browsing and similarity matching. For browsing, only the root node of the tree (keyframe) is used, whereas for similarity matching, two or three levels of tree can be used, employing standard tree matching algorithms.

Another approach to video summarization based on a low-resolution video clip has been proposed by Lelescu and Schonfeld (2001). In this approach, a low-resolution video clip is provided by an efficient representation of the dc frames of the video shot using an iterative algorithm for the computation of PCA. Efficient representation of the dc frames is obtained by their projection onto the eigenspace characterized by the dominant eigenvectors for the video shot. The eigenvectors obtained by PCA can also be used for conventional keyframe representation of the video shot by considering the similarity of frames in the video shot to the eigenvectors with the largest eigenvalues.

Compensation for Camera and Background Movement

The motion content in a video sequence is the result of either camera motion (e.g., pan, zoom, or tilt) or object and background motion. **Panning motion** of a camera is defined as rotation along the horizontal axis, whereas **tilt** is rotation along the vertical axis. The major concern in motion content-based video indexing and retrieval is almost always the object's motion and not the camera effects. This is because while querying video indexing and retrieval systems, users tend to be more interested in the maneuvering of the objects in the scene and not the way camera is being tilted, rotated, or zoomed with respect to the object. The problem is that the true motion of the object cannot be assessed unless the camera motion is compensated for. This problem always arises in case of a video of a moving object recorded with a mobile camera. Similarly, quite often there is object motion as well as background movement in the video sequence. In such cases, background movement needs to be differentiated from object movement to give the true object motion. Once these motions have been separated, the object trajectory can be obtained and video data can be indexed based on this motion cue along with other features.

Oh and Chowdary (2002) expressed different motions accurately by estimating motions from the camera and object. First, the total motion (TM) in a shot is measured. This is achieved by computing the accumulated quantized pixel differences on all pairs of frames in the shot. Before computing pixel differences, the color at each pixel location is quantized into 32 bins to reduce the effect of noise. Once the total motion has been estimated, each frame in the shot is checked for the presence of camera motion. If pan and tilt of camera, are present, the amount and direction of camera motion are computed. Object motion (OM) is computed by a technique similar to the computation of TM, such as after compensation of camera motion. Bouthemy *et al.* (1999) addressed the problem of shot change detection as well as camera motion estimation in a single framework. The two objectives are met by computing, at each time instant, the dominant motion in the image sequence represented by a 2-D affine motion model. From each frame pair in the video sequence, a statistical module estimates the motion model parameters and the support for motion (i.e., the area of motion) in the successive frame. A least-squares motion estimation module then computes the confidence of the motion model and maps significant motion parameters onto predefined camera motion classes. These classes include pan, tilt, zoom, and many combinations.

Feature-Based Modeling

Most of the focus on the problems of content-based video indexing from the signal processing community concern the modeling of visual content by using low-level features. Since video is formed by a collection of images, most of the techniques that model visual content rely on extracting image-like features from the video sequence. Visual features can be extracted from keyframes or the sequence of frames after the video sequence has been segmented into shots. This section analyzes different low-level features used to represent the visual content of a video shot.

Temporal Motion Features

Video is a medium that is very rich in dynamic content. Motion stands out as the most distinguishing feature for indexing video data. Motion cue is hard to extract since computation of the motion trail often involves generation of optical flow. The problem of computing optical flow between successive frames of the image sequence is recognized to be computationally intensive, so few systems use motion cue to a full extent. The optical flow represents a 2-D field of instantaneous velocities corresponding to each pixel in the image sequence. Instead of computing the flow directly on image brightness values, it is also possible to first process the raw image sequence for contrast, entropy, or spatial derivatives. The computation of optical flow can then be performed on these transformed pixel brightness values instead of on the original images in an effort to reduce the computational overhead. In either case, a relatively dense flow field is obtained at each pixel in the image sequence. Another approach to estimating object motion in the scene can be performed by using a feature-matching based method. This approach involves computation of relatively sparse but highly discriminatory features in a frame. The features can be points, lines, or curves and are extracted from each frame of the video sequence. Interframe correspondence is then established between these features to compute the motion parameters in the video sequence.

Pioneering work in using motion to describe video object activity has been presented by Dimitrova and Golshani (1995) in their use of macroblock tracing and clustering to derive trajectories and their computation of similarity between these raw trajectories. In Dimitrova and Golshani (1994), a three-level motion analysis methodology has been proposed. Starting from extracting the trajectory of a macroblock in an MPEG video, followed by averaging all trajectories of the macroblocks of objects, and finally estimating the relative position and timing information among objects, a dual hierarchy of spatio-temporal logic is established for representing video. More recently, Schonfeld and Lelescu (2000) developed a video tracking and retrieval system know as *VORTEX*. In this system, a bounding box is used to track an object throughout the compressed video stream. This is accomplished by exploiting the motion vector information embedded in the coded video bit stream. A k-means clustering of the motion vectors is used to avoid occlusions. Schonfeld *et al.* (2003) presented an extension of this approach. After initial segmentation of the object contour, they used an adaptive block matching process to predict the object contour in successive image sequences.

Further research has also been devoted to the indexing and retrieval of object trajectories. One such system that makes use of low-level features extracted from objects in the video sequence with particular emphasis on object motion is VideoQ (Chang *et al.*, 1998). Once the object trajectory has been extracted, modeling of this motion trail is essential for indexing and retrieval applications. A trajectory in this sense is a set of *2-tuples* $\{(x_k, y_k)\colon k = 1, \ldots, N\}$, where (x_k, y_k) is the location of the object's centroid in the kth frame, and the object has been tracked for a total of N frames. The trajectory is treated as separable in its x and y-coordinates, and the two are processed separately as 1-D signals. VideoQ models object trajectory based on physical features like acceleration, velocity, and arc length. In this approach, the trajectory is first segmented into smaller units called subtrajectories. The motivation of this is two-fold. First, modeling of full object trajectories can be very computationally intensive. Second, there might be many scenarios in which a part of the object trajectory is not available due to occlusion. Moreover, the user might be interested in certain partial movements of the objects. Physical feature-based modeling is used to index each subtrajectory using acceleration and velocity, for example. These features are extracted from the original subtrajectory by fitting it with a second-order polynomial as in the following equation:

$$\begin{aligned} r(t) &= (x(t), y(t)) = 0.5at^2 + v_0 t, \\ a &= (a_x, a_y) = \text{acceleration},\ v_0 = (v_x, v_y) = \text{velocity}, \end{aligned} \tag{6.12}$$

where *r(t)* is the parametric representation of the object trajectory.

Spatial Image Features

Low-level image representation features can be extracted from keyframes in an effort to efficiently model the visual content. At this level, any of the techniques from representation of image indexing schemes can be used. The obvious candidates for feature space are color, texture, and shape. Thus, features used to represent video data have conventionally been the same ones used for images, extracted from keyframes of the video sequence, with additional motion features used to capture temporal aspects of video data. Nephade *et al.* (1998) first segmented the video spatiotemporally obtaining regions in each shot. According to their experiments, each region is then processed for feature extraction. A linearized HSV histogram is used that has 12 bins per channel as the color feature.

The HSV color space is used because it is perceptually closer to human vision as compared to the RGB space. The three histograms corresponding to the three channels (hue, saturation, and value) are then combined into one vector of dimension 36. Texture is represented by gray-level co-occurrence matrices at four orientations. Shape is captured by moment invariants. A similar approach proposed by Shih-Fu Chang *et al.* (1998) uses quantized CIE–LUV space as the color feature, three Tamura texture measures (coarseness, contrast, and orientation) as texture feature, and shape components and motion vectors. All these features are extracted from objects detected and tracked in video sequence after spatiotemporal segmentation.

High-Level Semantic Modeling

As pointed out earlier, high-level indexing and retrieval of visual information, as depicted at level 2 or level 3 in Figure 6.1, requires semantic analysis that is beyond the scope of many of the low-level feature-based techniques. One important consideration that many existing content modeling schemes overlook is the importance of the multimodal nature of video data composed of a sequence of images along with associated audio and, in many cases, textual captions. Fusing data from multiple modalities improves the overall performance of the system. Many of the content modeling schemes based on low-level features work on a query by example (QBE) paradigm in which the user is required to submit a video clip or an image illustrating the desired visual features. At times, this constraint becomes prohibitive when an example video clip or image depicting what the person is seeking is not at hand. Query by keyword (QBK) offers an alternative to QBE in the high-level semantic representation. In this scenario, a single keyword or a combination of many can be used to search through the video database. This requires more sophisticated indexing, however, because keywords summarizing the video content need to be generated during the indexing stage. This capability can be achieved by incorporating knowledge base into video indexing and retrieval systems. There has been a drive toward incorporating intelligence into CBVIR systems, and intelligence-based ideas and systems will be covered in this section. Modeling video data and designing semantic reasoning-based video database management systems (VDBMSs) facilitate high-level querying and manipulating of video data. A prominent issue associated with this domain is the development of formal techniques for semantic modeling of multimedia information. Another problem in this context is the design of powerful indexing, searching, and organization methods for multimedia data.

Multimodal Probabilistic Frameworks

Multimedia indexing and retrieval presents a challenging task of developing algorithms that fuse information from multiple media to support queries. Content modeling schemes operating in this domain have to bridge the gap between low-level features and high-level semantics often called the **semantic gap**. This effort has to take into account the information from audio as well as from video sources. Naphade *et al.* (1998b) have proposed the concept of **Multiject**, a multimedia object. A Multiject is the high-level representation of a certain object, event, or site having features from audio as well as from video. It has a semantic label, that describes the object in words. It also has associated multimodal features (including both audio and video features) that represent its physical appearance. Multiject also has an associated probability of occurrence in conjunction with other objects in the same domain (shot). Experiments using Multiject concepts from three main categories of objects (e.g., airplane), sites (e.g., indoor), and events (e.g., gunshot) have been conducted. Given the multimodal feature vector $\vec{X}_j$ of the jth frame and assuming uniform priors on the presence or absence of any concept in any region, the probability of occurrence of each concept in the jth frame is obtained from Bayes' rule as:

$$P(R_{ij} = 1|\vec{X}_j) = \frac{P(\vec{X}_j|R_{ij} = 1)}{P(\vec{X}_j|R_{ij} = 1) + P(\vec{X}_j|R_{ij} = 0)}, \qquad (6.13)$$

where R_{ij} is a binary random variable taking value 1 if the concept i is present in frame j. During the training phase, the identified concepts are given labels, and the corresponding Multiject consists of a label along with its probability of occurrence and multimodal feature vector. Multijects are then integrated at the frame level by defining frame level features F_i, $i \in \{1 \ldots N\}$ (N is the number of concepts the system is being trained for) in the same way they are for R_{ij}. If M is the number of regions in the current frame, then given $\chi = \{\vec{X}_1, \ldots \vec{X}_M\}$, the conditional probability of Multiject i being present in any region in the current frame is:

$$P(F_i = 1|\chi) = \max_{j \in \{1, \ldots, M\}} P(R_{ij} = 1|\vec{X}_j). \qquad (6.14)$$

Observing the fact that semantic concepts in videos do not appear in isolation but rather interact and appear in context, their interaction is modeled explicitly, and a network of multijects, called **Multinet**, was proposed (Naphade *et al.*, 2002). This framework based on Multinet takes into account the fact that presence of some multijects in a scene boosts the detection of other semantically related multijects and reduces the chances for detection of others. Based on this Multinet framework, spatiotemporal constraints can be imposed to enhance detection, support inference, and impose a priori information.

Intelligence-Based Systems

The next step toward future CBVIR systems will be marked by the introduction of intelligence into the systems as they need to be capable of communicating with the user, understanding audio–visual content at a higher semantic level, and reasoning and planning at a human level. **Intelligence** is referred to as the capabilities of the system to build and maintain situational or world models, use dynamic knowledge representation, exploit context, and leverage advanced reasoning and learning capabilities. Insight into human intelligence can help designers to better understand users of CBVIR systems and construct more intelligent systems. Benitez *et al.* (2000) proposed an intelligent information system framework known as **MediaNet** that incorporates both perceptual and conceptual representations of knowledge based on multimedia information in a single framework. MediaNet accomplishes this by augmenting the standard knowledge representation frameworks with the capacity to include data from multiple media. It models the real world by concepts, which are real-world entities and relationships between those concepts that can be either semantic (car Is-A-Subtype-Of vehicles) or perceptual (donkey Is-Similar-To mule). In MediaNet, concepts can be as diverse-natured as living entities (humans), inanimate objects (cars), events in the real world (explosions), or certain property (blue). Media representation of the concepts involves data from heterogeneous sources. Multimodal data from all such sources is combined using the framework that intelligently captures the relationships between its various entities.

Semantic Modeling and Querying of Video Data

Owing to its distinguished characteristics from textual or image data—very rich information content, temporal as well as spatial dimensions, unstructured organization, massive volume, and complex and ill-defined relationship among entities—robust video data modeling is an active area of research. The most important issue that arises in the design of video database management systems (VDBMSs) is the description of video data structure in a form that is appropriate for querying, that is sufficiently easy for updating, and that is compact enough for capturing the rich information content of the video. The process of designing the high-level abstraction of raw video facilitates various information retrieval and manipulation operations is the crux of VDBMSs. To this end, current semantic-based approaches can be classified into **segmentation-based** and **stratification-based**. The drawback of the former approaches is lack of flexibility and incapability of representing semantics residing in overlapping segments. The latter models, however, segment contextual information of video instead of simply partitioning it.

SemVideo (Tran *et al.*, 2000) presents a video model in which semantic content having unrelated time information is modeled as one that does; moreover, not only is the temporal feature used for semantic descriptions but the temporal relationships among the descriptions are components of the model. The model encapsulates information about **videos**, each being represented by a unique identifier; **semantic objects**, relating to the description of knowledge about video having a number of attribute–value pairs; **entities**, which are any of the above two; **relationship**, referring to an association between two entities. Many functions are also defined that help in organizing data and arranging relations between different objects in the video. Tran *et al.* (2000) proposed a graphical model, **VideoGraph** that supports not only the event description but also the interevent description that describes the temporal relationship between two events—a functionality overlooked by most of the existing video data models. Tran *et al.* (2000) also have a provision for exploiting incomplete information by associating the temporal event with a Boolean-like expression. A query language based on their framework is proposed in which query processing involves only simple graph traversal routines.

Khokhar *et al.* (1999) introduced a multilevel architecture for video data in which semantics are shared among various levels. An object-oriented paradigm is proposed for management of information at higher levels of abstraction. For each video sequence to be indexed, they first identified objects inside the video sequence, their sizes and locations, and their relative positions and movements, they encoded this information in a spatiotemporal model. This approach integrates both intraclip and interclip modeling and uses both bottom-up as well as top-down object-oriented data abstraction concepts. Decleir *et al.* (1999) have developed a data model that goes one step beyond the existing stratification-based approaches using **generalized intervals**. Here instead of a time segment to be associated with a description, a set of time segments is associated with a description—an approach that allows handling with a single object all occurrences of an entity in a video document. Also proposed was a declarative, rule-based, constraint query language that can be used to infer relationships from information represented in the model and to intentionally specify relationships among objects.

6.4 Conclusion

This chapter focuses on two major issues pertaining to multimedia systems: (1) storage and encoding standards for image and video data and (2) content-based indexing and retrieval of multimedia data. First, the chapter briefly outlines theoretical foundations of image and video compression and then explores some widely used compression and encoding standards for multimedia. Content-based indexing and retrieval of multimedia is an emerging research area that has received wide attention from the research community over the past decade. This chapter surveys the domain of content-based indexing and retrieval for image and video data in depth. Issues, such as low-level feature-based modeling, dimensionality reduction, and relevance feedback, are discussed. Video is normally thought of as a sequence of images, but the sheer size of the data yields an altogether different set of problems to be addressed. In this context, issues, such as temporal segmentation, video summarization, and high-level semantic modeling, are discussed.

7.1 Preface

Paul Baran from the RAND Corporation first proposed the notion of a distributed communication network in 1964 (Schonfeld, 2000; Tanenbaum, 1996). The aim of the proposal was to provide a communication network that could survive the impact of a nuclear war and employ a new approach to data communication based on packet switching. The Department of Defense (DoD) through the Advanced Research Projects Agency (ARPA) commissioned the ARPANET in 1969. ARPANET was initially an experimental communication network that consisted of only four nodes: UCLA, UCSB, SRI, and the University of Utah. Its popularity grew very rapidly over the next two decades, and by the end of 1989, there were over 100,000 nodes connecting research universities and government organizations around the world. This network later came to be known as the Internet, and a layered protocol architecture (i.e., Transmission Control Protocol/Internet Protocol, or TCP/IP, ref. Model) was adopted to facilitate services such as remote connection, file transfer, electronic mail, and news distribution. The proliferation of the Internet exploded over the past decade to more than 10 million nodes since the release of the World Wide Web.

The current Internet infrastructure, however, behaves as a "best-effort" delivery system. Simply put, it makes an honest attempt to deliver packets from a source to a destination, but it provides no guarantees on the packet either being actually delivered and/or the time it would take to deliver it (Kurose and Ross, 2001). Although this behavior is appropriate for textual data that require correct delivery rather than timely delivery, it is not suitable for time-constraint multimedia data such as video and audio. Recently, there has been a tremendous growth in demand for distributed multimedia applications over the Internet that operate by exchanging multimedia involving a myriad of media types. These applications have shown their value as powerful technologies that can enable remote sharing of resources or interactive work collaborations, thus saving both time and money. Typical applications of distributed multimedia systems include Internet-based radio/television broadcast, video conferencing, video telephony, real-time interactive and collaborative work environments, video/audio on demand, multimedia mail, and distant learning.

The popularity of these applications has highlighted the limitations of the current best-effort Internet service model and viability of its associated networking protocol stack (i.e., TCP/IP) for the communication of multimedia data. The different media types exchanged by these applications have significantly different **traffic requirements**—such as **bandwidth**, **delay, jitter**, and **reliability**—from the traditional textual data and demand different constraints or service guarantees from the underlying communication network to deliver an acceptable performance. In networking terminology, such performance guarantees are referred to as **quality of service** (QoS) guarantees that can be provided only by suitable enhancements to the basic Internet service model (Kurose and Ross, 2001). Circuit-switched networks, like the telephony system or plain old telephone service (POTS), have been designed from the ground up to support such QoS guarantees. However, this approach suffers from many shortcomings like scalability, resource wastage, high complexity, and high overhead (Leon-Garcia and Widjaja, 2000). Another approach, known as the asynchronous transfer mode (ATM), relies on cell switching to form virtual circuits that provide some of the QoS guarantees of traditional circuit-switched networks. Although ATM has become very popular as the backbone of high bandwidth and local networks, it has not been widely accepted as a substitute for the protocol stack used on the Internet. Providing QoS in packet-switched Internet, without completely sacrificing the gain of statistical multiplexing, has been a major challenge of multimedia networking. In addition to the QoS guarantees, distributed multimedia applications also demand many **functional requirements**—such as support for **multicasting**, **security**, **session management**, and **mobility**—for effective operation, and these can be provided by introducing new protocols residing above the traditional protocol stack used on the Internet (Wolf *et al.*, 1997). In this chapter, we discuss two popular protocol architectures, H.323 (Thom, 1996; Liu and Mouchtaris, 2000) and SIP (Johnston, 2000; Schulzrinne and Rosenburg, 2000) that have been specifically designed to support distributed multimedia applications.

Apart from the Internet, cellular networks have also seen an unprecedented growth in their usage [13] and consequent demand for multimedia applications. The second generation (2G) cellular systems like GSM, IS-95, IS-136 or PDC, which offered circuit-switched voice services, are now evolving towards third generation (3G) systems that are capable of transmitting high-speed data, video, and multimedia traffic to mobile users. IMT-2000 is composed of several 3G standards under development by the International Telecommunication Union (ITU) that will provide enhanced voice, data, and multimedia services over wireless networks. We will discuss the layered QoS approach adopted by IMT-2000 to provide end-to-end QoS guarantees.

Section 7.2 starts with a general classification of media types from a networking/communication point of view. In this section, we introduce the reader to some common media types like text, audio, images, and video, and we also discuss their **traffic** and **functional** requirements. Section 7.3 discusses the inadequacy of the current best-effort Internet model to satisfy the multimedia **traffic requirements**. We describe three enhanced architectures: Integrated Services (White, 2001), Differentiated Services (Blake *et al.*, 1998) and Multi-Protocol Label Switching (Rosen *et al.*, 2001). These architectures have been proposed to overcome these shortcomings. Section 7.4 presents some standard approaches for meeting the functional requirements posed by multimedia traffic. Later in this section, we present two protocol architectures (H.323 and SIP) that have been introduced for the Internet protocol stack to satisfy these requirements. Section 7.5 describes current efforts to support multimedia traffic over the cellular/wireless networks; we illustrate issues related to internetworking between wired and wireless networks.

7.2 Introduction to Multimedia

The term **multimedia** refers to diverse classess of media employed to represent information. **Multimedia traffic** refers to the transmission of data representing diverse media over communication networks. Figure 7.1 shows the diversity of the media classified into three groups: (1) text, (2) visuals, and (3) sound. As illustrated in this figure symbolic textual material may include not only the traditional unformatted plain text but also formatted text with numerous control characters, mathematical expressions, phonetic transcription of speech, music scores, and other symbolic representations such as

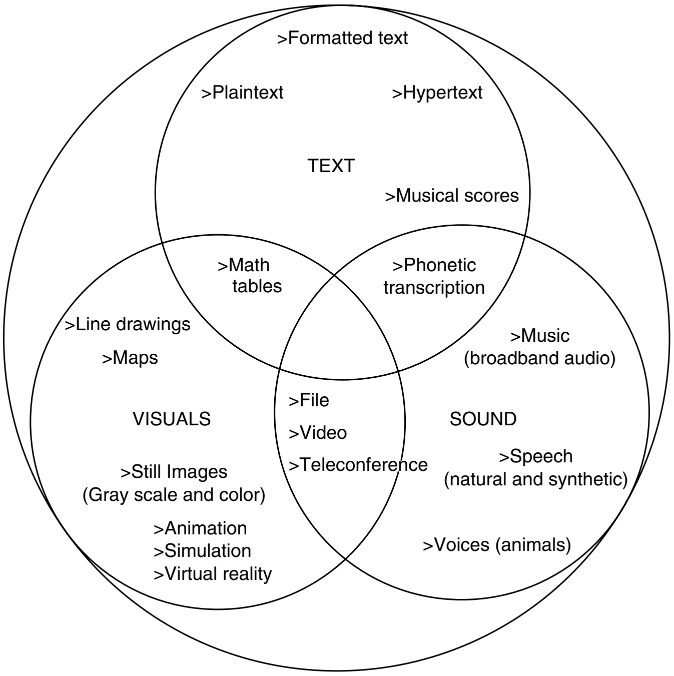

FIGURE 7.1 Diversity of Multimedia Data Signals. Adapted from Kinsner (2002).

hypertext. The visual material may include line drawings, maps, gray-scale or colored images, and photographs as well as animation, simulation, virtual reality objects, and video conferencing and teleconferencing. The sound material may include telephone/broadcast-quality speech to represent voice, wideband audio for music reproduction, and recordings of sounds such as from electrocardiograms or other biomedical signals. Other perceptory senses, such as touch and smell, can very well be considered as part of multimedia but are considered out of scope of this chapter.

Text is inherently digital, whereas other media types like sound and visuals can be analog and need to be converted into digital form using appropriate analog to digital conversion techniques. In this chapter, we assume that all media types have been suitably digitized; the reader is invited to read a book by Chapman and Chapman (2000) that gives an excellent introduction to the principles and standards used to convert many such analog media to digital form. In this chapter, we focus on typical characteristics of different media types when transported over a network. In this regard, multimedia networking deals with the design of networks that can handle multiple media types with ease and deliver scalable performance.

7.2.1 Multimedia Classification

From a networking perspective, all media types can be classified as either real-time (RT) or non real-time (NRT), as shown in Figure 7.2. RT media types require either hard or soft bounds on the end-to-end packet delay/jitter, while NRT media types, like text and image files, do not have any strict delay constraints but may have rigid constraints on error. There are basically two approaches to error control (Leon-Garcia and Widjaja, 2000):

1. **Error detection followed by Automatic Retransmission reQuest** (ARQ): This approach requests retransmission of lost or damaged packets. It is used by Transport Control Protocol (TCP), a transport layer protocol in the TCP/IP protocol stack, to provide reliable connection-oriented service. Applications that require an error-free delivery of NRT media typically use TCP for transport.
2. **Forward error correction** (FEC): This second approach provides sufficient redundancy in packets so that errors can be corrected without the need for retransmissions. It can be used by User Datagram Protocol (UDP), another transport layer protocol in the TCP/IP protocol stack that provides connectionless unreliable service. Applications that exchange error-tolerant media types (both RT and NRT) typically use UDP for transport because it eliminates time lost in retransmissions. Leigh *et al.* (2001) have conducted experiments using FEC along with UDP over a global high-bandwidth communication network, **STARTAP.**

The RT media types are further classified as **discrete media** (DM) or **continuous media** (CM), depending on whether the data is transmitted in discrete quantum as a file or message or continuously as a stream of messages with intermessage dependency. The real-time discrete type of media has recently gained high popularity because of ubiquitous applications like MSN/Yahoo messengers (which are error intolerant) and instant messaging services like stock quote updates (which are error tolerant).

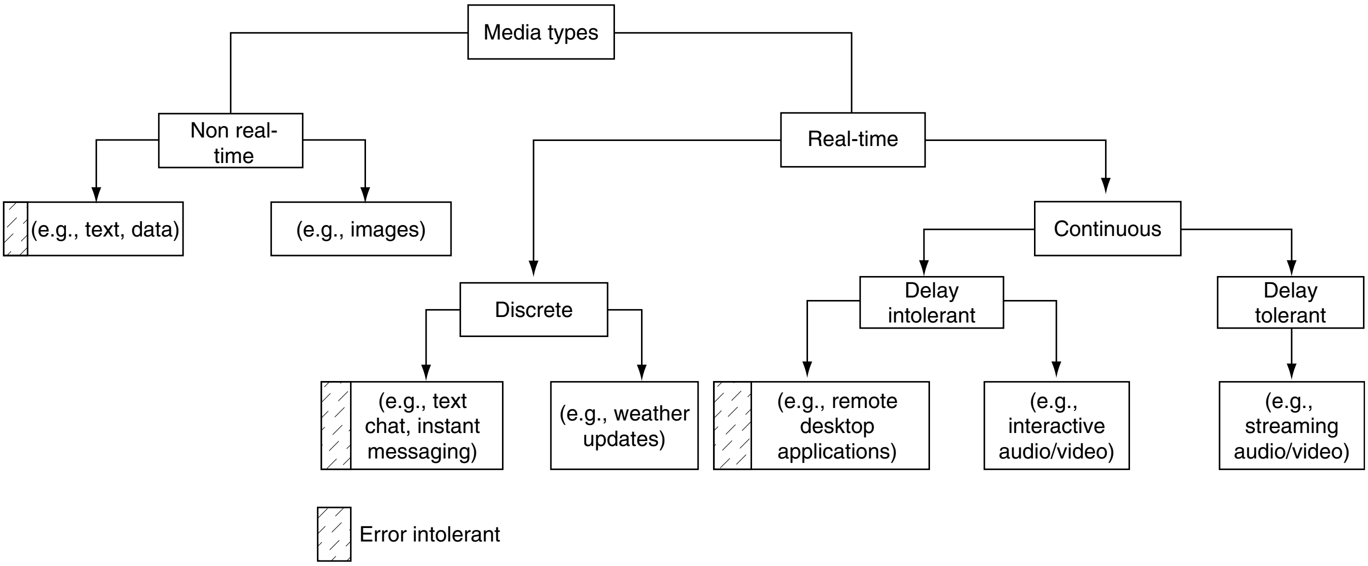

FIGURE 7.2 Network-Oriented Classification of Media Types

The RT continuous type of media can further be classified as **delay tolerant** or **delay intolerant**. We cautiously use the term delay tolerant to signify that such media type can tolerate higher amounts of delay than their delay-intolerant counterparts without significant performance degradation. Examples of RT, continuous, and delay-intolerant media are audio and video streams used in audio or video conferencing systems, and remote desktop applications. Streaming audio/video media used in applications like Internet Webcast are examples of delay-tolerant media types. Their delay dependency is significantly diminished by having an adaptive buffer at the receiver that downloads and stores a certain portion of the media stream before starting playout. The entire classification has been carefully illustrated in Figure 7.2.

We now discuss some common media types and their defining characteristics in terms of bandwidth usage, error requirements, and real-time nature.

7.2.2 Text

Text is the most popular of all the media types. It is distributed over the Internet in many forms, including files or messages using different transfer protocols such as File Transfer Protocol (FTP), which is used to transfer binary and ASCII files over the Internet; Hyper Text Transfer Protocol (HTTP), which is used to transmit HTML pages; or Simple Mail Transfer Protocol (SMTP), which is used for exchanging e-mails. Text is represented in binary as 7-bit US-ASCII, 8-bit ISO-8859, 16-bit Unicode, or 32-bit ISO 10646 character sets, depending on the language of choice and the country of origin. Bandwidth requirements of text media mainly depend on their size, which can be easily reduced using common compression schemes (Salomon, 1998) as detailed by Table 7.1.

The error characteristics of text media depend largely on the application under consideration. Some text applications, such as file transfer, require text communication to be completely loss/error free and therefore use TCP for transport. Other text applications, such as instant messaging, may tolerate some errors as well as losses and therefore can use UDP for transport.

Shannon-Fano coding	This coding uses variable length code words (i.e., symbols with higher probability of occurrence are represented by smaller codes-words).
Huffman coding Lempel-Ziv-Welch (LZW)	This coding is the same as Shannon-Fano coding LZW compression replaces strings of characters with single codes. It does analyze the incoming text. Instead, it just adds every new string of characters it sees to a table of strings. Compression occurs when a single code is output instead of a string of characters.
Unix compress	This compression scheme uses LZW with growing dictionary. Initially, the dictionary contains 512 entries and is subsequently doubled until it reaches the maximum value set by the user.

TABLE 7.2 Audio Compression Schemes

Voice/audio codec	Used for	Bit rate (Kbps)
Pulse code modulation (G.711)	Narrowband speech (300–3300 Hz)	64
GSM	Narrowband speech (300–3300 Hz)	13
CS-ACELP (G.729)	Narrowband speech (300–3300 Hz)	8
G.723.3	Narrowband speech (300–3300 Hz)	6.4 and 5.3
Adaptive differential PCM (G.726)	Narrowband speech (300–3300 Hz)	32
SBC (G.722)	Wideband speech (50–7000 Hz)	48/56/64
MPEG layer III (MP3)	CD-quality music wideband audio (10–22 Khz)	128–112 Kbps

Applications that use text as primary media (e.g., Web browsing or e-mail) do not have any real-time constraints, such as bounded delay or jitter. These applications are called **elastic applications**. Applications like instant messaging, however, do require some guarantees on the experienced delay.

Overall, the text media has been around since the birth of the Internet and can be considered as the primary means of information exchange.

7.2.3 Audio

Audio media is sound/speech converted into digital form using sampling and quantization. Digitized audio media is transmitted as a stream of discrete packets over the network. The bandwidth requirements of digitized audio depend on its dynamic range and/or spectrum. For example, telephone-grade voice uses dynamic range reduction using the logarithmic A-law (Europe) or μ-law (North America) capable of reducing the linear range of 12 bits to nonlinear range of only 8 bits. This reduces the throughput from 96 kbps to 64 kbps. A number of compression schemes (Garg, 1999) along with their bit rates, as illustrated in Table 7.2, are commonly used for audio media types.

The audio media type has loose requirements on packet loss/errors (or loss/error tolerance) in the sense that it can tolerate up to 1 to 2% packet loss/error without much degradation. Today, most multimedia applications that use audio have built-in mechanisms to deal with the lost packets using advanced interpolation techniques.

The real-time requirements of audio strictly depend on the expected interactivity between the involved parties. Some applications like Internet–telephony, which involves two-way communication, are highly interactive and require shorter response times. The audio media, in this case, requires strong bounds on end-to-end packet delay/jitter to be of acceptable/decipherable quality. Applications that use this media type are called **real-time intolerant** (RTI) applications. In most RTI applications, the end-to-end delay must be limited to ~ 200 msec to get an acceptable performance. Other applications like Internet Webcast, which involves one-way communication, have relatively low interactivity. Interactivity, in this case, is limited to commands that allow the user to change radio channels, for example, which can tolerate higher response times. Consequently, the Webcast requires weaker bounds on delay/jitter, and the applications that use such kind of media are termed as **real-time tolerant** (RTT) applications. **Streaming audio** is also used to refer to this media type.

7.2.4 Graphics and Animation

Graphics and animation include static media types like digital images and dynamic media types like flash presentations. An uncompressed, digitally encoded image consists of an array of pixels, with each pixel encoded in a number of bits to represent luminance and color. Compared to text or digital audio, digital images tend to be large in size. For example, a typical 4 × 6 inch digital image, with a spatial resolution of 480 × 640 pixels and color resolution of 24 bits requires ~ 1 MB of storage. To transmit this image on a 56.6 Kbps line will take at least 2 min. If the image is compressed at the modest 10:1 compression ratio, the storage is reduced to ~ 100 KB, and transmission time drops to ~ 14 sec. Thus, some form of compression schemes is always used that cashes on the property of high spatial redundancy in digital images. Some popular compression schemes (Salomon, 1998) are illustrated in Table 7.3. Most modern image compression schemes are progressive and have important implications for transmission over the communication networks (Kisner, 2002). When such an image is received and decompressed, the receiver can display the image in a low-quality format and then improve the display as subsequent image information is received and decompressed. A user watching the image display on the screen can recognize most of the image features after only 5 to 10% of the information has been decompressed. Progressive compression can be achieved by: (1) encoding spatial frequency data progressively, (2) using vector quantization that starts with a gray image and later adds colors to it, and (3) using pyramid coding that encodes images into layers, in which early layers are low resolution and later layers progressively increase the resolution.

Images are error tolerant and can sustain packet loss, provided the application used to render them knows how to handle lost packets. Moreover, images, like text files, do not have any real-time constraints.

7.2.5 Video

Video is a sequence of images or frames displayed at a certain rate (e.g., 24 or 30 frames per second). Digitized video, like digitized audio, is also transmitted as a stream of discrete packets over the network. The bandwidth requirements for digitized video depend on the spatial redundancy present in every frame as well as the temporal redundancy present in consecutive frames. Both these redundancies can be exploited to achieve efficient compression of video data. Table 7.4, illustrates some common compression schemes that are used in video (Watkinson, 2001).

The error- and real-time requirements of video media are similar to the audio media type. Hence, for the sake of brevity, we do not discuss them here.

TABLE 7.3 Image Compression Schemes

Compression scheme	Comments
Graphics interchange format (GIF)	GIF supports a maximum of 256 colors and is best used on images with sharply defined edges and large, flat areas of color like text and line-based drawings. GIF uses LZW compression to make files small. This is a lossless compression scheme.
Portable network graphics (PNG)	PNG supports any number of colors and works best with almost any type of image. PNG uses the zlib compression scheme, compressing data in blocks dependent on the "filter" of choice (usually *adaptive*). This is a lossless compression scheme and does not support animation.
Joint photographic experts group (JPEG)	JPEG is best suited for images with subtle and smooth color transitions, such as photographs gray-scale, and colored images. This compression standard is based on the Huffman and run-length encoding of the quantized discrete cosine transform (DCT) coefficients of image blocks. JPEG is a lossy compression. Standard JPEG encoding does not allow interlacing, but the progressive JPEG format does. Progressive JPEGs start out with large blocks of color that gradually become more detailed.
JPEG 2000	JPEG 2000 is suitable for a wide range of images, from those produced by portable digital cameras to advanced prepress and medical imaging. JPEG 2000 is a new image coding system that uses state-of-the-art compression techniques based on wavelet technology that stores its information in a data stream instead of blocks as in JPEG. This is a scalable lossy compression scheme.
JPEG-LS	JPEG-LS is suitable for continuous-tone images. The standard is based on the LOCO-I algorithm (Low COmplexity LOssless COmpression for images) developed by HP. This is a lossless/near-lossless compression standard.
Joint bilevel image experts group (JBIG)	JBIG is suitable for compressing black-and-white monochromatic images. It uses multiple arithmetic coding schemes to compress the image. This is a lossless type of compression.

TABLE 7.4 Video Compression Schemes

Compression scheme	Comments
MPEG-I	MPEG-I is used to produce VCR NTSC (352 × 240) quality video compression to be stored on CD-ROM (CD-I and CD-video format) using a data rate of 1.2 Mbps. MPEG-I uses heavy down-sampling of images limits image rate between 24 to 30 Hz to achieve this goal.
MPEG-II	MPEG-II is a generic standard for a variety of audio–visual coding applications and supports error resilience for broadcasting. It supports broadcast-quality video compression (DVB) and high-definition television (HDTV). MPEG-2 supports four resolution levels: low (352 × 240), main (720 × 480), high-1440 (1440 × 1152), and high (1920 × 1080). The MPEG-2 compressed video data rates are in the range of 3 to 100 Mbps.
MPEG-IV	MPEG-IV supports low-bandwidth video compression at a data rate of 64 Kbps that can be transmitted over a single N-ISDN B-channel. MPEG-4 is a genuine multimedia compression standard that supports audio and video as well as synthetic and animated images, text, graphics, texture, and speech synthesis.
H.261	H.261 supports video communications over ISDN at data rates of p × 64 Kbps. It relies on intraframe and interframe coding where integer–pixel accuracy motion estimation is required for intermode coding
H.263	The H.263 standard is aimed at video communications over POTS and wireless networks at very low data rates (as low as 18 to 64 Kbps). Improvements in this standard are due to the incorporation of several features such as half-pixel motion estimation, overlapping and variable block sizes, bidirectional temporal prediction, and improved variable length coding options.

7.2.6 Multimedia Expectations from a Communication Network

In this section, we identify and analyze the requirements that a distributed multimedia application may enforce on the communication network. Due to the vastness of this field, we do not claim that this list is exhaustive, but we have tried to include all the important aspects (from our view point) that have significantly impacted the enhancements to the basic Internet architecture and its associated protocols. In Sections 7.3 and 7.4, we further explore these aspects and give readers a sense of understanding of the efforts made to help the Internet deal with the challenges posed by such applications.

We divide these requirements into two categories (Wolf *et al.*, 1997): **traffic requirements** and **functional requirements**. The traffic requirements include limits on real-time parameters (e.g., delay and jitter), bandwidth, and reliability; functional requirements include support for multimedia services, such as multicasting, security, mobility, and session management. The traffic requirements can be met only by enhancements to the basic Internet architecture, whereas the functional requirements can be met by introducing newer protocols over the TCP/IP networking stack. The functional requirements are not an absolute necessity in the sense that a distributed multimedia application can still operate with high performance by incorporating the necessary functions into the application itself. They represent, however, the most common functionality required among distributed multimedia applications, and it would only help to have standardized protocols operating over the networking protocol stack to satisfy them.

Real-Time Characteristics (Limits on Delay and Jitter)

As discussed in Subsections 7.2.1 to 7.2.5, media types such as audio and video have real-time traffic requirements, and the communication network must honor these requirements. For example, audio and video data must be played back continuously at the rate at which they are sampled. If the data does not arrive in time, the playback process will stop, and human ears and eyes can easily pick up the artifact. In Internet telephony, human beings can tolerate a latency of ~ 200 msec. If the latency exceeds this limit, the voice will sound like a call routed over a long satellite link, which amounts to degradation in quality of the call. Thus real-time traffic enforces strict bounds on end-to-end packet delay (time taken by the packet to travel from the source to the destination) and jitter (variability in the interpacket delay at the receiver). The performance of distributed multimedia applications improves with decrease in both these quantities.

Need for Higher Bandwidth

Multimedia applications require significantly higher bandwidths than conventional textual applications of the past. Moreover, media streams are transmitted using UDP that does not have any mechanism to control congestion. The communication network must be able to handle such high bandwidth requirements without being unfair to other conventional flows. Table 7.5 summarizes the bandwidth requirements of some common audio/video media types. We discussed several compression schemes that take advantage of spatial/temporal redundancy present in audio/video media, but the compressed media still requires significantly higher bandwidth than what is typically required for text-oriented services. Moreover, compression schemes cannot be expected to be used for all multimedia transmissions. There are two types of compression techniques: **lossy** and **lossless**. The lossy compression techniques eliminate redundant information from data and subsequently introduce distortion or noise in the original data. The lossless compression techniques do not loose any information, and data received by the user is exactly identical to the original data. Lossy compression usually yields significantly higher compression ratios than lossless

TABLE 7.5 Sources of Multimedia and Their Effective Bandwidth Requirements

Audio source	Sampling rate	Bits/sample	Bandwidth Requirements
Telephone grade voice (up to 3.4 KHz)	8000 samples/sec	12	96 Kbps
Wideband speech (up to 7 KHz)	1600 samples/sec	14	224 Kbps
Wideband audio two channels (up to 20 KHz)	44.1 K samples/sec	16 per channel	1.412 Mbps for both channels
Image source	Pixels	Bits/Pixel	Bit rate
Color image	512 × 512	24	6.3 Mbps
CCIR TV	720 × 576 × 30	24	300 Mbps
HDTV	1280 × 720 × 60	24	1.327 Gbps

compression. However, lossy compression might not be acceptable for all media types or applications (e.g., medical images such as X-rays, telemedicine, etc.), and it may be necessary to use either lossless compression or not use compression at all.

Error Requirements

As discussed in earlier sections, different media types have vastly different error requirements, ranging from being completely error intolerant to being somewhat error tolerant depending on the application. An error is said to have occurred when a packet is either lost or damaged. Most error-tolerant multimedia applications use error concealment techniques to deal with lost or damaged packets by predicting lost information from correctly received packets. Errors are handled using various Forward Error Correction (FEC) codes that can be used to detect and correct single or multiple errors.

The use of FEC codes implies that extra information has to be added to the packet stream to handle errors. However, if the communication path over which the packets are transmitted introduces additional errors beyond the level of degradation for which the FEC was designed, then some errors will remain undetected or may not be corrected, and the performance will surely degrade. Thus, it is essential for a multimedia application to know the error characteristics of the communication network so that an adequate level of FEC is introduced to supplement the packet stream and protect against data loss or damage. As an example, wireless networks usually rely much more heavily on FEC than wired networks because the latter has a higher probability of packet loss. The minimization of packet retransmission achieved by using FEC can be too costly in wired networks that are characterized by very low probability of packet loss. The cost incurred is attributed to the additional bandwidth required for the representation of FEC information. The use of FEC is also critically dependent on the application. For instance, in real-time applications, some level of FEC is introduced for both wired and wireless communication networks because retransmissions are generally prohibited due to delay constraints.

Multicasting Support

Multicasting refers to a single source of communication with simultaneous multiple receivers. Most popular distributed multimedia applications require multicasting. For example, multiparty audio/video conferencing is one of the most widely used services in Internet telephony. If multicasting is not naturally supported by the communication network (as was the case in some circuit-switched networks) then significant efforts need to be invested in building multimedia applications that support this functionality in an overlaid fashion, which often leads to inefficient bandwidth utilization.

Multicasting is relatively easier to achieve for one-way communication than for two-way communication. For example, in the case of Internet radio, multicasting can be achieved by creating a spanning tree consisting of the sender at the root and the receiver at the leaves as well as replicating packets over all links that reach the receivers. In the case of two-way communication like Internet telephony among multiple parties, however, some form of audio mixing functionality is required that mixes the audios from all participants and only relays the correct information. Without this audio mixer, a two-way communication channel needs to be established between each participant in an all-to-all mesh fashion, which may amount to waste of bandwidth.

Session Management

The session management functionality includes the following features.

- **Media description:** This enables a distributed multimedia application to distribute session information, such as media type (audio, video, or data) used in the session, media encoding schemes (PCM, MPEG-II), session start time, session stop time, and IP addresses of the involved hosts, for example. It is often essential to describe the session before establishment because most participants involved in the session will have different multimedia capabilities.
- **Session announcement**: This allows participants to announce future sessions. For example, there are hundreds of Internet radio stations, each Webcasting different channels. Session announcement allows such radio stations to distribute information regarding their scheduled shows so that a user finds it easier to tune in to the preferred show.

- **Session identification**: A multimedia session often consists of multiple media streams (including continuous media (e.g., audio, video) and discrete media (e.g., text, images) that need to be separately identified. For example, the sender might choose to send the audio and video as two separate streams over the same network connection, and the receiver needs to decode each synchronously. Another example is that the sender might put the audio and video streams together but divide quality into a base layer and some enhancement layers so that low-bandwidth receivers might be able to receive only the base layer, whereas high-bandwidth receivers might also receive the enhancement layers.
- **Session control**: As said previously, a multimedia session involves multiple media streams. The information contained in these data streams is often interrelated, and the multimedia communication network must guarantee to maintain such relationships as the streams are transmitted and presented to the user. This is called **multimedia synchronization** and can be achieved by putting time stamps in every media packet. Moreover, many Internet multimedia users may want to control the playback of continuous media by pausing, playing back, repositioning the playback to a future or past point in time, visual fast-forwarding, or visual rewinding of the playback (Kurose and Ross, 2001). This functionality is similar to what we have in a VCR while watching a video or is similar to what we have in a CD player when listening to a CD.

Security

The security issue has been neglected in almost all discussions of multimedia communication. With the increasing use of online services and issues related to digital asset management, however, it is now apparent that security issues are quite significant. Security provides the following three aspects to multimedia data: **integrity** (data cannot be changed in mid-flight), **authenticity** (data comes from the right source), and **encryption** (data cannot be deciphered by any third party). For example, public broadcasts require data integrity and data authenticity, while private communication requires data encryption. All the above aspects can be provided using different cryptographic techniques like secret key cryptography, public key cryptography, and hash functions (Kessler, 2002).

Another issue is that of protecting the intellectual copyrights for different media components. For example, consider digital movies that are distributed over the Internet using a pay-per-view service. It is possible for any entrepreneur to download such movies and sell them illegally. Digital watermarking techniques (Su *et al.*, 1999), which embed extra information into multimedia data (such information is imperceptible to the normal user (Su *et al.*, 1999) as well as unremovable), can help prevent copyright violations.

Mobility Support

The advent of wireless and cellular networks has also enhanced multimedia applications with mobility. Cellular systems have a large coverage area and hence permit high mobility. Another emerging network is IEEE 802.11x wireless LAN (Crow *et al.*, 1997), which can operate at speeds exceeding 54 Mbps. Wireless LANs (WLAN) typically cover a smaller area and have limited mobility. Their main advantage, however, is that they work in the ISM band (no licensing required, thus eliminating significant investments into license purchase) and are relatively easy to set up; moreover, there is a vast availability of cheap WLAN products in the market that cost much less.

Mobility aspect has added another dimension of complexity to multimedia networks. It opens up questions on a host of complex issues like routing to mobile terminals, maintaining the QoS when the host is in motion, and internetworking between wireless and wired networks.

7.3 Best-Effort Internet Support for Distributed Multimedia Traffic Requirements

In this section, we further analyze why the current Internet, having the best-effort delivery model, is inadequate in supporting **traffic requirements** of multimedia traffic streams and justify the need for enhancements to this basic model. We also point out the research approaches that have been adopted to make best-effort Internet more accommodating to real-time multimedia traffic. To preserve the brevity of this chapter, we do not discuss every such approach at length but provide appropriate references for interested readers.

7.3.1 Best-Effort Internet Support for Real-Time Traffic

Real-time traffic requires strong bounds on packet delay and jitter, and the current Internet cannot provide any such bounds. Packet delay and jitter effects are contributed at different stages of packet transmission, and different techniques are used to reduce them. An analysis of these different components is essential in understanding the overall cause because almost all enhancements to the current Internet architecture aim to reduce one of these components. We explain each of these components (Bertsekas and Gallager, 1987) in more detail in the following subsection.

Packet Processing Delay

Packet processing delay is a constant amount of delay faced at both the source and the destination. At the source, this delay might include the time taken to convert analog data to digital form and packetize them through different layers of protocols until data are handed over to the physical layer for transmission. We can define similar packet processing delay at the receiver in the reverse direction. Usually this delay is the characteristic of the operating system (OS) and the multimedia application under consideration. For a lightly loaded system, this delay can be considered as negligible; however, with increasing load, this delay can become significant. Packet processing delay is independent of the Internet model (whether best-effort or any other enhanced version), and any reductions in this delay would imply software enhancements to the OS kernel—such OSs are called multimedia operating systems (Steinmetz, 1995) that provide enhanced process-, resource-, file-, and memory-management techniques with real-time scheduling—and the application.

Packet Transmission Delay

Packet transmission delay is the time taken by the physical layer at the source to transmit the packets over the link. This delay depends on multiple factors, including the following:

- **Number of active sessions**: The physical layer processes the packets in the FIFO order. Hence, if there are multiple active sessions, this delay becomes quite significant, especially if the OS does not support real-time scheduling algorithms to support multimedia traffic.
- **Transmission capacity of the link**: Increasing the transmission capacity reduces the transmission delay. For example, upgrading from the 10 Mbps ethernet to 100 Mbps fast ethernet will ideally reduce the transmission delay by a factor of 10.
- **Medium access control (MAC) access delay**: If the transmission link is shared, a suitable MAC protocol must be used for accessing the link (Yu and Khanvilkar, 2002). The choice of MAC protocol largely influences this delay. For example, if the transmission capacity is C bps, and the packet length is L bits, time taken to transmit is L/C, assuming a dedicated link. However, if the MAC protocol uses time division multiple access (TDMA) with m slots, this delay becomes mL/C, which is m times larger than the earlier case. The widespread ethernet networks cannot provide any firm guarantees on this access delay (and hence the overall QoS) due to the indeterminism of the carrier sense multiple access/collision detection (CSMA/CD) approach toward sharing of network capacity (Wolf *et al.*, 1997). The reason for this is that the collisions, which occur in the bus-based ethernet when two stations start transmitting at the same time, lead to delayed service time. Fast ethernet exploits the same configuration as 10 Mbps ethernet and increases the bandwidth with the use of new hardware in hubs and end stations to 100 Mbps but provides no QoS guarantees. Isochronous ethernet (integrated voice data LAN, IEEE 802.9) and demand priority ethernet (100Base-VG, AnyLAN, IEEE 802.12) can provide QoS, yet their market potential remains questionable.
- **Context switch in the OS**: Sending or receiving a packet involves context switch in the OS, which takes a finite time. Hence, there exists a theoretical maximum at which a computer can transmit packets. For a 10 Mbps LAN, this delay might seem insignificant; however, for gigabit networks, this delay becomes quite significant. Again, reduction in this delay will require enhancing the device drivers and increasing the operating speed of the computer.

Propagation Delay

Propagation delay is defined as the flight time of packets over the transmission link and is limited by the speed of light. For example, if the source and destination are in the same building at the distance of 200 m, the propagation delay will be ~ 1 μsec. If they are located in different countries at a distance of 20,000 km, however, the delay is in order of 0.1 sec. The above values represent the physical limits and cannot be reduced. This has major implications for interactive multimedia applications that require the response time to be less than $\sim$200 msec. Thus if the one-way propagation delay is greater than this value, then no enhancements can improve the quality of the interactive sessions, and the user will have to settle for a less responsive system.

Routing and Queuing Delay

The routing and queuing delay, is the only delay components that we can reduce (or control) by introducing newer enhanced Internet architecture models. In the best-effort Internet, every packet is treated equally, regardless of whether it is a real-time packet or a non real-time packet. All intermediate routers make independent routing decisions for every incoming packet. Thus, a router can be ideally considered as a First-In First-Out (FIFO) queuing system. When packets arrive at a queue, they have to wait for a random amount of time before they can be serviced, which depends on the current load on the router. This adds up to the queuing delay. The routing and queuing delay is random and, hence, is the major contributor to jitter in the traffic streams. Sometimes when the queuing delay becomes large, the sender application times out and resends the packet. This can lead to an avalanche effect that leads to congestion and thus increase in queuing delays. Different techniques have been adopted to reduce precisely this delay component and thus have given rise to newer Internet service models. For example, in the simplest case, if there is a dedicated virtual circuit connection (with dedicated resources in the form of buffers and bandwidth) from the source to the destination, then this delay will be negligible. The Integrated Services (IntServ) model and Multi-Protocol Label Switching (MPLS) model follow this approach. Another option is to use a combination of traffic policing, admission control, and sophisticated queuing techniques (e.g., priority queuing, weighted fair queuing) to provide a firm upper bound on delay and jitter. The Differentiated Services (DiffServ) model follows this approach. Later, we will discuss in some more detail the principles that need to be followed to reduce this delay component.

7.3.2 High Bandwidth Requirements

Multimedia traffic streams have high bandwidth requirements (refer to Table 7.5). The best-effort Internet model does not provide any mechanism for applications to reserve network resources to meet such high bandwidth requirements and also does not prevent anyone from sending data at such high rates. Uncontrolled transmissions at such high rates can cause heavy congestion in the network, leading to a congestion collapse that can completely halt the Internet. There is no mechanism in the best-effort Internet to prevent this from happening (except using a brute force technique of disconnecting the source of such congestion). It is left to the discretion of the application to dynamically adapt to network congestions. Elastic applications that use TCP utilize a closed-loop feedback mechanism (built into TCP) to prevent congestion (this method of congestion control is called reactive congestion control). However, most multimedia applications use UDP for transmitting media streams; UDP does not have any mechanism to control congestion and has the capability to create a congestion collapse.

To remove these shortcomings, the enhanced Internet service models use admission control, bandwidth reservations, and traffic policing mechanisms. The application must first get permission from some authority to send traffic at a given rate and with some given traffic characteristics. If the authority accepts admission, it will reserve appropriate resources (bandwidth and buffers) along the path for the application to send data at the requested rate. Traffic policing mechanisms are used to ensure that applications do not send at a rate higher than what was initially negotiated.

7.3.3 Error Characteristics

Multimedia streams require some guarantees on the error characteristics of the communication network, and the best-effort Internet cannot provide such guarantees because the path that a packet follows from the source to the destination is not fixed; hence, the network has no idea about the error characteristics of each individual segment. Thus, the sender application has no knowledge of the error characteristics of the network and may end up using an error correction/detection mechanism that may not be optimum.

For the newer Internet service models, the sender application has to go through admission control. At this time, the sender can specify the maximum error that it can tolerate. If the network uses a QoS-based routing algorithm, explained later in this discussion, and is unable to find a path that can satisfy this requirement, it will just reject the connection or make a counteroffer to the sender specifying the error rate at which it is willing to accept the connection. In other words, the sender is made aware of the error characteristics of the network.

7.3.4 Proposed Service Models for the Internet

We now discuss several new architecture models: Integrated Services (IntServ), Differentiated Services (DiffServ), and Multi-Protocol Label Switching (MPLS). These have been proposed for the best-effort Internet to satisfy the traffic requirements of distributed multimedia applications. But, before delving into the discussion of these QoS service models proposed for the Internet, we would like to summarize some of the principles that are common to all of them and are also expected to be seen in any future proposals.

Clearly Defined Service Expectations and Traffic Descriptions

To enhance the current Internet to support service guarantees, it is necessary to define such service guarantees in clear mathematical terms. QoS quantifies the level of service that a distributed multimedia application expects from the communication network. In general, three QoS parameters are of prime interest: **bandwidth**, **delay**, and **reliability**.

Bandwidth, as the most prominent QoS parameter, specifies how much data (maximum or average) are to be transferred in the networked system (Wolf, 1997). In general, it is not sufficient to specify the rate only in terms of bits, as the QoS scheme shall be applicable to various networks as well as to general-purpose end systems. For example, in the context of protocol processing, issues such as buffer management, timer management, and the retrieval of control information play an important role. The costs of these operations are all related to the number of packets processed (and are mostly independent of the packet size), emphasizing the importance of a packet-oriented specification of bandwidth. Information about the packetization can be given by specifying the maximum and the average packet size and the packet rate.

Delay, as the second parameter, specifies the maximum delay observed by a data unit on an end-to-end transmission (Furht, 1994). The delay encountered in transmitting the elements of a multimedia object stream can vary from one element to the next. This delay variance can take two forms: **delay jitter** and **delay skew**. Jitter implies that in an object stream, the actual presentation times of various objects shift with respect to their desired presentation times. The effect of jitter on an object stream is shown in Figure 7.3. In Figure 7.3(A), each arrow represents the position of an object that is equally spaced in time. In Figure 3(B), the dotted arrows represent the desired positions of the objects, and the solid arrows represent their actual positions. It can be seen in Figure 3(B) that these objects are randomly displaced from their original positions. This effect is called jitter in the timing of

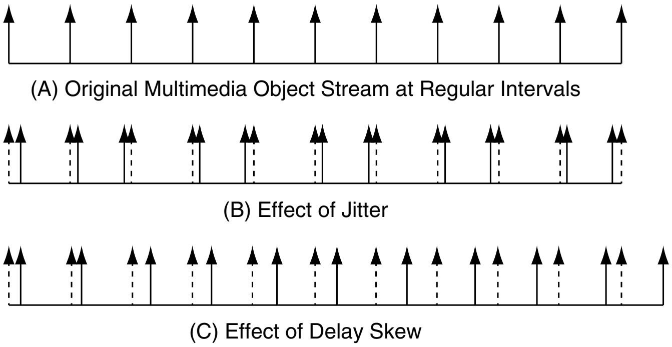

FIGURE 7.3 Effect of Jitter on an Object Stream. Adapted from Furht (1994).

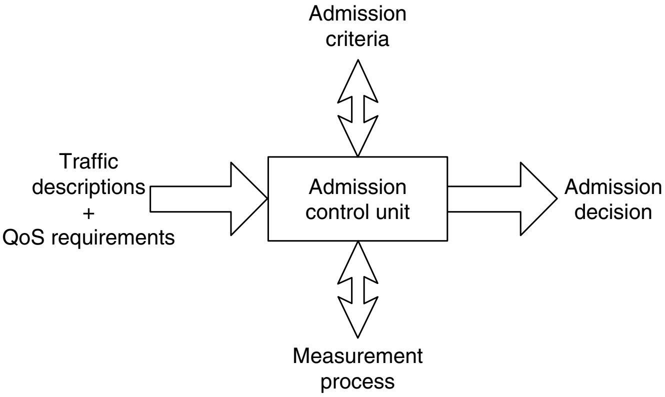

FIGURE 7.4 Admission Control Components. Adapted from Tang *et al.* (1999).

the object stream. The effect of jitter on a video clip is a shaky picture.

Skew implies constantly increasing the difference between the desired presentation times and the actual presentation times of streamed multimedia objects. This effect is shown in Figure 7.3(C). The effect of skew in the presentation times of consecutive frames in a video will be a slow- or fast-moving picture. Jitter can be removed only by buffering at the receiver side.

Reliability pertains to the loss and corruption of data. Loss probability and the method for dealing with erroneous data can also be specified.

It also becomes necessary for every source to mathematically describe the traffic characteristics of the traffic it will be sending. For example, every source can describe its traffic flow characteristics using a **traffic descriptor** that contains the peak rate, average rate, and maximum burst size (Kurose and Ross, 2001). This can be specified in terms of leaky bucket parameters, like the bucket size *b*, and the token rate *r*. In this case, the maximum burst size will be equal to the size of the bucket (i.e., *b* peak rate will be $r\mathrm{T} + b$, where T is the time taken to empty the whole bucket, and the average rate over time t is $rt + b$).

Admission Control

Admission control is a *proactive* form of congestion control (as opposed to reactive congestion control used in protocols like TCP) that ensures that demand for network resources never exceeds the supply. Preventing congestions from occurring reduces packet delay and loss, which improves real-time performance.

An admission control module (refer Figure 7.4) takes as input the traffic descriptor and the QoS requirements of the flow, and the module outputs its decision of either accepting the flow at the requested QoS or rejecting it if that QoS is not met (Sun and Jain, 1999). For this it consults **admission criteria** module, which refers to the rules by which an admission control scheme accepts or rejects a flow. Since the network resources are shared by all admitted flows, the decision to accept a new flow may affect the QoS commitments made to the admitted flows. Therefore, an admission control decision is usually made based on an estimation of the effect the new flow will have on other flows and the utilization target of the network.

Another useful component of admission control is the **measurement process** module. If we assume sources can characterize their traffic accurately using traffic descriptors, the admission control unit can simply use parameters in the traffic descriptors. It is observed, however, that real-time traffic sources are very difficult to characterize, and the leaky bucket parameters may only provide a very loose upper bound of the traffic rate. When the real traffic becomes bursty, the network utilization can get very low if admission control is solely based on the parameters provided at call setup time. Therefore, the admission control unit should monitor the network dynamics and use measurements such as instantaneous network load and packet delay to make its admission decisions.

Traffic Shaping and Policing

After a traffic stream gets admitted with a given QoS requirement and a given traffic descriptor, it becomes binding on the source to stick to that profile. If a rogue source breaks its contract and sends more than what it had bargained for, there will be breakdown in the service model. To prevent this possibility, **traffic shaping and policing** becomes essential.

Token bucket algorithm (Tanenbaum, 1996) is almost always used for traffic shaping. Token bucket is synonymous to a bucket with depth *b*, in which tokens are collected at a rate *r*. When the bucket becomes full, extra tokens are lost. A source can send data only if it can grab and destroy sufficient tokens from the bucket.

Leaky bucket algorithm (Tanenbaum, 1996) is used for traffic policing, in which excessive traffic is dropped. Leaky bucket is synonymous to a bucket of dept *b* with a hole at the bottom that allows traffic to flow at a fixed rate *r*. If the bucket is full, the extra packets are just dropped.

Packet Classification

Every packet, regardless of whether it is a real-time packet or a non real-time packet, is treated equally at all routers in the best-effort Internet. However, real-time multimedia traffic demands differential treatment in the network. Thus the newer service models will have to use some mechanism to distinguish between real-time and non real-time packets. In practice, this is usually done by **packet marking**. The type of service (ToS) field in the IP header can be used for this purpose. Some newer Internet architectures like MPLS make use of short labels that are attached to the front of the IP packets for this purpose.

Packet Scheduling

If differential treatment is to be provided in the network, then FIFO scheduling, traditionally used in routers, must be replaced by sophisticated queuing disciplines like **priority queuing** and **weighted fair queuing**. Priority queuing provides different queues for different traffic types. Every queue has an associated priority in which it is served. Queues with lower priority are served only when there are no packets in all the higher priority queues. One disadvantage of priority queuing is that it might lead to starvation of some low-priority flows.

Weighted fair queuing also has different queues for different traffic classes. Every queue, however, is assigned a certain weight *w*, and the packets in that queue always get a fraction *w*/*C* of the bandwidth, where *C* is the total link capacity.

Packet Dropping

Under congestion, some packets need to be dropped by the routers. In the past, this was done at random, leading to inefficient performance for multimedia traffic. For example, an MPEG-encoded packet stream contains *I*, *P*, and *B* frames. The *I* frames are compressed without using any temporal redundancy between frames, while the *P* and *B* frames are constructed using motion vectors from *I* (or *P*) frames. Thus the packets containing *I* frames are more important than those containing *P* or *B* frames. When it comes to packet dropping, the network should give higher dropping priority to the *P* and *B* frames than the *I* frame packets. For a survey on the different packet dropping schemes, refer to Labrador and Banerjee (1999).

QoS-Based Routing

The best-effort Internet uses routing protocols such as Open Shortest Path First (OSPF), Routing Information Protocol (RIP), and Border Gateway Protocol (BGP) (Sun and Jain, 1999). These protocols are called best-effort routing protocols, and they normally use single objective optimization algorithms that consider only one metric (either hop count or line cost) and minimize it to find the shortest path from the source to the destination. Thus, all traffic is routed along the shortest path leading to congestion on some links, while other links might remain underutilized. Furthermore, if link congestion is used to derive the line cost such that highly congested links have a higher cost, then such algorithms can cause oscillations in the network, where traffic load continuously shifts from heavily congested links to lightly congested links, and this will increase the delay and jitter experienced by end users.

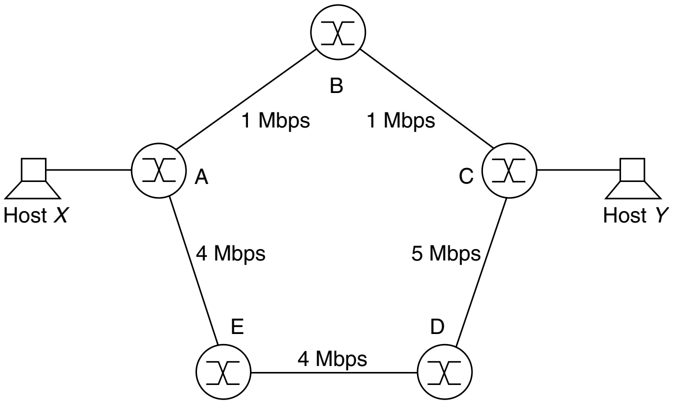

FIGURE 7.5 QoS-Based Routing

In QoS-based routing, paths for different traffic flows are determined based on some knowledge of resource availability in the network as well as the QoS requirement of the flows. For example, in Figure 7.5, suppose there is a traffic flow from host *X* to host *Y*, which requires 4 Mbps bandwidth. Although path A–B–C is shorter (with just two hops), it will not be selected because it does not have enough bandwidth. Instead, path A–E–D–C is selected because it satisfies the bandwidth requirement.

Besides QoS-based routing, there are two relevant concepts called **policy-based routing** and **constraint-based routing**. Policy-based routing (Avramovic, 1992) commonly means the routing decision is not based on the knowledge of the network topology and metrics but on some administrative policies. For example, a policy may prohibit a traffic flow from using a specific link for security reason even if the link satisfies all the QoS constraints. Constraint-based routing (Kuipers *et al*., 2002) is another new concept that is derived from QoS-based routing but has a broader sense. In this routing, algorithm routes are computed based on multiple constraints, including both QoS constraints and policy constraints. Both QoS-based routing and policy-based routing can be considered as special cases of constraint-based routing.

7.3.5 Integrated Services

To support multimedia traffic over the Internet, the Integrated Services working group in the Internet Engineering Task Force

(IETF) has developed an enhanced Internet service model called Integrated Services (IntServ) (White, 1997). This model is characterized by resource reservations. It requires applications to know their traffic characteristics and QoS requirements beforehand and signal the intermediate network routers to reserve resources, like bandwidth and buffers, to meet them. Accordingly, if the requested resources are available, the routers reserve them and send back a positive acknowledgment to the source, which allows data to be sent. If, on the other hand, sufficient resources are not available at any router in the path, the request is turned down, and the source has to try again after some time. This model also requires the use of **packet classifiers** to identify flows that are to receive a certain level of service as well as **packet schedulers** to handle the forwarding of different packets in a manner to ensure that the QoS commitments are met.

The core of IntServ is almost exclusively concerned with controlling the queuing component of the end-to-end packet delay. Thus, per-packet delay is the central quantity about which the network makes service commitments.

Intserv introduces three service classes to support RTI, RTT, and elastic multimedia applications. They are **Guaranteed service**, **Controlled Load service**, and the **Best-Effort service**. A **flow descriptor** is used to describe the traffic and QoS requirements of a flow (Leon-Garcia and Widjaja, 2000). The flow descriptor consists of two parts: a **filter specification** (filterspec) and a **flow specification** (flowspec). The filterspec provides the information required by the packet classifier to identify the packets that belong to that flow. The flowspec consists of a **traffic specification** (Tspec) and **service request specification** (Rspec). Tspec specifies the traffic behavior of the flow in terms of token bucket parameters (b,r), while the Rspec specifies the requested QoS requirements in terms of bandwidth, delay, jitter, and packet loss.

Since all network nodes along the path from source to destination must be informed of the requested resources, a signaling protocol is needed. Resource Reservation Protocol (RSVP) is used for this purpose (Braden *et al.*, 1997). The signaling process is illustrated in Figure 7.6. The sender sends a PATH message to the receiver, specifying the characteristics of the traffic. Every intermediate router along the path forwards the PATH message to the next hop determined by the routing protocol. The receiver, upon receiving the PATH message, responds with the RESV message to request resources for the flow. Every intermediate router along the path can reject or accept the request of the RESV message. If the request is rejected, the router will send an error message to the receiver, and the signaling process terminates. If the request is accepted, link buffer and bandwidth are allocated to the flow, and related flow state information will be installed in the router.

The design of RSVP lends itself to be used with a variety of QoS control services. RSVP specification does not define the internal format of the RSVP protocol fields or objects and treats them as opaque; it deals only with the setup mechanism. RSVP was designed to support both unicast and multicast applications. RSVP supports heterogeneous QoS, which means different receivers in the same multicast group can request different QoS. This heterogeneity allows some receivers to have reservations, whereas others could receive the same traffic using the best-effort service. We now discuss the service classes offered by IntServ.

Guaranteed Service Class

The **Guaranteed** service class provides firm end-to-end delay guarantees. Guaranteed service does not control the minimum or average delay of packets; merely the maximal queuing delay. This service guarantees that packets will arrive at the receiver but in a requested delivery time and will not be discarded due to queue overflows, provided the flow's traffic stays in its specified traffic limits, which are controlled using traffic policing. This service is intended for applications that need a firm guarantee that a packet will arrive no later than a certain delay bound.

Using traffic specification (Tspec), the network can compute various parameters describing how it will handle the flow. By combining the parameters, it is possible to compute the maximum queuing and routing delay that a packet can experience. Using the fluid flow model, the queuing delay is approximately a function of two parameters: the token bucket size b and the data rate R that the application requests and gets when admitted.

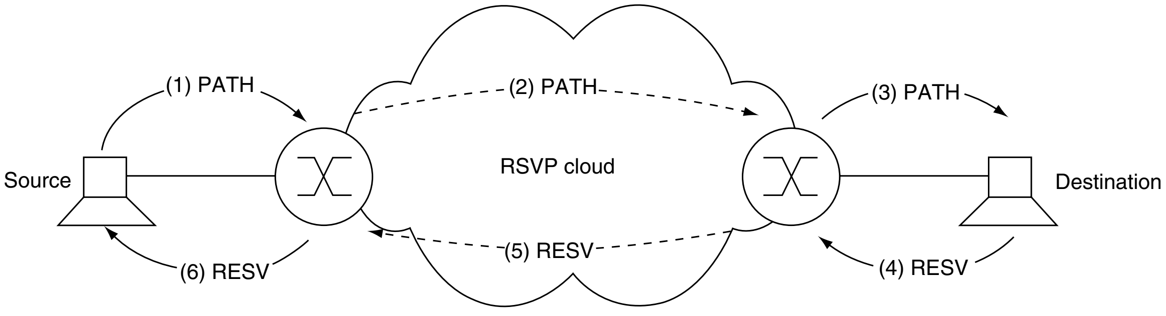

FIGURE 7.6 RSVP Signaling

Controlled Load Service

Controlled Load service is an enhanced quality of service intended to support RTT applications requiring better performance than that provided by the traditional best-effort service. It approximates the end-to-end behavior provided by best effort under unloaded conditions. The assumption here is that under unloaded conditions, a very high percentage of the transmitted packets are successfully delivered to the end nodes, and the transmission delay experienced by a very high percentage of the delivered packets will not vary much from the minimum transit delay.

The network ensures that adequate bandwidth and packet processing resources are available to handle the requested level of traffic. The controlled load service does not make use of specific target values for delay or loss. Acceptance of a controlled-load request is merely a commitment to provide the flow with a service closely equivalent to that provided to uncontrolled traffic under lightly loaded conditions. Over all timescales significantly larger than the burst time, a controlled load service flow may experience little or no average packet queuing delay and little or no congestion loss.

The controlled load service is described only using a Tspec. Since the network does not give any quantitative guarantees, Rspec is not required. The controlled load flows not experiencing excess traffic will get the contracted quality of service, and the network elements will prevent excess controlled load traffic from unfairly impacting the handling of arriving best-effort traffic. The excess traffic will be forwarded on a best-effort basis.

Best-Effort Service

The **Best-Effort** service class does not have a Tspec or an Rspec. There are no guarantees by the network whatsoever. The network does not do any admission control for this class.

Disadvantages of the IntServ Service Model for the Internet

IntServ uses RSVP to make per-flow reservations at routers along a network path. Although this allows the network to provide service guarantees at the flow level, it causes it to suffer from scalability problems. The routers have to maintain per-flow state for every flow that passes through the router, which can lead to huge overhead. Moreover, RSVP is a soft-state protocol, which means that the router state has to be refreshed at regular intervals. This increases traffic overhead.

7.3.6 Differentiated Services

The Differentiated Services working group in the IETF proposed the Differentiated Services (DiffServ) service model for the Internet, which removes some of the shortcomings of the IntServ architecture (Blake *et al.*, 1998). DiffServ divides the network into distinct regions called DS domains, and each DS domain can be controlled by a single entity. For example, an organization's intranet or an ISP can form its own DS domain. One important implication of this is that to provide any service guarantees the entire path between the source and destination must be under some DS domain (possibly multiple). Even if a single hop is not under some DS domain, then service cannot be guaranteed. DiffServ architecture can be extended across multiple domains using a service level agreement (SLA) between them. An SLA specifies rules for traffic remarking, actions to be taken for out-of-profile traffic, and other such specifications.

Every node in a DS domain can be a boundary node or an interior node.

- **Boundary node:** Boundary nodes are the gatekeepers of the DS domain. A boundary node is the first (or last) node that a packet can encounter when entering (or exiting) a DS domain. It performs certain edge functions like admission control, packet classification, and traffic conditioning. The admission control algorithm limits the number of flows that are admitted into the DiffServ domain and is distributed in nature. For example, in the simplest case, the admission control algorithm may maintain a central data structure that contains the current status of all links in the DS domain. When a flow is considered for admission, the corresponding boundary node might check this data structure to verify if all the links of the flow path can satisfy the requested QoS. Every packet belonging to an admitted flow and arriving into the DS domain is classified and marked as belonging to one of the service classes called **behavior aggregates** in DiffServ terminology. Each such behavior aggregate is assigned a distinct 8-bit code word, called the DS code point. Packet marking is achieved by updating the TOS field in the packet's IP header with the appropriate DS code point. Boundary nodes also enforce traffic conditioning agreements (TCA) between their own DS domain and other connected domains, if any.
- **Interior node:** An interior node is completely inside a DS domain and is connected to other interior nodes or boundary nodes in the same DS domain. The interior nodes only perform packet forwarding. When a packet with a particular DS code point arrives at this node, it is forwarded to the next hop according to some predefined rule associated with the packet class. Such predefined rules are called **perhop behaviors** (PHBs), which are discussed next.

Thus unlike IntServ, only the edge routers have to maintain per-flow states, which makes DiffServ relatively more scalable.

Per Hop Behaviors

A **per hop behavior** (PHB) is a predefined rule that influences how the router buffers and link bandwidth are shared among competing behavior aggregates. PHBs can be defined either in terms of router resources (e.g., buffer and bandwidth), in terms of their priority relative to other PHBs, or in terms of their relative traffic properties (e.g., delay and loss). Multiple PHBs can be lumped together to form a PHB group. A particular PHB group can be implemented in a variety of ways because PHBs are defined in terms of behavior characteristics and are not implementation dependent. Thus PHBs can be considered as basic building blocks for creating services. A PHB for a packet is selected at the first node on the basis of its DS code point. The mapping from the DS code point to PHB may be 1 to 1 or *N* to 1. Examples of the parameters of the forwarding behavior that each traffic should receive are **bandwidth partition** and the **drop priority**. Examples of these implementations are weighted fair queuing (WFQ) for bandwidth partition and random early detect (RED) for drop priority. Two commonly used PHBs defined by IETF are the following:

- **Assured forwarding (AF) PHB:** AF PHB divides incoming traffic into four classes; each AF class is guaranteed some minimum bandwidth and buffer space. In each AF class, packets are further assigned one of three drop priorities. By varying the amount of resources allocated to each AF class, different levels of performance can be offered.
- **Expedited forwarding (EF) PHB:** EF PHB dictates that the departure rate of a traffic class from any router must equal or exceed the configured rate. Thus, for a traffic class belonging to EF PHB, during any interval of time, it can be confidently said that departure rate from any router will equal or exceed the aggregate arrival rate at that router. This has strong implications on the queuing delay that is experience by the packet. In this case, the queuing delay can be guaranteed to be bounded and is negligible (limited by the link bandwidth). EF PHB is used to provide premium service (having low delay and jitter) to the customer. However, EF PHB requires a very strong admission control mechanism. The admission control algorithm will basically ensure that the arrival rate of traffic belonging to EF PHB is less than the departure rate configured at any router in its path. Moreover, proper functioning of EF PHB demands strict policing. This job can be carried out by the Ingress routers. If packets are found to be in violation of the contract, they can be either dropped or demoted to a lower traffic class.

7.3.7 Multi-Protocol Label Switching

When an IP packet arrives at a router (Rosen *et al.*, 2001) the next hop for this packet is determined by the routing algorithm in operation, which uses the **longest prefix match** (i.e., matching the longest prefix of an IP destination address to the entries in a routing table) to determine the appropriate outgoing link. This process introduces some latency because the routing tables are very large and table lookups take time. The same process also needs to be repeated independently for every incoming packet, even though all packets may belong to the same flow and may be going toward the same destination. This shortcoming of IP routing can be removed by using IP switching, in which a short label is attached to a packet and updated at every hop. When this modified packet arrives at a switch (*router* in our previous description), this label is used to index into a short switching table [an O(1) operation] to determine the outgoing link and new label for the next hop. The old label is then replaced by new label, and the packet is forwarded to the next hop. All this can be easily done in hardware and results in very high speeds. This concept was applied earlier in ATM for cell switching that used the VPI/VCI field in the packet as the label. MPLS introduces the same switching concept in IP networks. It is called **Multi-Protocol** because this technique can also be used with any network layer protocol other than IP. Label switching provides a low-cost hardware implementation, scalability to very high speeds, and flexibility in the management of traffic flows.

Similar to DiffServ, an MPLS network is divided into domains with boundary nodes called **label edge routers** (LER) and interior nodes called **label switching routers** (LSR). Packets entering an MPLS domain are assigned a label at the ingress LER and are switched inside the domain by a simple label lookup. The labels determine the quality of service that the flow receives in the network. The labels are stripped off the packets at the egress LER, and the packets might be routed in the conventional fashion before they reach their final destination. A sequence of LSRs that is to be followed by a packet in an MPLS domain is called **label switched path** (LSP). Again, similar to DiffServ, to guarantee a certain quality of service to the packet, both the source and destination have to be attached to the same MPLS domain, or if they are attached to different domains, then there should be some service agreement between the two.

MPLS uses the concept of **forward equivalence class** (FEC) to provide differential treatment to different media types. A group of packets that are forwarded in the same manner are said to belong to the same FEC. There is no limit to the number and granularity of FECs that can exists. Thus, it is possible to define a separate FEC for every flow (which is not advisable due to large overheads) or for every media type, each tailored for that media type. One important thing to note here is that labels have only local significance in the sense that two LSRs agree to use a particular label to signify a particular FEC among themselves. The same label can be used to distinguish a different FEC by another pair of LSRs. Thus, it becomes necessary to do label assignments, which includes label allocation and label-to-FEC bindings on every hop of the LSP before the traffic flow can use the LSP. Label assignments can be initiated in one of the following three ways:

(1) **Topology-driven label assignment**: In this assignment, LSPs (for every possible FEC) are automatically set up between every pair of LSR (full mesh). Thus, this scheme can place a heavy demand on the usage of labels at each LSR. However, the main advantage is that there is no latency involved in setting up an LSP before the traffic flow can use it (i.e., zero-call setup delay).

(2) **Request-driven label assignment**. Here, the LSPs are set up based on explicit requests. RSVP can be used to make the request. The advantage of this scheme is that LSPs will be set up only when required, and a full mesh is avoided. However, the disadvantage is the added setup latency, which can dominate short-lived flows.

(3) **Traffic-driven label assignment**. This assignment combines the advantages of the above two methods. LSPs are set up only when the LSR identifies traffic patterns that justify the setup of an LSP. Those that are identified as not needing an established LSP are routed using the normal routing method.

MPLS also supports **label stacking**, which can be very useful for performing tunneling operations. In label stacking, labels are stacked in a FILO order. In any particular domain, only the topmost label can be used to make forwarding decisions. This functionality can be very useful for providing mobility: a home agent can push another label on incoming packets and forward the packet to a foreign agent that pops it off and finally forwards the packet to the destination mobile host.

7.4 Enhancing the TCP/IP Protocol Stack to Support Functional Requirements of Distributed Multimedia Applications

In this section, we illustrate standards/protocols that have been introduced to operate over the basic TCP/IP protocol stack to satisfy the **functional requirements** of multimedia traffic streams. We later describe two protocol architectures: H.323 and Session Initiation Protocol (SIP) that have been standardized to support these functional requirements. Again, to preserve the brevity of this chapter, we do not discuss every such approach at length but provide appropriate references for interested readers.

7.4.1 Supporting Multicasting

The easiest way to achieve multicasting over the Internet is by sending packets to a multicast IP address (Class D IP addresses are multicast IP addresses) (Banikazemi *et al.*, 1997). Hosts willing to receive multicast messages for particular multicast groups inform their immediate-neighboring routers using the Internet Group Management Protocol (IGMP). Multicasting is trivial on a single ethernet segment (where packets can be multicast using the multicast MAC address). For delivering a multicast packet from the source to the destination nodes on other networks, however, multicast routers need to exchange the information they have gathered from the group membership of the hosts directly connected to them. There are many different algorithms such as *flooding*, *spanning tree*, *reverse path broadcasting*, and *reverse path multicasting* for exchanging the routing information among the routers. Some of these algorithms have been used in dynamic multicast routing protocols such as Distance Vector Multicast Routing Protocol (DVMRP), Multicast Extension to Open Shortest Path First (MOSPF), and Protocol Independent Multicast (PIM) (Sahasrabuddhe and Mukherjee, 2000). Based on the routing information obtained through one of these protocols, whenever a multicast packet is sent out to a multicast group, multicast routers will decide whether to forward that packet to their network(s) or not.

Another approach is MBone or Multicast Backbone. Mbone is essentially a virtual network implemented on top of some portions of the Internet. In the MBone, islands of multicast-capable networks are connected to each other by virtual links called **tunnels**. Multicast messages are forwarded through these tunnels in non multicast-capable portions of the Internet. For forwarding multicast packets through these tunnels, they are encapsulated as IP-over-IP (with protocol number set to four) such that they look like normal unicast packets to interventing routers.

ITU-T H.323 and IETF Session Initiation Protocol (SIP), as discussed in detail later, support multicasting through the presence of a multipoint control unit that provides both mixing and conferencing functionalies needed for audio/video conferencing. Striegel and Manimaran (2002) offer a survey of QoS multicasting issues.

7.4.2 Session Management

We now discuss the different protocols that have been standardized to meet different aspects of session management.

- **Session description**: Session Description Protocol (Handley and Jacobson, 1998; Garg, 1999), developed by IETF, can be used for providing the session description functionality (to describe media type and media encoding used for that session). It is more of a description syntax than a protocol because it does not provide a full-range media negotiation capability (this is provided by SIP, as discussed in later sections). SDP encodes media descriptions in simple text format. An SDP message is composed of a series of lines, called **fields**, whose names are abbreviated by a single lowercase letter and are in a required order to facilitate parsing. The fields are in the form

FIGURE 7.7 Sample SDP Message

attribute_type = **value**. A sample SDP message is illustrated in Figure 7.7. The meaning of all attributes is illustrated on the left, while the actual message is illustrated on the right.

- **Session announcement**: Session Announcement Protocol (SAP) (Handley *et al.*, 2000; Arora and Jain, 1999) is used for advertising multicast conferences and other multicast sessions. An SAP announcer periodically multicasts announcement packets to a well-known multicast address and port (port number 9875) with the same scope as the session it is announcing, ensuring that the recipients of the announcement can also be potential recipients of the session being advertised. Multiple announcers may also announce a single session to increase robustness against packet loss or failure of one or more announcers. The time period between repetitions of an announcement is chosen such that the total bandwidth used by all announcements on a single SAP group remains below a preconfigured limit. Each announcer is expected to listen to other announcements to determine the total number of sessions being announced on a particular group. SAP is intended to announce the existence of a long-lived wide area multicast sessions and involves a large startup delay before a complete set of announcements is heard by a listener. SAP also contains mechanisms for ensuring integrity of session announcements, for authenticating the origin of an announcement, and for encrypting such announcements.
- **Session identification**: In the best-effort Internet, every flow (or session) can be identified using the tuple <*Src Ip, Src Port, Dst IP, Dst Port, Protocol*>. Thus, individual transport layer sockets have to be established for every session. If there ever arises a need to bunch sessions together (for cutting costs), however, there is no available mechanism. Hence, there is clearly a need to multiplex different streams into the same transport layer socket. This functionality is similar to that of the **session layer** in the seven-layer OSI model, which has been notably absent in TCP/IP protocol stack used in the Internet. Session identification can be done using RTP and is described in more detail in the next point.
- **Session control**: All the session control functionalities can be satisfied using a combination of RTP, RTCP, and RTSP. Real-Time Protocol (RTP) (Schulzrinne *et al.*, 1996) typically runs on top of UDP. Specifically, chunks of audio/video data that are generated by the sending side of the multimedia application are encapsulated in RTP packets, which in turn are encapsulated in UDP. The RTP functionality needs to be integrated into the application. The functions provided by RTP include (a) **sequence number** field in the RTP header to detect lost packets, (b) a **payload identifier** included in each RTP packet to dynamically change and describe the encoding of the media, (c) a **frame market** bit to indicate the beginning and end of a video or audio frame, (d) a **synchronization source** (SSRC) identifier to determine the originator of the frame because there are many participants in a multicast session and (e) **time stamp** to compensate for the different delay jitter for packets in the same stream, and to assist the play-out buffers.

Additional information pertaining to particular media types and compression standards can also be inserted in the RTP packets by using profile headers and extensions. Cavusoglu *et al.* (2003) have relied on the information contained in the RTP header extensions to provide an adaptive forward error correction (FEC) scheme for MPEG-2 video communications over RTP networks. This approach relies on the group of pictures (GOP) sequence and motion information to assign a dynamic weight to the video sequence. The fluctuations in the weight of the video stream are used to modulate the level of FEC assigned to the GOP. Much higher performance is achieved by the use of the adaptive FEC scheme in comparison to other methods that assign an uneven level of protection to video stream. The basic notion presented by the adaptive weight assignment procedure presented in Cavusoglu *et al.* (2003) can be employed in other applications such as DiffServ networks and selective retransmissions (see discussion on LSP networks later).

RTCP is a control protocol that works in conjunction with RTP and provides participants with useful statistics about the number of packets sent, number of packets lost, interarrival jitter, and round trip time. This information can be used by the sources to adjust their data rate. Other information, such as e-mail address, name, and phone number are included in the RTCP packets and allow all users to know the identities of the other users for that session.

Real-Time Streaming Protocol (RTSP) (Schulzrinne *et al.*, 1998) is an out-of-band control protocol that allows the media player to control the transmission of the media stream, including functions like **pause/resume** and **repositioning playback**. The use of the RTP above UDP provides for additional functionality required for reordering and time stamping the UDP packets. The inherent limitations of the UDP, however, are not completely overcome by the use of RTP. Specifically, the unreliability of UDP persists and, consequently, there is no guarantee of delivery of the transmitted packets at the receiver. On the other hand, the error-free transmission guarantees provided by the TCP pose severe time delays that render it useless for real-time applications. Mulabegovic *et al.* (Mulabegovic *et al.*, 2002) have proposed an alternative to RTP provided by the Lightweight Streaming Protocol (LSP). This protocol also resides on top of the transport layer and relies on the UDP. LSP provides sequence numbers and time stamps—as facilitated by RTP—to reorder the packets and manage the buffer at the receiver. However, unlike UDP and RTP, the LSP allows for limited use of retransmissions to minimize the effects of error over the communication network. This is accomplished by use of negative acknowledgments in the event of lost packets and satisfaction of timing delay constraints required to maintain real-time communication capability.

7.4.3 Security

IpSec (Chapman and Chapman, 2000; Opplinger, 1998) provides a suite of protocols that can be used to carry out secure transactions. IpSec adds security protection to IP packets. This approach allows applications to communicate securely without having to be modified. For example, before IpSec came into picture, applications often used SSH or SSL for having a secure peer-to-peer communication, but this required modifying certain APIs in the application source code and subsequent recompilation. IpSec cleanly separates policy from enforcement. The policy (which traffic flow is secured and how it is secured) is provided by the system administrator, while the enforcement of this policy is carried out by a set of protocols: Authentication Header (AH) and Encapsulated Security Payload (ESP). These policies are placed as rules in a Secure Policy Database (SPD), consulted for every inbound/outbound packet, and tell IpSec how to deal with a particular packet: if a IpSec mechanism needs to be applied to the packet, if the packet should be dropped, or if the packet should be forwarded without placing any security mechanism. If the administrator has configured the SPD to use some security for a particular traffic flow, then IpSec first negotiates the parameters involved in securing the traffic flow with the peer host. These negotiations result in the so-called Security Association (SA) between the two peers. The SA contains the type of IpSec mechanism to be applied to the traffic flow (AH or ESP), the encryption algorithms to be used and the security keys to be applied. SAs are negotiated using the Internet Key Exchange (IKE) protocol.

As said earlier, IpSec provides two protocols to secure traffic flow. The first is the **Authenticated Header** (AH) whose main function is to establish the authenticity of the sender to the receiver. It does not provide data confidentiality. In other words, AH does not encrypt the payload. It may seem, at first, that authentication without confidentiality might not be useful in the industry. However, there are many applications where this does provide a great help. For example, there may be many situations, such as news reports, where the data may not be encrypted, but it may be necessary to establish the authenticity of the sender. AH provides significantly less overhead as compared to ESP. The second protocol is the **Encapsulated Security Payload** (ESP). ESP provides both authentication and encryption services to the IP packets. Since every packet is encrypted, ESP puts a larger load on the processor.

Currently, IpSec can operate in **transport** mode or **tunnel** mode. In transport mode, IpSec takes a packet to be protected, preserves the packet's IP header, and modifies only the upper layer portions by adding IpSec headers and the requested kind of protection between the upper layers and the original IP header. In the tunnel mode, IpSec treats the entire packet as a block of data, adds a new packet header, and protects the data by making it part of the encrypted payload of the new packet.

IpSec can be easily integrated into the current operating system environment, by either changing the native implementation of IP protocol (and subsequent kernel compilation), inserting an additional layer below the IP layer of the TCP/IP protocol stack (also known as bump-in-the-stack [BITS]), or using some external hardware (also known as bump-in-the-wire [BITW]).

7.4.4 Mobility

Mobile IP (Perkins, 1998) is an Internet protocol used to support mobility. Its goal is to provide the ability of a host to stay connected to the Internet regardless of its location. Every site that wants to allow its users to roam has to create a **home agent** (HA) entity, and every site that wants to allow visitors has to create a **foreign agent** (FA) entity. When a mobile host (MH) roams into a foreign site (which allows roaming), it contacts and registers with the FA for that site. The FA, in turn, contacts the HA of that mobile host and gives it a **care-of address**, normally the FA's own IP address. All packets destined for the MH will eventually reach the HA that encapsulates the packets inside another IP packet and forward it to the FA. The FA decapsulates it and ultimately forwards the original packets, to the MH. The HA may also inform the source of the new IP address where the packets must be directly forwarded.

7.4.5 H.323

ITU-T recommendation H.323 (Thom, 1996; Liu and Mouchtaris, 2000; Arora and Jain, 1999) is an umbrella recommendation that specifies the components, protocols, and procedures used to enable voice, video, and data conferencing over a packet-based network like the IP-based Internet or IPX-based local-area networks. H.323 is a very flexible recommendation that can be applied in a variety of ways—audio only (IP telephony); audio and video (video telephony); audio and data; and audio, video, and data—over point-to-point and point-to-multipoint multimedia conferencing. It is not necessary for two different clients to support the same mechanisms to communicate because individual capabilities are exchanged at the beginning of any session, and communication is set up based on the lowest common denominator. Point-to-multipoint conferencing can also be supported without the presence of any specialized hardware or software.

H.323 is part of a family of ITU-T recommendations illustrated in Table 7.6. The family is called H.32x and provides multimedia communication services over a wide variety of networks. Interoperation between these different standards is obtained through a **Gateway** that provides data format translation as well as controls signaling translation, audio and video codec translation, and call setup/termination functionality.

The H.323 standard defines four components that, when networked together, provide the point-to-point and point-to-multipoint multimedia–communication services:

(1) **Terminals:** These are the endpoints of the H.323 conference. A multimedia PC with a H.323 compliant stack can act as a terminal.

(2) **Gateway:** As discussed earlier, gateway is only needed whenever conferencing needs to be done between different H.32X-based clients.

(3) **Gatekeeper**: This provides many functions, including admission control and bandwidth management. Terminals must get permission from the gatekeeper to place any call.

(4) **Multipoint control unit** (MCU): This is an optional component that provides point-to-multipoint conferencing capability to an H.323-enabled network. The MCU consists of a mandatory multipoint controller (MC) and optional multipoint processors (MP). The MC determines the common capabilities of the terminals by using H.245, but it does not perform the multiplexing of audio, video, and data. The multiplexing of media streams is handled by the MP under the control of the MC. Figure 7.8, illustrates an H.323-enabled network with all these different components.

Figure 7.9 illustrates the protocol stack for H.323. RTP and its associated control protocol, RTCP, are employed for timely and orderly delivery of packetized audio/video streams. The operation of RTP and RTCP has been discussed in earlier sections.

The H.225 RAS (registration, admission, and status) is mainly used by H.323 endpoints (terminals and gateways) to discover a gatekeeper, to register/unregister with the gatekeeper, to request call admission and bandwidth allocation, and to clear a call. The gatekeeper can also use this protocol for inquiring on an endpoint and for communicating with other peer gateways.

The Q.931 signaling protocol is used for call setup and teardown between two H.323 endpoints and is a lightweight version of the Q.931 protocol defined for PSTN/ISDN. The H.245 media control protocol is used for negotiating media processing capabilities, such as audio/video codec to be used for each media type between two terminals, and determining master–slave relationships.

Real-time data conferencing capability is required for activities such as application sharing, whiteboard sharing, file transfer, fax transmission, and instant messaging. Recommendation T.120 provides this optional capability to H.323. T.120 is a real-time data communication protocol designed specifically for conferencing needs. Like H.323, Recommendation T.120 is an umbrella for a set of standards that enable the real-time sharing of specific applications data among several clients across different networks.

Table 7.7 illustrates the different phases involved in setting up a point-to-point H.323 conference when a gatekeeper is present in an H.323 network. The first three phases correspond to call setup, whereas the last three correspond to call teardown. When no gatekeeper is involved, phases 1 and 7 are omitted.

Accordingly, two call control models are supported in H.323: **direct call** and **gatekeeper-routed call**. In the direct call model, all Q.931 and H.245 signaling messages are

exchanged directly between the two H.323 endpoints, which is similar to what happens for RTP media streams. As long as the calling endpoint knows the transport address of the called endpoint, it can set up a direct call with the other party. This model is unattractive for large-scale carrier deployments because carriers may be unaware of which calls are being set up, and this may prevent them from providing sufficient resources for the call and charging for it. In the gatekeeper-routed call model, all signaling messages are routed through the gatekeeper. In this case, use of RAS is necessary. This model allows endpoints to access services provided by the gatekeeper, such as address resolution and call routing. It also allows the gatekeepers to enforce admission control and bandwidth allocation over their respective zones. This model is more suitable for IP telephony service providers because they can control the network and exercise accounting and billing functions.

TABLE 7.7 Phases in an H.323 Call

Phase	Protocol	Intended functions
1. Call admission	RAS	Request permission from gatekeeper to make/receive a call. At the end of this phase, the calling endpoint receives the Q.931 transport address of the called endpoint.
2. Call setup	Q.931	Set up a call between the two endpoints. At the end of this phase, the calling endpoint receives the H.245 transport address of the called endpoint.
3. Endpoint capability	H.245	Negotiate capabilities between two endpoints. Determine master-slave relationship. Open logical channels between two endpoints. At the end of this phase, both endpoints know the RTP/RTCP addresses of each other.
4. Stable call	RTP	Two parties in conversation.
5. Channel closing	H.245	Close down the logical channels.
6. Call teardown	Q.931	Tear down the call.
7. Call disengage	RAS	Release the resources used for this call

7.4.6 Session Initiation Protocol

Session Initiation Protocol (SIP) is an application-layer signaling protocol for creating, modifying, and terminating multimedia sessions (voice, video, or data) with either one or more participants (Johnston, 2000; Schulzrinne and Rosenburg, 2000; Arora and Jain, 1999). SIP does not define what a session is; this is defined by the content carried opaquely in SIP messages. To establish a multimedia session, SIP has to go through the following stages.

- **Session initiation:** Initiating a session is perhaps the hardest part because it requires determining where the user to be contacted is residing at the current moment: the user may be at home working on a home PC or may be at work on an office PC. Thus, SIP allows users to be located and addressed by a single global address (usually an e-mail address) irrespective of the user's physical location.
- **Delivery of session description:** Once the user is located, SIP performs the second function of delivering a description of the session that the user is invited to. SIP itself is opaque to the session description in the sense that it does not know anything about the session. It merely notifies the user about the protocol to be used so that the user can understand the session description. Session Description Protocol (SDP) is the most common protocol used for this purpose. SIP can also be used to decide a common format to describe a session so that protocols other than SDP can also be used.
- **Active session management:** Once the session description is delivered, SIP conveys the response (accept or reject) to the session initiation point (the caller). If the response is "accept," the session becomes active. If the session involves multimedia, media streams can now be exchanged between the two users. RTP and RTCP are some common protocols for transporting real-time data. SIP can also be used to change the parameters of an active session, such as removing some video media stream or reducing the quality of the audio stream.
- **Session termination:** Finally, SIP is used to terminate the session.

Thus, SIP is only a signaling protocol and must be used in conjunction with other protocols like SDP, RTP, or RTCP to provide a complete multimedia service architecture as the one provided in H.323. Note that the basic functionality and operation of SIP does not depend on any of these protocols. The SIP signaling system consists of the following components:

- **User agents:** The end system acts on behalf of a user. If the user–agent initiates SIP requests, it is called user–agent client (UAC); a user–agent server (UAS) receives such requests and return responses.
- **Network servers:** There are three types of servers in a network:
  (1) **Registration server (or registrars)**: This server keeps track of the user location (i.e., the current PC or terminal on which the user resides). The user–agent sends a registration message to the SIP registrar, and the registrar stores the registration information in a location service via a non-SIP protocol (e.g., LDAP). Once the information is stored, the registrar sends the appropriate response back to the user–agent.
  (2) **Proxy server**: Proxy servers are application-layer routers that receive SIP requests and forward them to the next hop server that may have more information about the location of the called party.
  (3) **Redirect server**: Redirect servers receive requests and then return the location of another SIP user agent or server where the user might be found.

It is quite common to find proxy, redirect, and registrar servers implemented in the same program.

SIP is based on an HTTP-like request/response transaction model. Each transaction consists of a request that invokes a particular method, or function, on the server and at least one response. Just as for HTTP, all requests and responses use textual encoding for SIP. Some commands and responses of SIP and their use are illustrated in Table 7.8.

Message format for SIP is shown Figure 7.10. The message body is separated from the header by a blank line. The **Via** indicates the host and port at which the caller is expecting a

response. When an SIP message goes through a number of proxies, each such proxy appends to this field with its own address and port. This enables the receiver to send back an acknowledgment through the same set of proxies. The **From** (or **To**) field specifies the SIP URI of the sender (or receiver) of the invitation, which is usually the e-mail address assigned to the user. The **call-ID** contains a globally unique identifier of this call generated by a combination of a random string and IP address. The **Content-Length** and **Content-Type** fields describe the body of the SIP message.

We now illustrate a simple example (refer to Figure 7.11) that captures the essence of SIP operations. Here, a client (caller) is inviting a participant (callee) for a call. The SIP client creates an INVITE message for callee@uic.edu, which is normally sent to a proxy server (step 1). This proxy server tries to obtain the IP address of the SIP server that handles requests for the requested domain. The proxy server consults a location server to determine this next hop server (step 2). The location server is a non-SIP server that stores information about the next hop server for different users and returns the IP address of the machine where callee can be found (step 3). On getting this IP address, the proxy server forwards the INVITE message (step 5) to the host machine. After the UAS has been reached, it sends an OK response back to the proxy server (step 8), assuming that the callee wants to accept the call. The proxy server, in turn, sends back an OK response to the client (step 9). The client then confirms that he or she has received the response by sending an ACK (step 10). A full-fledged multimedia session is now initiated between the two participants. At the end of this session, the callee sends a BYE message to the caller (step 11), which in turn ends the session with another BYE message (step 12). Note that we have skipped the TRYING and RINGING message exchanges (step 4, step 6, and step 7) in the above explanation.

7.5 Quality of Service Architecture for Third-Generation Cellular Systems

Over the past decade, a phenomenal growth in the development of cellular networks around the world has occurred. Wireless communications technology has evolved over these years, from a simple first-generation (1G) analog system supporting only voice (e.g., AMPS, NMT, TACS, etc.) to the current second-generation (2G) digital systems (e.g., GSM, IS-95, IS-136, etc.) supporting voice and low-rate data. We are still evolving towards the third-generation (3G) digital system (e.g., IMT-2000, cdma2000 etc.) supporting multimedia (Garg, 1999).

IMT-2000/UMTS is the 3G specification under development by the ITU that will provide enhanced voice, data, and multimedia services over wireless networks. In its current state, the plan is for IMT-2000 to specify a **family of standards** that will provide at least a 384 kbps data rate at pedestrian speeds, 144 kbps at mobile speeds, and up to 2 Mbps in an indoor environment. Numerous standard bodies throughout the world have submitted proposals to the ITU on UMTS/IMT-2000.

In 1997, Japan's major standards body, the Association for Radio Industry and Business (ARIB), became the driving force behind a 3G radio transmission technology known as wideband CDMA (WCDMA) (Steinbugl and Jain, 1999). In Europe, the European Telecommunications Standards Institute (ETSI) Special Mobile Group (SMG) technical subcommittee has overall responsibility for UMTS standardization. ETSI and ARIB have managed to merge their technical proposal into one harmonized WCDMA standard air interface. In the United States, the Telecommunications Industry Association (TIA) has proposed two air interface standards for IMT-2000, one based on CDMA and the other based on TDMA. Technical committee TR45.5 in TIA proposed a CDMA-based air interface, referred to as cdma2000, that maintains backward compatibility with existing IS-95 networks. The second proposal comes from TR45.3, which adopted the Universal Wireless Communications Consortium's (UWCC) recommendation for a 3G air interface that builds off existing IS-136 networks. Last but not least, the South Korean Telecommunications Technology Association (TTA) supports two air interface proposals, one similar to WCDMA and the other to cdma2000.

In the discussion that follows, we describe the layered QoS architecture that has been adopted by the UMTS standard (Garg, 1999; Dixit *et al.*, 2001). In UMTS there is a clear separation between the radio access network (called UMTS Terrestrial Radio Access Network or UTRAN), which comprises of all the air interface related functions (like medium access), and the Core Network (CN) that comprises switching- and control-related functions. Such separation allows both the CN and the radio access network to evolve independently of each other. UTRAN and CN exchange information over the Iu air interface.

Network services are end-to-end (i.e., from Terminal Equipment (TE) to another TE). An end-to-end service has certain QoS requirements that are provided to the user by the network (called network bearer service in telecommunication terminology). A network bearer service describes how a given network provides QoS and is set up from the source to the destination. The UMTS bearer service layered architecture is illustrated in Figure 7.12. Each bearer service at layer N offers its service by using the services provided to it by the layer $(N-1)$.

In the UMTS architecture, the end-to-end bearer service has three main components: the **terminal equipment** (mobile terminal) TE/MT local bearer service, the **external local bearer service**, and the **UMTS bearer service**.

The TE/MT local bearer service enables communication between the different components of a mobile station. These

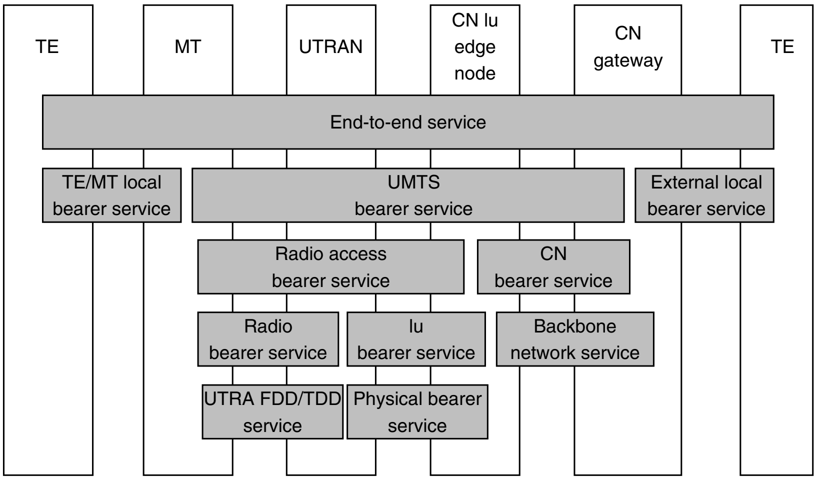

FIGURE 7.12 UMTS QoS Architecture. Adapted from Crow *et al.* (1997).

components make up an MT, mainly responsible for the physical connection to the UTRAN through the air interface, and one or several attached end user devices, also known as TEs. Examples of such devices are communicators, laptops, or traditional mobile phones.

The external bearer service connects the UMTS core network and the destination node located in an external network. This service may use IP transport or other alternatives (like those provided by IntServ, DiffServ, or MPLS).

The UMTS bearer service uses the radio access bearer service (RAB) and the core network bearer service (CN). Both the RAB and CN reflect the optimized way to realize UMTS bearer service over the respective cellular network topology, taking into account aspects such as mobility and mobile subscriber profiles. The RAB provides confidential transport of signaling and user data between the MT and the **CN Iu edge node** with the QoS negotiated by the UMTS bearer service. This service is based on the characteristics of the radio interface and is maintained even for a mobile MT.

The CN service connects the UMTS **CN Iu edge node** with the **CN gateway** to the external network. The role of this service is to efficiently control and use the backbone network to provide the contracted UMTS bearer service. The UMTS packet CN shall support different backbone bearer services for a variety of QoS options.

The RAB is realized by a radio bearer service and an Iu-bearer service. The role of the radio bearer service is to cover all the aspects of the radio interface transport. This bearer service uses the UTRA frequency/time–division duplex (FDD/TDD). The Iu bearer service provides the transport between the UTRAN and CN. Iu bearer services for packet traffic provide different bearer services for different levels of QoS.

The CN service uses a generic backbone network service. The backbone network service covers the layer 1 and layer 2 functionality and is selected according to the operator's choice to fulfill the QoS requirements of the CN bearer service. The backbone network service is not specific to UMTS but may reuse an existing standard.

8.1 Introduction

Computer and digital systems are becoming ubiquitous in all aspects of human endeavor, from everyday living (e.g., embedded systems in VCRs/VCDs and microwaves, personal computers) to business transactions (e.g., stock exchanges, efficient business-to-business transactions, economic predictions) to engineering and scientific applications (e.g., design of complex computer chips, mapping the human genome, numerical and non-numerical computations for various aspects of scientific research, weather prediction, modeling and simulation in astronomy and astrophysics, control of complex machine tools) and to life- and mission-critical systems (e.g., avionics, space-mission systems). Simultaneously, the complexity of these computer and digital systems are increasing every few months, and the electronic components (transistors and wires) used to design them are reducing in feature sizes dramatically over the same span. Current feature sizes have reached 90 nanometers, and further decreases are anticipated. Simultaneously, significant efforts are being undertaken in research on nanoelectronics, which will take feature sizes to the next level of compaction: nanometers. Voltage levels for these systems have also dropped significantly from the classical 5 V to its current levels of 1.1 V and lower. These developments augur well for more complex and faster processing on very large-scale integrated (VLSI) chips.

A crucial metric in which these rapidly advancing systems have fallen short is **reliability**. As feature sizes decrease, it

* This work was supported in part by the U.S. Department of Defense under the MURI grant F49620-01-1-0436.

becomes more likely that some latent fabrication defect on a chip shows up during operation (e.g., a transistor goes into permanent conduction mode, two wires placed too close to each other in violation of spacing requirements may get shorted during operation due to electromigration) (**permanent faults**)or some external disturbance such as alpha-particle or electromagnetic radiation can change voltage values in memory cells or interconnects (**soft errors/transient faults**). Reduction of voltage levels also means that digital circuits are more susceptible to external or internal noise, such as cross talk causing logic or delay faults. The study and development of techniques to detect faults in the operation of modern computer and digital systems and to reconfigure around them or correct them in some manner so that either the system performs correctly in the presence of such faults (**fault-tolerant** operation) or shuts down safely in the presence of irrecoverable errors (**fail-safe** operation) are thus exceedingly important. Furthermore, it is also wise to now have a somewhat different mind-set in designing these complex systems, namely, to invest some design time and chip real-estate to improving reliability of these systems, thereby increasing the dependability of a variety of applications that run on these systems.

Another dimension of system complexity, and thus, by definition, lower reliability (more things can fail) stems from multiprocessing. Currently, many critical and very computationally intensive applications (e.g., weather forecasting, environmental monitoring, and providing advanced prosthetic devices for the disabled) employ a number of multiple processors in either general-purpose multicomputer boxes or in embedded computing environments. The reliability problem of such complex computers increases by orders of magnitude. Many such multiprocessor systems have interconnection networks with topologies like meshes, toruses, and hypercubes that are integral to the correct and nondegraded operation of the overall system. In these systems, faulty components need to be reconfigured using spare ones, and structural integrity of the system needs to be preserved; that is, these systems need **structural fault tolerance** (Banerjee *et al.*, 1986; Bruck *et al.*, 1993a, 1993b; Chau and Liestman, 1989; Chung *et al.*, 1983; Dutt and Hayes, 1990, 1991, 1992, 1997; Dutt, 1993; Dutt and Mahapatra, 1997; Hayes, 1973; Mahapatra and Dutt, 2001; Raghavendra *et al.*, 1984; Rennels, 1986; Roy-Chowdhury *et al.*, 1990). A non fault-tolerant system consisting of a large number of highly reliable processors *can* have low system reliability because even a single component failure renders the system faulty or significantly degraded in performability. Thus, a 1024-processor system consisting of highly reliable individual components, each with a mean-time-to-failure (MTTF) of 85.34 years, has a system MTTF of only one month (Dutt and Mahapatra, 1997)! Large multiprocessor servers that power e-commerce and e-business enterprises have 99.9 to 99% availability or 8 to 80 hours of downtime per year (Patterson *et al.*, 2002). This translates to a $200,000 loss per hour for an Internet service like Amazon to a $6,000,000 loss per hour for a stock brokerage firm. It has been estimated that due to such downtime and associated system maintenance and recovery costs, the total cost of ownership is five to ten times or more compared to hardware and software purchase price (Patterson *et al.*, 2002). Consequently, system dependability today is a critical requirement for high-performance multiprocessor systems. This chapter focuses primarily on fault-tolerance techniques for uniprocessor computer systems and will not discuss multiprocessor fault-tolerance methods. The reader is directed to the various works cited previously for structural fault-tolerance methods for multiprocessor systems. There also exists a considerable amount of work on software-based fault-tolerance techniques, primarily **checkpointing** and **rollback recovery** for multiprocessor and distributed-processor systems that the reader can also peruse: Chandy and Ramamoorthy, Elnozahy *et al.* (2002), Huang and Kintala (1993), Koo and Toveg, Li and Fuchs (1990), Long *et al.* (1992), Ssu *et al.* (1999), and Wang *et al.*, (1995). Both classes of fault-tolerance techniques, structural/hardware and software/rollback-recovery are important for multiprocessor dependability.

8.1.1 Dependability and Fault-Tolerance Definitions

The trustworthiness of a computer system is characterized by its **dependability**. A system is dependable if "reliance can justifiably be placed on the service it delivers" (Laprie, 1992). There are many aspects under which a system can be dependable: two of the most important ones are **reliability** and **safety**. The first, reliability, is the ability to guarantee the continuity of the service provided, and the last, safety, is the certainty of avoidance of catastrophic consequences on the environment, either people or the system itself (Yu and Johnson, 2002; Johnson, 1989; Prasad, 1989). The reliability of a system is a time-dependent function and, unfortunately, cannot be always assured. System failures occur when the service of the system does not comply with the specification, and the behavior of the system deviates from that required by the user.

System **failures** are caused by erroneous transitions of the system state, due to either the failure of a system component or erroneous design. An **error** is a defective value in the system state that is liable to lead to failure: an error can lead to a failure depending on the system composition (applied redundancy) or on the activity of the system (an error may be overwritten). The adjudged or hypothesized cause of an error is a **fault**. This relation can be schematized as in Figure 8.1.

The types of faults and relative sources can be classified by nature, origin, and persistence (Yu and Johnson, 2002;

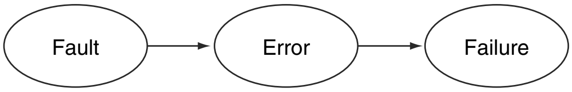

FIGURE 8.1 Fault, Error, and Failure Chain

Gunneflo *et al.*, 1989). The nature of a fault can be accidental or intentional, and the origin can be physically related or human-made. Taking into account the system boundaries, **internal faults** are parts of the system state, whereas **external faults** result from the interaction of the system with its physical environment (temperature, radiation) or human environment (operator).

A **permanent** fault is a fault whose presence is not related to internal or external time conditions and is usually caused by irreversible component damage. **Transient** faults are present for a limited amount of time and are usually triggered by environmental conditions, such as power-line fluctuation, electromagnetic interferences, or other radiation. These faults rarely do any lasting damage to the component affected although they can induce an erroneous state in the system. Finally, **intermittent** faults appear, disappear, and reappear repeatedly and are caused by unstable hardware or varying hardware state.

A fault is **active** when it produces an error and is **dormant** otherwise. An active fault is an external fault or a previously dormant one that was activated by the computation of the system. An error is **latent** prior to its detection and is **detected** if it is recognized by some mechanism.

To increase the dependability of a system, many strategies have been proposed in the literature for the different phases of the computing system development. In the design and implementation phase, **fault avoidance** can be achieved by proven design methodologies and technologies and by formal verification. In the test and debugging phase, **fault removal** can be performed. Both methods can be referred to as fault prevention and can avoid fault occurrence or introduction. In the operational phase, **fault-tolerance** methods are applied to provide a proper system service in spite of faults (Lee and Anderson, 1990).

8.1.2 Some Basics of Error Detection and Fault Tolerance

Detection mechanisms have to find out whether the actual state of the system is erroneous. To this end, the original system is supplemented by additional components that perform checks. Ideal checks are based solely on the specification and check the complete behavior of the system independently from the checked system to avoid the effects of errors to the checks (Lee and Anderson, 1990). The complexity of the system and the need of accessing the information to be checked usually prevents the implementation of an ideal checker. Less strict checks do not guarantee the absence of errors, but the results can still be accepted with a high probability.

The main metrics for error detectors are **hardware overhead** required to implement the check, **error latency** (time period between the occurrence of an error and its detection), and **error coverage** (percentage of errors that are detected).

Fault-tolerant operations and error detection are based on some form of redundancy and use of extra elements:

- **Hardware redundancy**: presence of extra hardware or data components (e.g., replication of the processor)
- **Information redundancy**: complementary information added to the original one (e.g., checksum, parity bits, error detection, and correction codes)
- **Functional or software redundancy**: presence of additional functions (e.g., *N*-version programming, reverse checking) for checking the results of a computation
- **Time redundancy**: additional time that is used to deliver the service of the system (e.g., multiple execution of the operation)

Error detection can be performed off-line, when the system is inactive (or in an idle state), or online, when the system is operational. The latter is referred to as **concurrent error detection**. The detection of transient faults requires continuous and concurrent error detection. Off-line checks usually include the systematic testing of the system by supplying special input test patterns to the components and investigating the outputs. The purpose is either to check whether the component satisfies the specification or to reveal some faults. These types of checks have high coverage but are expensive in resources and time, and so they are rarely implemented as diagnostic checks during the operational period of the system. For high availability-requirement systems, such as Web and database servers, the operational period is almost 100% of the time. Thus, concurrent error detection becomes very important for ensuring the dependability of such systems.

Fault-tolerance (FT) as well as fault-detection (FD) schemes can be implemented at various levels of a computing system. At the highest level is **algorithm/application based fault tolerance** (ABFT), where some property of the computation or algorithm is used to check the correctness of the results and possibly correct erroneous ones (Assaad and Dutt, 1992; Banerjee *et al.*, 1990; Boley and Luk, 1991; Boley *et al.*, 1995; Dutt and Assaad, 1996; Dutt and Boley, 1999; Huang and Abraham, 1984; Jou and Abraham, 1986; Luk and Park, 1988; Roy-Chowdhury and Banerjee, 1993). The most prevalent form of redundancies applied here are information and time redundancies. The next level is the **system level**, where the control and data flow of a computation being executed by a computer are concurrently checked for "reasonableness" by various FD schemes (DeLord and Saucier, 1991; Lu, 1982; Mahmood and McCluskey, 1988; Ohlsson and Rimen, 1995; Rota, 2002; Trovo, 2002). If the computation flow is in the given high-level specifications of the program, it is deemed correct. System level FT techniques include rolling back the state of the computer to the state prior to the occurrence of a detected error and restarting from that correct state, called **microrollback** (Tamir and Tremblay, 1990; Trovo, 2002). System-level FT and FD techniques primarily use hardware redundancy. The third and most detailed level of FT and FD is at the **circuit level**. These include FT and FD techniques for random-access memories (RAMs) (Tanner, 1984; Mazumder and

Chakraborty, 1996; Mazdumer and Yih, 1993) and arithmetic circuits (Al-Arian and Gumusel, 1992; Avizienis, 1973; Chen *et al.*, 1992; Dutt and Hanchek, 1999; Hsu and Swartzlander, 1992; Johnson *et al.*, 1988; Johnson, 1989; Laha and Patel, 1983; Lo *et al.*, 1993; Nicolaidis, 1993; Patel and Fung, 1982, 1983; Rao, 1968, 1974; Sparmann and Reddy, 1994), and general logic circuits (Johnson, 1989; Lala, 1985; Pradhan, 1990; Roth, 1975). Circuit-level FT and FD mechanisms generally involve all three forms of redundancies: hardware, information, and time. A highly dependable computer system is one that will have FT/FD mechanisms implemented at least in the last two levels (system and circuit levels).

8.1.3 Fault Models

We focus here on faults resulting from physical problems, discounting specification, design, implementation, and operator mistakes in the system. The causes of physical faults in computer and digital systems are many and varied. They range from **fabrication defects** (e.g., shorting of the drain and source of an nMOS or pMOS transistor), to **operational faults** caused by extreme operation conditions (e.g., electromigration in adjacent interconnects from high current density resulting in shorting of the interconnects, overheating in a portion of a chip resulting in damage or unpredictable behavior of transistors), and to **external disturbance** (e.g., alpha-particle or electromagnetic radiation that can change voltage values on interconnects and capacitances such as those present in dynamic RAM cells and in environmental extremes of temperature, pressure, and moisture).

To design effective FD and FT techniques, it is necessary to encapsulate the primary effects of such faults in a manageable and general **fault model** that accounts for the behavior for most, if not all, fault types. Mechanisms to tackle faults can then be designed in a general and effective way by addressing the fault model rather than the very large number of faults underlying that model (Hayes, 1985; Johnson, 1989). Two classical fault models that have proven reasonably effective are the **logical stuck-at-fault** model used at the logic circuit level and the **transistor stuck-at-fault** model used at the transistor circuit level.

In the logical stuck-at-fault model, it is assumed that a fault causes a module to respond as if one of its inputs or outputs is physically stuck at a logic 1 (called **stuck-at-1**) or 0 (called **stuck-at-0**) without its basic functionality being altered (Johnson, 1989; Kohavi, 1978). In other words, this fault model assumes that the effect of faults is the same as that of interconnects being stuck-at-0/1. Consider, for example, an AND gate with two inputs A and B and with the A input wire being shorted to a ground wire due to electromigration. This will cause both the A input wire (and the AND gate's output) to be always at logic 0, and thus this physical fault can be modeled as a stuck- at-0 fault of A. Another example is that of a two-input CMOS NAND gate that has two pMOS transistors in parallel connected to the supply voltage and two nMOS transistors in series connected to ground (Johnson, 1989). If the source and drain of one of the pMOS transistors is shorted, then it always conducts irrespective of its gate voltage; the output of the NAND gate is always connected to the supply voltage and thus always at logic 1. Thus, this fault can be modeled by the NAND gate output being stuck-at-1.

This fault model, however, does not cover all types of faults. One example is that of two signal wires X and Y being shorted to each other (called a **bridging fault**). If the driver strength of X is significantly greater then that of Y, then Y's logic value will follow X's, which can take on either 0 or 1 values depending on the input to the circuit. Thus Y is neither stuck-at-0 nor stuck-at-1 permanently, though, of course, it can cause an error in the circuit output. This fault cannot be modeled by the logical stuck-at-fault model. Another example is that of a CMOS NOR gate with inputs A and B. This gate has two pMOS transistors in series connected to the supply voltage and two nMOS transistors in parallel connected to ground. The A input feeds a pMOS and an nMOS transistor. If the branch of the A wire that feeds the nMOS transistor is broken, then the gate of this transistor is at logic 0, and it never conducts. When the inputs are A, $B = 1$, 0, the pMOS network is not conducting, and the nMOS network is not connected to ground (the latter due to the wire break—the correct operation would have been for the nMOS network to conduct). This leaves the output of the NOR gate connected to neither supply voltage nor ground, and it assumes the voltage is stored at its load capacitance, which is its previous value. Thus, this fault does not manifests itself as the NOR gate's output (or for that matter any of its inputs) being either stuck-at-0 or stuck-at-1.

Some of the inadequacies of the logic stuck-at-fault model are overcome by the transistor stuck-at-fault model that assumes a fault's behavior is akin to one or more transistors always conducting (**stuck-at-on**) or always in a nonconducting state (**stuck-at-off**) irrespective of gate inputs. For example, the above wire-break fault in the NOR gate can be modeled as the corresponding nMOS transistor stuck-at-off. Even this model, however, cannot simulate a bridging fault. A clear disadvantage of the transistor stuck-at-fault model vis-a-vis the logic stuck-at-fault model is the additional complexity in terms of the number of components that must be represented, manipulated, and simulated (Johnson, 1989).

In the sequel, we model faults using the logic stuck-at fault model, which, in spite of its limitations, covers a large number of physical fault types.

The rest of this chapter is organized as follows. We discuss various FD and FT techniques at various levels of application, down from the circuit up to the application level. For each of these discussions, we present various important work in that area and then give a more detailed discussion of work done in our group. In Section 8.2, we present FD and FT techniques for arithmetic circuits, whereas in Section 8.3, we explain methods for field-programmable gate arrays that can be considered a mix of circuit-level and system-level techniques. In Section 8.4, we discuss various control-flow checking methods using a watchdog processor, and in Section 8.5, we present processor micro rollback techniques for recovering from detected errors like CFC errors. In Section 8.6, we describe ABFT methods for achieving FD and/or FT at the application level. We conclude in Section 8.7 with a summary of our findings.

8.2 Fault Detection and Tolerance for Arithmetic Circuits

In this section, we discuss various FD and FT techniques for arithmetic circuits. Many previous designs are only able to detect one error in the operation and are classified as one-fault detecting (1-FD). If the error is caused by a transient fault, the arithmetic circuit can still be used. Otherwise, the circuit and possibly the entire processor in which it is embedded become useless and must be replaced. Single error detecting designs include duplication, time-redundancy techniques like recomputation with shifted operands (RESO) (Patel and Fung, 1982, 1995), or recomputation with duplication with comparison (REDWC) (Johnson *et al.* 1988) and information redundancy methods that use residue codes (Avizienis, 1973; Rao, 1968), Berger codes (Lo *et al.*, 1993), *AN* codes (Avizienis, 1973), or parity prediction (Nicolaidis, 1993). While time redundancy techniques have a very high time overhead, duplication has high hardware overhead, and coding methods have appreciable time as well as hardware overhead. Duplication is the classic hardware redundant method for error detection and simply compares the results of two copies of a circuit. It is fast but cannot correct an error. RESO (Patel and Fung, 1982, 1995) is a well-known time redundant error detection method. After an original computation in RESO, operands are shifted left so that a fault, if present, will affect a different output bit, and then a second computation is performed. The result is shifted right, and any difference from the first result indicates an error. The time overhead is 100%, and no error correction is possible without additional recomputations. Another error detecting technique is REDWC (Johnson *et al.*, 1988), which divides a circuit into identical upper and lower partitions. The lower halves of the operands are applied to both partitions, and results are compared. For the upper portions of the operands, the procedure is repeated. If the partitions are linearly dependent, as in a ripple-carry adder, then time overhead is due only to comparisons and can be very low. If the partitions are independent, however, then the time overhead becomes 100%.

Arithmetic codes provide information redundancy, where extra information is encoded with the operands, and this information is processed concurrently with the operands. For residue codes (Avizienis, 1973; Rao, 1968; Sparmann and Reddy, 1994), the additional information is a **residue**, which is generated by performing a **mod** operation on each operand. Processing these residues yields a value that matches the residue of the result if there is no error. Area overhead can be reasonable when applied to a large circuit such as a multiplier (Sparmann and Reddy, 1994) but is generally quite high for an adder. Residues mod $(2^i - 1)$ are considered the easiest to compute, and a tree of $(2^i - 1)$-bit end-around-carry adders is typically used for this purpose, but time overhead is very high, even for a multiplier. In Berger codes (Lo *et al.*, 1993), the extra information encoded is the number of zeros in an operand. This information, combined with information about the internal carries generated during the operation, is used to predict the number of zeros in the result. Berger check prediction methods have been applied to adders and array multipliers with time overheads of less than 100%, but area overhead is very high for low-complexity circuits like ripple-carry adders. *AN* coding (Avizienis, 1973) involves multiplying each data word *N* by a selected constant *A*. Results of arithmetic operations on these codes are checked by dividing by *A*; a nonzero remainder indicates an error. Although *A* is selected to make encoding and decoding easy, these operations are still hardware and time intensive. Parity prediction (Nicolaidis, 1993) uses the parities of the operands and the parity of the internal carries generated during an operation (Nicolaidis, 1993) to predict the parity of the result. A disagreement between predicted and actual result parities indicates an error. Since this method depends on the correctness of the internal carries, it must ensure this by generating them independently of the arithmetic functional unit, thus increasing the area overhead.

There have also been designs proposed that can correct a single error, and these are classified as one-fault tolerant (1-FT). These designs arise by using fault masking as in error-correcting RESO (Laha and Patel, 1983) and triple modular redundancy (TMR) (Johnson, 1989), using a hybrid redundancy scheme as in partitioned TMR (PTMR) (Arian and Gumusel, 1992; Chen *et al.*, 1992; Hsu and Swartzlander, 1992), or using arithmetic codes (Rao, 1971). In such schemes, the circuit can still operate correctly in the presence of a single permanent fault but will become useless when a second permanent fault occurs.

Error-correcting RESO (Laha and Patel, 1983) is essentially triple-time redundancy. The circuit and its operands are divided into at least three partitions. Successive recomputations are performed while shifting the operand portions such that each portion is recomputed into three different circuit partitions. In a circuit with dependent partitions, such as an adder, an erroneous carry may propagate an error between partitions, making it impossible for a given portion of the result to be computed correctly. To avoid this problem, comparison of intermediate results produces error syndromes that can identify the faulty partition and allow correct carries to be saved and then rerouted in successive recomputations. Variations on the technique trade off additional hardware with a fourth computation. Finally, correct result portions are located and assembled into a complete result. Hardware overhead can be quite reasonable for a sufficiently complex original circuit, but the necessity of at least three complete computations makes the time overhead excessively high ($\geq$200%).

In TMR (Johnson, 1989), the classic hardware redundant technique for error correction, three copies of a module perform the same computation simultaneously. A majority voter selects the result upon which at least two of the modules have agreed. Time overhead is very small, but hardware overhead is greater than 200%. A related technique, PTMR, has been developed by three independent groups (Arian and Gumusel, 1992; Chen *et al.*, 1992; Hsu and Swartzlander, 1992), and is also known as hardware partition in time redundancy (HPTR) (Arian and Gumusel, 1992) and recomputing with triplication with voting (RETWV) (Hsu and Swartzlander, 1992). In this technique, three copies of a single partition of the circuit simultaneously process a portion of the operands, and the results are voted on, as in TMR. The remaining portions of the operands are processed similarly by the same triplicated partition. When there are three independent partitions, the time overhead is 200%. For linearly dependent partitions in adders and multipliers, time overhead can be lower, and area overheads range from under 100% to about 150%.

Some arithmetic codes can also provide error correction by generating unique error syndromes for each single-bit error (Rao, 1974). In the case of residue coding, this requires multiple residues, thus increasing the area. For *AN* coding, it precludes the use of "low cost" *A* values, thus increasing the time spent on decoding. Error correcting codes, therefore, have such high time and/or area overheads, making them uncompetitive with other methods.

8.2.1 The Reprocessing with Micro Delays Method

We now discuss the reprocessing with micro delays (REMOD) technique for designing FT arithmetic circuits that can detect errors and reconfigure around the fault for correct operation (Dutt and Hanchek, 1997). REMOD has much smaller time overheads than RESO and REDWC, and its hardware and time overheads are typically less than or comparable to methods that are only 1-FD, such as duplication or information redundancy.

A key feature of REMOD designs is that they are extendible to multiple fault tolerance, with only small increments of hardware and time—in some cases, the designs have virtually no increase in time. On the other hand, PTMR and the other techniques are not as easily extendible, if at all. As a result, the mean time to failure (MTTF) of processors using REMOD-based arithmetic circuits will increase substantially. This is especially crucial in computer systems used in life- and property-critical applications, such as avionics, spacecraft control, military applications, and the control of industrial processes and nuclear reactors. Not only are these environments hostile with regard to increasing fault probabilities, but maintenance is either very difficult or impossible to perform during the operation of these systems. This underscores the need for very high MTTF computer systems in these applications, and REMOD is a means to achieving this in the execution part of a system. It is also a means to increase the availability of more general purpose computer systems and to reduce their maintenance costs.

REMOD Operation

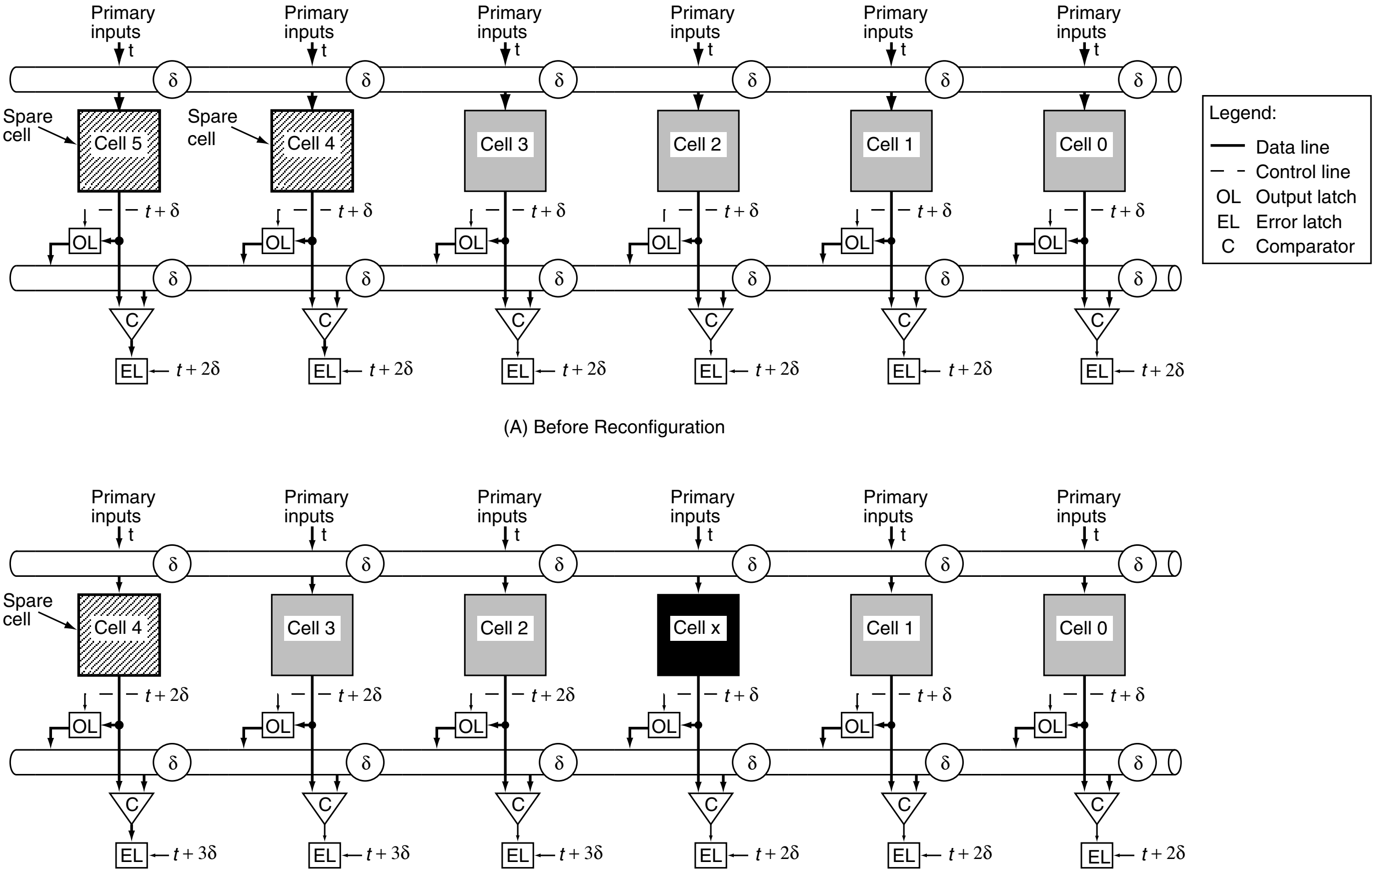
The main idea behind REMOD is to assign a cover v to each cell u of the circuit, where the cover is a functionally identical cell that checks the computation of u after both have finished their original computations. The **original computation** of a cell is the computation it performs in the non-FT circuit. All inputs to cell u are transmitted to its cover v after some delay that depends on the delay of the cells. After cell v repeats u's original computation (called v's **checking computation**), the corresponding outputs of this computation are compared to the original outputs of u. A mismatch indicates a fault in either u or v, and a diagnostic routine can determine which of the two is actually faulty. REMOD circuits are then reconfigured around the faulty cell to resume normal operation.

REMOD can be applied to circuits containing an array of independent cells, such as a carry-save adder, or an array of linearly dependent cells, such as a ripple-carry adder. REMOD has also been applied to partially dependent cells found in a multiplier by partitioning the circuit into sub-arrays of independent cells.

Array of Independent Cells

In Figure 8.2, each cell i is covered by cell $i+1$. Suppose that all inputs are available to the circuit at time t and that the maximum propagation delay of a cell is δ. Then all original outputs are available from the primary cells at time $t+\delta$. At time $t+\delta$, the outputs are latched, and the inputs are forwarded to the cover cells for the checking computation. At time $t+2\delta$, the checking outputs are available from the cover cells. These are compared with the latched original outputs, which have also been forwarded to the cover cells, and any error signals are latched.

To provide reconfigurability and multiple fault tolerance, it is necessary to forward inputs and outputs past faulty cells for recomputation and comparison. We refer to such forwarding as **pipelining** and illustrate the concept in Figure 8.2(B), where it is seen that cell 2 has become faulty. Each covering cell $j>2$ *replaces* its dependent cell $j-1$ in the sense that it now does the original computation of cell $j-1$, and a spare cell replaces the last primary cell in the array. In the reconfigured circuit, the second computations (produced at $t+2\delta$) of all cells $j\geq 2$ become the original outputs, as shown in Figure 8.2(B). The third computation of these cells is now the checking computation, and the pipeline continues to forward the original outputs at the proper time for comparison.



(A) Before Reconfiguration

(B) After Reconfiguration

FIGURE 8.2 Array of Independent Cells. (A) This image shows an FT design for independent cells before reconfiguration. (B) Shown here is a reconfiguration around faulty cell 2; cell labels are those after reconfiguration.

Array of Dependent Cells

The FT designs for linearly connected dependent cells can be obtained by some simple modifications to the designs for independent cells presented in the previous paragraphs. Essentially, the fact that the original inputs of all cells are not available at the same time differentiates between arrays of independent and dependent cells.

Consider a ripple-carry adder for which each stage is a full-adder cell dependent on the carry out from the previous stage. Each cell can receive all of its original inputs δ time units only after the previous cell receives its inputs, and so it is not ready to perform a checking operation until after an additional δ time units. Checking inputs must then be forwarded to each cell 2δ time units after they have been input for the primary computation. The last checking computation completes (in the spare cell) 2δ time units after the last original computation, giving a time overhead factor of $2/n$ for error detection in an n-cell adder. This can be reduced to $1/n$ since the spare is not needed for an original computation and can thus perform a checking computation earlier.

Reconfiguration in a circuit of dependent cells is analogous to the method employed for independent cells. Inputs are forwarded past the faulty cell and the computations, original and checking, in all cells beyond the faulty cell are delayed by δ time units compared to those in the circuit that is not faulty.

Multiple FT can be obtained in either independent or dependent cells by adding more spares. The pipelines forward inputs (and outputs used for comparison) past the faulty cells, and the computations in those cells beyond the faults are delayed an additional δ time units each time the pipeline flows past a faulty cell. If there are $f \leq k$ faults in a k-FT REMOD design, then the original computation has a time overhead of $f\delta$ in the worst case. Pipelines implemented with banks of multiplexers rather than delay lines can reduce this overhead to 0, however (Dutt and Hanchek, 1997). In all cases, error detection takes δ more time after the original computation.

Adder and Multiplier Applications

The REMOD method was applied to a ripple-carry adder, which consist of fully dependent linearly connected cells (Dutt and

Hanchek, 1997). The cells are either 1-bit or 4-bit carry lookahead (CLA) adders. REMOD was also applied to multipliers based on a Wallace tree and on a carry-save array for the summation of partial product terms (Dutt and Hanchek, 1997). The multipliers are partitioned into arrays of independent subcells, but the high time overhead normally associated with independent cells is masked through a clever application of REMOD. Original and checking computations overlap in time between adjacent rows of subcells as the computations proceed down the array or Wallace tree. The designs were laid out using the Berkeley MAGIC tools for CMOS. The multiplier designs were implemented in CMOS dynamic logic. Delay elements were implemented as strings of inverters. Error injection gates were inserted into the layout to simulate stuck-at faults. The layout tools allow geometry information to be extracted and converted to SPICE parameters. Simulations of the circuits using delay element pipelining were then performed using HSPICE. The simulations successfully tested the functions of error detection and reconfiguration, with selected nodes in the SPICE files for the circuits forced to logic *high* or *low* to simulate faults.

Adders

Table 8.1 compares the REMOD method for adders to other methods of fault tolerance. For REMOD adders, multiplexer forwarding was used, and data are presented both for cell output comparison and for output parity comparison (Dutt and Hanchek, 1997). Since most of the available information concerning area overheads for the various fault tolerance methods is given in terms of transistor counts, comparisons are made using these numbers.

Some coding methods can provide error correction, but, as shown in Table 8.1, the area and/or time overheads of several hundred percent are excessively high. Since error-correcting RESO is essentially triple-time redundancy, it is much slower than REMOD although it has a small advantage in area overhead. TMR is very fast, but REMOD has a significant advantage in area, and with similar area overhead REMOD can even tolerate three faults. Partitioned TMR is most comparable to 1-FT REMOD in terms of overhead, with both of these techniques having area overheads of about 100 to 150% and time overheads of 10 to 30%. The big advantage of REMOD, however, is that it can be extended to tolerate multiple sequential faults.

Multipliers

Parallel multipliers have more complex structures than parallel adders. For example, an array multiplier has $\Theta(n)$ diagonals of linearly connected full adders, where n is the input length in bits, whereas the Wallace tree multiplier has a tree structure. The trick to applying REMOD to such complex structures is to bit-slice them and add some components, if needed, to bit-slice $i + 1$ so that it can cover bit-slice i. Each bit slice is then a cell of the circuit pertaining to the definition of covering and related concepts discussed earlier. Figure 8.3 shows a

generic circuit with a binary-tree structure that has been bit-sliced with added spare components (shown shaded) in this manner. The last bit slice is composed only of spares. Such a structure with the appropriate input and output pipelines will be 1-FD and, with some slight modifications, would also be 1-FT.

Two bit slices of a 6-bit FT Wallace tree multiplier are obtained using the "bit-slice-and-add" approach, shown in Figure 8.4. A 16-bit version was also laid out. Table 8.2 compares the area and time overheads of REMOD multipliers to those of other FT multipliers. Of the error-correcting multipliers, error-correcting RESO has the lowest area overhead, but its time overhead of up to 300% is extremely high. TMR has by far the lowest time overhead, but its 200% area overhead is extremely high. Comparing REMOD to PTMR for array multipliers shows that the time overheads are much the same, reaching less than 10%. REMOD's area overhead, however, is better than 30% less than that of PTMR. The area overhead fraction for a REMOD Wallace tree is even lower, with a transistor overhead of 48% and a layout area overhead of only 36%. The time overhead fraction *is* higher because the Wallace tree is a faster circuit than a carry-save array. Finally, we note that the hardware overhead for both types of 2-FT REMOD multiplier is also lower than that of a 1-FT PTMR multiplier; for 3-FT REMOD multipliers, the overhead is comparable to that of a 1-FT PTMR and

significantly lower than that of a 1-FT TMR multipliers. Thus, REMOD provides a very good balance between time and area efficiencies and provides greater fault tolerance than all the other methods.

Yield Improvement

In addition to increasing the reliability and availability of a circuit, improvement in chip yield is another important benefit of fault tolerance. With the aid of a model relating yield to circuit area and defect density, the yield improvement provided by a REMOD implementation has been analyzed taking into account the possibility of faults due to defects in the redundant portions of the circuitry (Dutt and Hanchek, 1997). Chip yield is defined as the percentage of usable chips. The Poisson yield model (Cunningham, 1990) was used for defect distribution where defects are assumed to occur uniformly and independently.[1] For a k-FT circuit, the yield is the sum of the circuit yields for each number of faulty cells up to k.

For adders, which have small, relatively simple cells, the yield improvement obtained is small. For a circuit with reasonably complex cells, however, very good yield improvement is obtained. This is shown in Figure 8.5 for 32-bit Wallace tree multipliers. It is also apparent in this figure that greater degrees of FT do provide greater yield improvement of well over 50%.

8.3 Fault Tolerance in Field-Programmable Gate Arrays

Field-programmable gate arrays (FPGAs) are now being used in production-scale quantities in various commerical and consumer products. Recent increases in speed and size (of the order of 300-MHz and 1-M gates) will expand this trend further. FPGAs have also found use in mission- and life-critical applications (e.g., the 1996 Mars Pathfinder mission) (Lach *et al.*, 1998). FPGAs form the core of adaptive computing platforms used in aircraft avionics, in which the FPGA hardware is rapidly reconfigured in run time to map the desired application to the platform. Current technology trends for FPGA devices are in the deep-submicron (DSM) regime with recent chips using 90 nanometer and seven metal layers. This trend, however, has also resulted in a decrease of fabrication yield (due to the extreme accuracy requirement of the process technology resulting in low error margins) as well as decreased reliability in operation (stemming, for example, from greater risk of electromigration and increased susceptibility to ionized

[1] While the Poisson model tends to underestimate yield when the product of defect density and chip area increases beyond unity, it is perfectly acceptable for the purposes of estimating yield improvement.

particle radiation). The larger die sizes also mean that there is more likelihood of failure. Thus, increasing the reliability of FPGA devices via testing and fault-tolerance techniques is necessary for achieving various goals ranging from increasing device fabrication yield (thus lowering costs) to increasing the availability and reliability of systems ranging from office products to mission- and life-critical systems.

As we mentioned in Section 8.1.1, the generic approach to increasing system reliability is to use some form of redundancy. However, redundancy at the chip level is not cost-effective for FPGAs, especially given the fact that such chips already lag behind in device density to custom ASIC chips. Furthermore, chip-level redundancy is not a feasible solution for various space-based and other systems for which weight, space, and power are at a premium and need to be optimized. Fortunately, FPGAs provide a fine granularity of replicated identical components (logic cells and interconnect segments) that can potentially be exploited to provide both testing and fault tolerance capabilities at low hardware and time overheads. We focus here on reprogrammable SRAM-based FPGAs (with a segmented wiring architecture) that are the most prevalent kind (e.g., Xilinx [Xilinx, 1994], Lucent ORCA [Lucent Technologies, 1998] and Altera Flex 8000 [Altera corporation, 1993] FPGA families) and also offer the most reprogramming flexibility needed for reconfiguration. Such a generic FPGA is shown in Figure 8.6.

Most fault-tolerance (FT) approaches for FPGAs make use of their inherent flexibility, replicability, and homogenity in the logic (PLB) and interconnect architecture. There are two broad classes of techniques: those requiring architectural modifications and those that are software-based.

One technique of the former type is adding spare rows and/or columns of cells and replacing every *i*-length-segment track with an $(i+1)$-length track and employing an extra such track to retain the original routing flexibility (Hatori, 1993). Another technique that assumes a nonconventional FPGA architecture results from work by Shnidman *et al.* (1998). The architecture required is one in which the entire routing area is composed of busses that run the entire span of rows or columns, with row busses being inputs only and column busses being outputs only—the interconnects are not segmented. Fault tolerance is then simply achieved by transposing configuration bits of a faulty PLB and that of the column busses to which it is connected to a spare PLB in its row and its corresponding column busses. However, bus-based FPGAs have several drawbacks, including inefficient use of interconnect resources, which means that only very sparsely wired designs—not typical of modern circuits—are implementable on such FPGAs, and timing delays for short nets are excessive, leading to slow designs.

One software-based method focuses on noting the locations of faulty cells and/or interconnects and rerouting the circuit to avoid using spares or unused cells/interconnects (McDonald *et al.*, 1991; Narasimhan *et al.*, 1994; Roy and Nag, 1995). This has been proposed for use in factory programmable gate arrays and potentially requires a different routing for every chip to which the user's circuit is mapped (Narasimhan *et al.*, 1994). This software-based method has also been proposed in the context of field reconfiguration for logic cell faults by McDonald *et al.* (1991) and for interconnect faults by Roy and Nag (1995). Requiring the layout tools to perform a new routing of a circuit for each new faulty cell or interconnect location encountered, however, puts a heavy burden on the user who must also keep track of all of the different routings for a given circuit design. Furthermore, in a mission- or life-critical system, it is desirable to perform fault reconfiguration quickly so that system function is suspended for only seconds. Complete rerouting of large FPGA circuits can take hours, which is unacceptable in such systems.

A newer approach of partial rerouting only in faulty tiles—a **tile** is a subarray of logic cells including a spare cell—has been proposed by Lach *et al.* (1998); this is a significant improvement over past full rerouting methods. In this technique, fast reconfiguration is achieved by precomputing all possible configurations of a tile (assuming one fault in it) and storing them for loading into the tile as and when a fault is detected. However, this technique has some of the other disadvantages of full rerouting methods. A rip-up-and-reroute approach for

incremental routing was developed by Emmert and Bhatia (1998) in a later work. Some results have been presented on the success of rerouting and computation times that are reasonable.

8.3.1 The Static Node-Covering Approach

Another software-based FT technique is the **node-covering** (NC) method (Hanchek and Dutt, 1998). It has several distinguishing features from other methods of this type. The NC method does not require the factory or the user to generate new routing maps to reconfigure around faulty cells or interconnects, as is required by other techniques (Lach *et al.*, 1998; McDonald *et al.*, 1991; Narasimhan *et al.*, 1994; Roy and Nag, 1995). Instead, the original configuration data can be reused. This FT method involves a routing strategy that requires the use of additional interconnect segments at all branch points of the original (non-FT) circuit routing. On the other hand, no explicit additional tracks are needed in the channels to avoid the loss of connection flexibility as explained by Hatori *et al.* (1993). Further, circuit electrical properties are minimally affected by these additional interconnect segments (called **cover segments** (CSs) or **reserved segments**); reconfiguration does not involve any rerouting and, hence, is very fast. CSs, however, cause some track overhead in the routing. This results in retaining total functionality with somewhat reduced routability or total routability with reduced functionality. We describe this method briefly in the subsequent paragraphs.

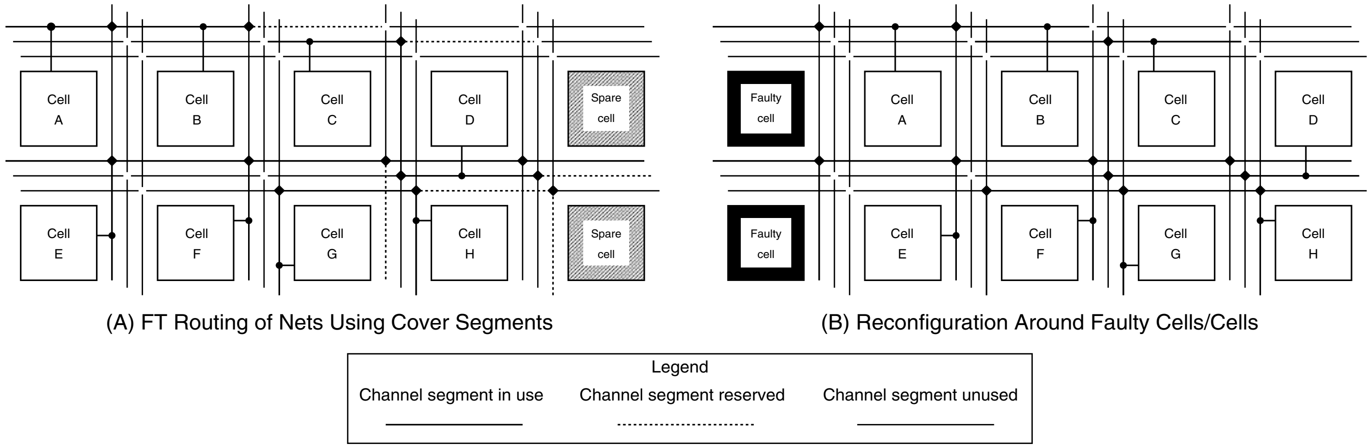
Under the NC approach, each logic cell u in the FPGA is assigned a **cover cell** that can be reconfigured to replace the logic cell in the event that cell u becomes faulty. Reconfiguration around a faulty u is completed by a **replacement sequence** in which u is replaced by one of its covers which in turn is replaced by one of its covers, and so on until a spare cell is configured in.

For a cell to cover another cell (the **dependent cell**), the cover cell must be able to duplicate the functionality of the dependent cell. In an FPGA, all cells are identical, so configuration data for the dependent cell can simply be transposed to the cover cell. The cover cell must also be able to duplicate the connectivity of the dependent cell with respect to the rest of the array. This is accomplished by ensuring that each net connected to a cell through a channel segment also includes the corresponding cover segment, CS, bordering the cover cell. Cover segments are included in a net in one of two ways. First, segments in the net may already be in positions to act as covers. In case the above condition does not hold, additional segments should be attached to the net to provide covers. Figure 8.7 illustrates the use of CSs.

There are two approaches for incorporating the required CSs in a circuit mapped to an FPGA: **static** and **dynamic**. These approaches are discussed next.

In the static method, reconfiguration paths are predetermined to conform to a certain pattern, such as from going left to right along rows (as depicted in Figure 8.7). CSs are then inserted wherever needed along these paths (also shown in Figure 8.7) as part of the original routing. This is a static approach in the sense that the CS insertion is oblivious to the presence and location of faults. Whenever faults occur that conform to the predetermined reconfigurable pattern (e.g., one fault per row), the transposition of configuration bits from dependent to cover cells automatically achieves complete reconfiguration—the interconnect "hooks" needed by the cover cells to connect to nets routed to their dependent cells are already in place. Thus, reconfiguration is extremely fast with times determined primarily by transposition of cell configuration bits.

In Hanchek and Dutt (1996a, 1996b, 1998), this technique was implemented by modifying the routing tools obtained from the University of Toronto. It was found that, on the average, for 18 benchmark circuits ranging in size from 79 to



(A) FT Routing of Nets Using Cover Segments

(B) Reconfiguration Around Faulty Cells/Cells

FIGURE 8.7 Using Cover Segments

508 nets, 34% more tracks are required than in a non-FT circuit to put the necessary CSs in place for reconfiguration. Good reliability and yield improvements are afforded by static CS insertion that can tolerate one faulty cell per row; for example, the percentage doubles a 35% non-FT yield for a 16×16 array and increases a non-FT reliability of 0.7 to 0.95. Net delays changed minimally (by at most approximately 7%) after reconfiguration. These results establish the static NC method as one of the best available for software-based reconfiguration of FPGAs with respect to several metrics: track overhead, reliability improvement, reconfiguration time, and circuit delay increase.

An even better-performing technique can potentially be developed by using the dynamic reconfiguration paradigm. Using such an approach will make it much easier to perform online testing and diagnosis, to reduce track overhead significantly, and to increase the number of possible fault patterns (and thus reliability) that can be reconfigured. Such a technique is discussed in Subsection 8.3.2.

8.3.2 The Dynamic Node-Covering Approach

The dynamic NC method has the following advantages: (1) better utilization of track resources—this will mean a higher rate of successful reconfigurations and thus greater fault tolerance; (2) fast on-line reconfiguration; (3) greater flexibility in tolerating fault patterns; (4) minimal changes in a circuit's electrical properties, including timing and power; (5) applicability to both cell and interconnect faults; and (6) applicability to other domains, such as online testing and diagnosis, wherein a "roving tester" can move around the FPGA during FPGA run time to test different parts of the FPGA (this requires run-time reconfiguration of the FPGA for remapping the working circuit and the tester) (Verma *et al.*, 2001).

The primary difference between static and dynamic methods is that, in the latter, CS insertions will not be part of the initial routing but will be made as and when required for fault reconfiguration (or in general, circuit reconfiguration for performing other functions like testing and diagnosis) and only to those nets connected to cells along reconfiguration paths. The dynamic method will thus significantly reduce the number of CSs required for FT, thereby making it easier to retain total functionality with much lower track overheads. Further, it allows reconfiguration paths from faulty cells to spare ones to be chosen dynamically, thus maximizing FT flexibility. The paths can have any arbitrary shape unlike the predetermined straight horizontal paths in the static NC method. The needed CSs can then be put in dynamically along any such chosen path. Since the configuration bits can be transposed along reconfiguration paths of any shape in FPGAs with incremental run-time-reconfiguration (RTR) capabilities, coupled with dynamic CS insertion, this allows reconfiguration around many more fault patterns than possible with the static method (e.g., fault clusters).

The shift from a static method to a dynamic one, however, introduces several interesting algorithmic problems. One of these is the fundamental issue of minimally changing the circuit routing to accommodate the needed CSs for reconfiguration in a fast and (near-)optimal manner with minimal effect on the circuit's electrical properties.

An approach to this problem that has yielded satisfactory results is shifting track assignments of nets (a process called **net bumping**) for accommodating the CSs needed for reconfiguration and "refitting" the bumped nets on other track positions. For simplicity of exposition, we describe this "bump-and-refit" (B&R) algorithm in the context of track segment lengths of one.

The general problem is the following. When a cell u is replaced by another cell v along a reconfiguration path, a net n_i connected to u may need its route to be extended to connect to v [as shown for $u =$ the dark node $B2$ and $v = C2$ in Figure 8.8(A) if the current route of n_i does not include the required track segment. The required extension is the CS. For each CS, if the required interconnect segment where the CS is to be inserted is vacant, the net extension is straightforward, and no other nets are disturbed. If the required interconnect segment is occupied by another net, then the CS insertion will cause a displacement or "bumping" of this net. The net requiring the CS extension is termed the **CS-net** [n_1 in Figure 8.8(A)], and the net occupying the required track segment is termed the **occupying net** or **O-net** [n_2 in Figure 8.8(A)].

The O-net needs to be moved out of its current track to make space for the CS. We use $n_i^{T_j}$ to denote a net n_i on track T_j. Let a **transition** be defined as the movement of net n_i on a track T_j to another track T_k and that is denoted by $n_i^{T_j \to T_k}$. This transition may result in net n_i bumping into one or more nets on track T_k. These nets will have to move out of their current track T_k, giving rise to a transition for each of them. This transition sequence is shown in Figure 8.8(B) by dark arcs, where net n_2 initiates a set of transitions that finally terminate in **spare track segments**, which are vacant segments of appropriate total lengths into which bumped nets can move without bumping other nets. As seen in the figure, the set of transitions take on a directed-acyclic graph (DAG) structure, termed a **transition DAG (T-DAG)**, with the spares forming the leaf nodes. The CS insertion is successful if a T-DAG rooted at the corresponding O-net can be found whose leaves are spare segments; such a T-DAG is termed a **converging T-DAG**. As stated earlier, because net bumpings only involve nets changing their track positions but not their topologies, their timing and power properties remain intact. Because CS insertions affect CS-net delays minimally (by about 7% [Hanchek and Dutt, 1998]), the B&R incremental rerouting approach only marginally affects FPGA performance.

The concept of an **overlap graph (OG)**, which is a graph representation of the circuit routing on the FPGA, was introduced in Dutt *et al.* (1999). The OG is an undirected graph with the circuit nets represented by the nodes of the graph.

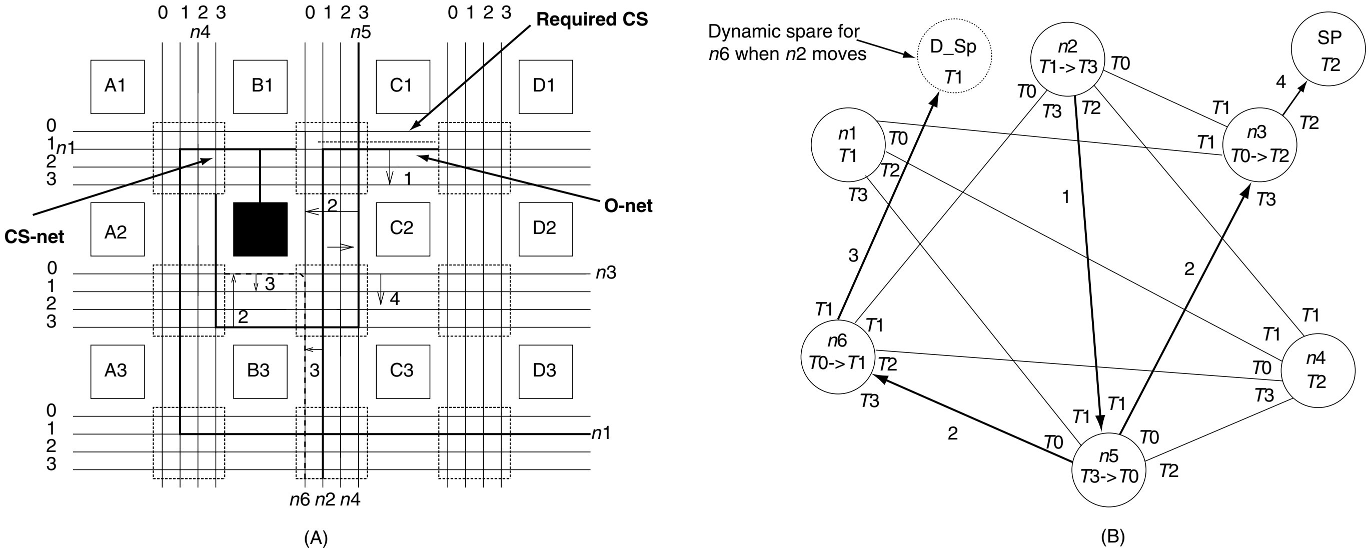


FIGURE 8.8 Searching the OG for a Converging Transition DAG to Determine Feasibility of CS Insertion

In the overlap graph OG (V, E), the set of nodes $V = S \cup \{n_1, n_2, \ldots, n_m\}$, where each n_i is a routed net of the circuit and where S is the set of "spare" track segments as described above. There exists an edge between n_i and n_j in the OG if nets n_i and n_j share a channel[2] in the FPGA. Figure 8.8(B) shows net n_2 and n_6 having an edge between them in the OG since they are routed through a common vertical channel to the right of cell B3.

The OG can be used as an effective model in the evaluation of the required T-DAG. Since it represents the circuit routing in the FPGA, a T-DAG is a DAG embedded in the OG (the undirected edges of the OG become directed arcs in the direction of the transitions 8b), as in Figure 8.8(B). A converging T-DAG rooted at an O-net can be determined by performing a search on the DAG until all leaf nodes of the search DAG are spare nodes.

This process is illustrated in Figure 8.8(B) for a small circuit and for a single CS insertion for extending net n_1, the CS-net. The corresponding O-net n_2 transits from T_1 to T_3 and bumps into n_5. The movement of n_2 from T_1 creates a "dynamic" spare node (labeled by D_Sp in the figure) for net n_6, for which information is added to the OG. The bumped net n_5 then transits from T_3 to T_0 where it bumps n_6 and n_3. Net n_6 then transits to the above dynamically created spare on T_1, while n_3 transits to its spare node on T_2. Thus, a converging T-DAG (here a tree) is determined in the OG. The transition arcs are shown dark in Figure 8.8(B) and numbered chronologically in the order in which they are traversed in the search process. After every transition, the track labels of the nodes and those of their edges need to be updated.

The B&R incremental rerouting algorithm Conv_T-DAG that performs a depth-first based T-DAG search in the OG is given in Figure 8.9 (Dutt *et al.*, 1999). It recursively searches for converging T-DAGs rooted at each net bumped by the O-net. A depth-first path terminates in success if a spare node is reached and in failure either when all OG nodes have been visited in that path or a cycle is detected (an ancestor along the current path is revisited). When an $n_i^{T_j \to T_k}$ transition fails in this manner, the search backtracks and tries an unexplored transition $n_i^{T_j \to T_l}$. The algorithm was shown to be optimal—if a converging T-DAG exists among the currently used tracks for a CS, Conv_T-DAG will find it (Dutt *et al.*, 1999). The entire reconfiguration process that invokes Conv_T-DAG for each CS is impervious to the order of insertion of most CSs but not of a certain class of CSs (called "vertical" CSs). Thus, the reconfiguration process is near optimal.

While an existing converging T-DAG will ultimately be found by Conv_T-DAG, it will be time-efficient if some suitable "cost" measure can be used to determine which transitions are more likely to be successful so that fewer T-DAGs are searched and backtracked. A good cost measure will consider both the "magnitude" of bumpings (total length of bumped nets) and the likelihood of convergence of these bumpings.

Two transition cost (TC) measures evaluated are as follows: The first is written as:

$$sum(n_i^{T_j \to T_k}) = \sum\nolimits_{n_j \in ad\ j^{T_k}(n_i)} l(n_j), \qquad (8.1)$$

where $l(n_j)$ is the total length of n_j in terms of the track segments (each of length 1) that it occupies. This heuristic is reasonable but only considers the bumping magnitude.

[2] A **channel** is the set of all track segments between two adjacent switch boxes of the FPGA.

FIGURE 8.9 The Optimal Depth-First Search Algorithm for Finding a Converging T-DAG

For example, according to it, it is equally costly to bump a net of length 9 as it is to bump three nets each of length 3. The latter case, however, has a higher likelihood of convergence because there is greater flexibility in moving three bumped nets (e.g., each can transit to a different track) than a single net of the same total length. This leads to the second cost function:

$$(2) sqrt(n_i^{T_j \rightarrow T_k}) = \left[\sum\nolimits_{n_j \in ad\ j^{T_k}(n_i)} l(n_j)\right] / \sqrt{|ad\ j^{T_k}(n_i)|}. \quad (8.2)$$

Using such TC functions 8.1 and 8.2 to guide the search results in tremendous savings in computation time compared to a blind depth-first search, as discussed in the following paragraphs.

Experimental Results

The algorithms in Figure 8.9 were coded for the FPGA model of single-length segments and tested on a number of benchmark circuits (obtained from the University of Toronto FPGA group) ranging from about 80 cells and nets to about 500 cells and nets. The input to the incremental routing software of Dutt *et al.* (1999) is the mapped and routed circuits produced by the Toronto's group SEGA tools (Lemieux and Brown, 1993). Two important metrics, track overhead and reconfiguration time (essentially, rerouting time), are the focus of these experiments.

- The dynamic method shows considerable improvement over the static method (Hanchek and Dutt, 1996a, 1996b, 1998) for all the different transition costs (TCs). The static method has a track overhead of 34% with its best combination routing heuristics. The dynamic method's overheads are 25.96% for a worst-case fault pattern and 15.58% for average-case patterns. This represents a 24–54% improvement over the static method.
- The sum TC heuristic is the most time-efficient for both the worst- and average-case simulations with average reconfiguration times over all circuits of about 43 sec and 18 sec, respectively. These times are quite promising.
- The suitability of heuristic TCs for time-efficiency was demonstrated by an experiment in which we randomly chose transitions only for the O-net (root of the T-DAG); the transitions for the other nodes were chosen based on the sum TC[3]. On the average, the partial-random case shows an increase in reconfiguration time over that of the full sum TC case by 65% for the worst-case fault-pattern and by 126% for the average-case pattern. The track overheads remain the same as that of the sum TC used.
- One example considered a limited number of faults; this case occurs mostly in fabrication defects and short-life missions. The track overheads for all cases are very small: 1.75% for one fault to 4.49% for four faults. Except for one circuit, all other circuits require an absolute of one extra track to tolerate four faults; a few do not require any extra tracks.

8.4 Control Flow Checking With a Watchdog Processor

A **watchdog processor** (WD) is a relatively small and simple coprocessor used to perform concurrent system-level error detection by monitoring the behavior of the main processor. Because the WD is much simpler than the processor being tested, this approach is significantly more inexpensive than if system-level redundancy techniques, like duplication, were used. A WD can also be added incrementally to an existing processor system without requiring any significant modification to it. The general configuration of a system with a WD is shown in Figure 8.10.

One behavioral aspect of the main processor that can be concurrently monitored by the WD snooping onto the memory bus is whether control flows of programs being executed are being correctly followed. This section is devoted to discussing various control flow monitoring techniques using a WD as well as presenting some of our recent results on a

[3] The reason for having partial randomness as opposed to randomizing all transition choices was to keep the simulation time tractable.

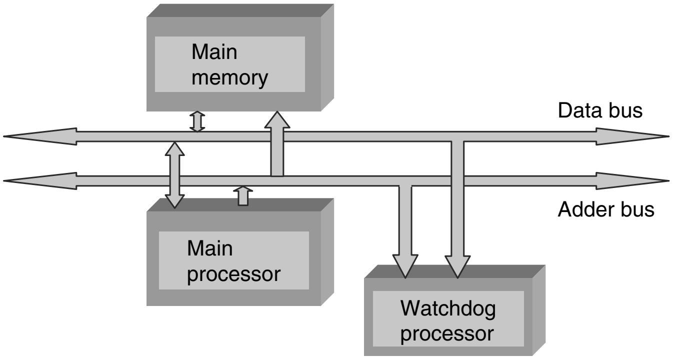

FIGURE 8.10 General Structure of a System with a Watchdog Processor

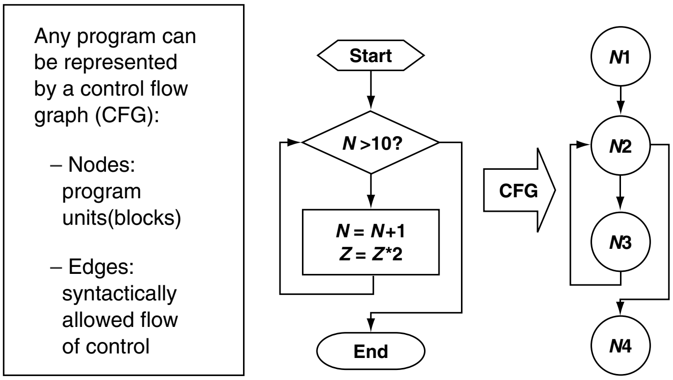
solution to the problem of monitoring program control flow by an external WD when there is an internal cache in the main processor.

Every application or program consists of processes. A process consists of procedures, and a procedure is composed of statements or instructions. Execution of programs, processes, and a procedures follow well-defined paths of instructions.

The control flow of a program can be represented by a **control flow graph** (CFG) in which the nodes represent some program unit, and edges represent the syntactically allowed flow of control. A node can be a single statement or a block of statements. Formally, a *node* of the CFG is a *block* of the program with exactly one entry point at the top of the block and exactly one exit point at the bottom of the block. The last instruction in a block may be a **branch** or **jump** instruction, although this is not necessary. There is an *arc* in the CFG from node *i* to node *j* if the program execution can correctly flow from the last instruction of block *i* to the first instruction of block *j*. An example of CFG extraction from a program is shown in Figure 8.11.

A correct control flow is a fundamental part of the correct execution of computer programs, and so it should be monitored to ensure the processor/program dependability. Such monitoring is called **control flow checking** (CFC).



Any program can be represented by a control flow graph (CFG):
– Nodes: program units(blocks)
– Edges: syntactically allowed flow of control

FIGURE 8.11 The Control Flow Graph (CFG) of a Simple Program

The most widely used techniques assign signatures as labels to the nodes of the CFG to determine the control flow. The WD is provided with the reference signatures and the relationships among them (represented by the CFG). During run time, the WD monitors the program run and concurrently computes the signatures that are then compared to the reference ones provided earlier. If a discrepancy is detected, then an error is signaled.

From this basic idea, methods have been developed that differ from each other in the augmentation of a node, by the representation of the reference information, and by the derivation of the run-time information. Figure 8.12 shows a possible augmentation of a basic block of a program for the purpose of CFC. Each "signature instruction" can be one or two NOPS containing the signature in the non-opcode fields.

According to Mahmood and McCluskey (1988), the reference CFG can be provided to the WD in three different ways:

- The control flow graph with the signature of each block is **stored in the local memory of the WD**. If a run-time signature is received or computed by the WD, then the stored reference is searched to determine whether the signature is a valid successor to the previous one.
- The reference information is **stored in the checked processor**, and it is transferred to the WD in run time. No local storage is needed in the WD, and this reduces the hardware overhead significantly. The transfer of the reference information, however, increases the overhead of the checked processor.
- The WD executes a **specialized reference program** that has the same control flow structure as the program executed by the checked processor. Based on the checked run-time information, the WD program performs a compiled graph tracing, which is faster than checking the

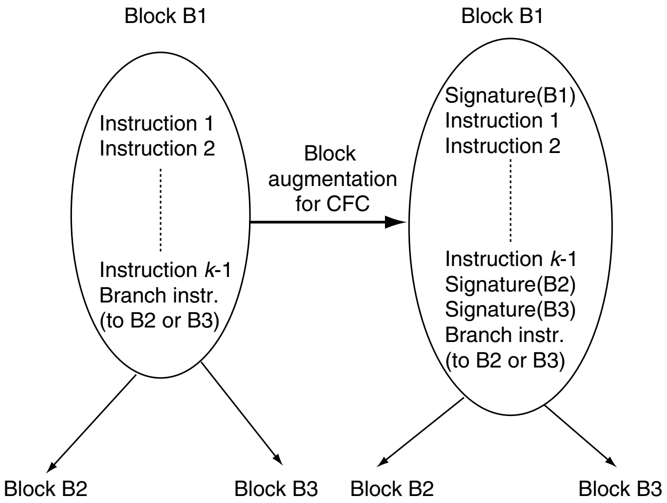

FIGURE 8.12 A Block in a CFG and Its Possible Augmentation for the Purpose of CFC

actual run-time signature by comparing it with the reference one of the WD; the tracing also does not require a separate data structure.

There are also two different ways of assigning the labels (signatures) to each node of the CFG: **assigned signatures** or **derived signatures** (Mahmood and McCluskey, 1988). Various techniques for these two approaches to signature determination are discussed next.

8.4.1 CFC with Assigned Signatures

The signatures labeling the nodes of the CFG are assigned arbitrarily using prime numbers or successive integers. These signatures are transferred to the WD explicitly by the checked processor. For this purpose, signature transfer statements are added into the source of the checked program.

Assigned signature-based methods check only that the nodes are executed in an allowed sequence (i.e., that the main processor traverses the CFG correctly), which is not necessarily the correct sequence of the program execution since the selection itself is unchecked. To check the contents of a node and the type and sequence of the instructions in it, derived signature methods are required. One of the first methods developed to perform CFC using assigned signatures is structural integrity checking (SIC) (Lu, 1982; Mahmood and McCluskey, 1988), which makes use of the control structure embedded in the syntax of the programming language.

To perform CFC, the source code to be executed by the checked system is preprocessed: the CFG is extracted, signatures are assigned to the nodes (blocks), the blocks are augmented with these signatures, and possibly the program of the main processor is modified by inserting the statements that transfer the signatures to the WD.

Methods differ in the way the signatures are assigned to the nodes and in how the reference information is represented. In SIC (Lu, 1982), the nodes are encoded (labeled) by selecting 8-bit numbers randomly and independently from a uniform distribution. The reference information for the WD is represented under the form of a reference program that has the same CFG as the checked program. In place of computations, it contains statements to receive and check the signatures from the main processor.

A newer control flow technique is the extended structural integrity checking (ESIC) (Mahmood and McCluskey, 1988), which extends the checking capabilities of SIC to check run-time computed procedure calls and interrupt handlers. The nodes of the CFG are encoded by successive numbers, and the reference information is extracted in the form of a stored reference signature database in which the valid successors of each signature are given in a sparse matrix format. The first and last nodes of a procedure are tagged by special flags, SOP start of procedure (SOP) and end of procedure (EOP). If an SOP signature is received (procedure call), then the actual state (pointer to the previous signature) is pushed to a WD internal stack and the reference state corresponding to the called procedure is reached. After an EOP signature (return from a procedure call), the original state (pointer to the original reference signature) is popped from the stack.

With this technique, procedure calls that are nondeterministic in the preprocessing phase and interrupt handler procedures can be checked. Whether the correct procedure is called remains unchecked, but the return address is checked using the signature stack.

The relatively easy implementation of the preprocessor and the ability of asynchronous checking are the advantages of the assigned signature-based methods. The disadvantages are the performance degradation of the checked processor due to explicit signature transfer, the need of recompilation of the source code that prevents checking of existing executables, and the fact that the sequence of instructions in a node is unchecked.

8.4.2 CFC with Derived Signatures

In this approach, the signatures labeling the nodes are derived from the opcode sequence of the node by information compaction (mod-2 addition, a checksum, or a linear feedback shift register [LSFR]). The run-time signatures are also computed concurrently by the WD by reading instructions from the memory data bus when they are fetched by the main processor. The WD computed signatures are compared to WD reference information to perform the checking.

A large number of schemes, improvements, and modifications have been proposed in past work, but the methods mainly differ in the augmentation of a node or block and in the representation of the reference information.

A simple method is basic path signature analysis (BPSA), in which the nodes of the CFG are a branch-free sequence of assembly level instructions, and the reference information is given by embedded signatures inserted at the beginning of each block (Mahmood and McCluskey, 1988); see Figure 8.12. The WD monitors the memory data bus of the processor and captures the reference signatures using tag bits to differentiate them from the normal instructions. At the end of each block, this signature is compared to the concurrently computed one (from the read instruction sequence).

Improvements have been proposed to reduce the hardware complexity of the WD: justifying signatures or using the embedded signature for the computation of the concurrent one. These were proposed to make the concurrent computed signature all zeros at the end of a node; thus, a simple gate instead of the comparator can be used for the checking.

Because we can decide during compile time the maximum dimension (number of instructions) of a block by splitting it into two separate but consecutive ones, we can find a trade-off between the overhead caused by the embedded signatures (increased memory usage and reduced performances) and the error coverage and latency.

Another method to reduce memory overhead is generalized path signature analysis (GPSA), which checks paths rather than simple nodes (Mahmood and McCluskey, 1988): the CFG is divided into path sets made of paths starting from the same node. Because there is only one reference signature for each path set, the run-time signature of each path is made the same by inserting justifying signatures in some paths.

To improve the error detection coverage, the universal signature monitor (USM) scheme uses path tags to check the validity of the sequence of nodes at the beginning of the next node and block signatures to check that the block is started at its entry point.

A similar method is implicit signature checking (Patel and Fung, 1983), which assigns unique signatures to each basic block by using the block's start address, and obtaining an implicit signature checking point at the beginning of each block. Justifying signatures are embedded at each branch instruction.

Other methods use advanced techniques of signature encoding, such as hashing of instructions or addresses by reference signatures (Mahmood and McCluskey, 1988).

The overhead caused by the embedded reference signatures can be completely eliminated if the reference information is moved to the environment of the WD. Two main solutions are possible: WD with stored reference information or WD based on a reference program.

The Roving Monitoring Processor implements a scheme based on stored reference signatures. The CFG is stored in a linked list format in the local memory of the WD. Receiving a signature, the WD examines whether it belongs to a node that can be reached from the previous one.

Cerberus–16 is the first synchronous scheme that checks processors by a reference program (Mahmood and McCluskey, 1988). The WD is implemented by a specialized processor that has a restricted instruction set. The program executed by the WD has the same CFG structure as that of the the program being checked. Each instruction of the WD includes the number of instructions in the corresponding node, a justifying signature, and the label of the next instruction in the WD. The reference signature of a path is computed at the end of a node and the justifying signature is fed to this unit to be compared to the run-time one. When a branch is executed at the end of a node, a signal is activated, and the WD takes the same branch as well; otherwise, the next instruction is executed.

The specifications of required performance are sometimes such that it is not possible to build a WD that can fetch all the required signatures or instructions. For these cases, asynchronous versions have been proposed in past work (Mahmood and McCluskey, 1988). These solutions make use of a signature queue allowing an asynchronous checking of the run-time signatures transferred to the WD.

8.4.3 CFC for Modern Processor Architectures

In derived signature methods, run-time signatures can only be computed if the sequence of instructions executed by the checked processor can be monitored by the WD. In the case of traditional processor architectures, signatures can be easily computed by monitoring the memory data bus of the checked processor. The sequence of instructions fetched by the processor is exactly the sequence executed by it. However, modern processor architectures include on-chip instruction caches and prefetch queues (pipelines). The sequence of instructions fetched by the processor can still be monitored by the WD, but it is not exactly the sequence of instructions executed by the processor. Some instructions are executed in a different order or are not executed at all.

The problem of monitoring pipelined RISC processors was addressed in (Delord and Savcier, 1991). The main idea was that the reference signatures were computed on the basis of the instruction sequence fetched by the main processor, and the basic functions of the pipeline were imitated in the WD. Delayed branching and exceptions events, which make a classical signature inconsistent, are handled by some new notions. Delayed branching is resolved by anticipated signatures (i.e., always taking into account in the compaction the delayed instructions following a branch, independent of whether they are executed). Exceptions and the corresponding flush of the pipeline are handled by delayed signatures (i.e., an instruction code is compacted only if a given number of successors are regularly fetched).

The problem of derived signature-based monitoring of processors with built-in caches was, to the best of our knowledge, addressed for the first time by Rota (2002). An external observer cannot guess the instructions fetched by the processor from its cache, and the integration of the WD into the processor core cannot be performed in off-the-shelf commercial systems. Rota (2002) developed a solution to this problem in which the processor explicitly sends information about the instructions that are actually being fetched from the cache. A very simple solution would be to modify the processor in such a way that every instruction fetched from the cache is also asserted on the external bus. Unfortunately, it is not realistic to assume that the external signature transfer time on the external memory bus followed by the concurrent signature computation and error analysis that a WD needs to perform is comparable to the processing speed of a pipelined processor with one or more cache levels. A solution was needed that would allow the watchdog to perform a derived signature control flow checking at a reasonable speed. It was assumed that the external watchdog is able to process instructions at the rate of the external bus clock frequency, which is usually smaller than the processor clock frequency.

The **speed factor** (K) is defined as the ratio of the internal versus the external clock frequency:

$$K = \frac{\text{Processor clock frequency}}{\text{Bus clock frequency}} \tag{8.3}$$

During the execution of the program, the lines of the cache will be filled successively until a branch in the program flow is taken. The design technique of Rota (2002) introduces a small hardware modification in the cache system: a counter that counts the number of accesses by the processor to the cache, and every K that accesses the accessed instruction is sent to an FIFO buffer placed in a bus controller that interfaces with the external memory bus. The WD then performs a derived signature checking of each block based on the instructions of the block that it receives.

Note that to perform control flow checking, each block must have three embedded signatures: the current block signature and the signatures of the two possible blocks following the branch instruction at the end of the block (see Figure 8.12). These three signatures must be sent to the WD (via the buffer) whenever fetched by the processor irrespective of their position in the block and of the counter value.

The buffer will put its entries on the bus as soon as it is available, and if the buffer gets full, the bus controller will stop CPU accesses to the cache until the buffer empties one entry. A block diagram of this approach is shown in Figure 8.13.

According to the technique described above, the WD will always receive the three signatures added to the basic blocks and some other instructions according to the length of the block and its alignment in the memory. A generic example is shown in Figure 8.14.

An assigned signature checking for the program flow was used so that the WD will always know when a new block is started or ending, which block has been taken after the branch, and when a derived signature checking for each block is based on the received instructions. Because which instruction in a block that will be passed first to the WD is not known a priori (except that it will be one of the first K instructions), the derived signature is different for each of the K possibilities of the first instruction of the block seen by the WD. Thus, every block must be assigned K signatures, each one for a different possible alignment. The signature is concurrently computed by the WD and compared with the K references stored in its memory to verify the correctness of the fetches.

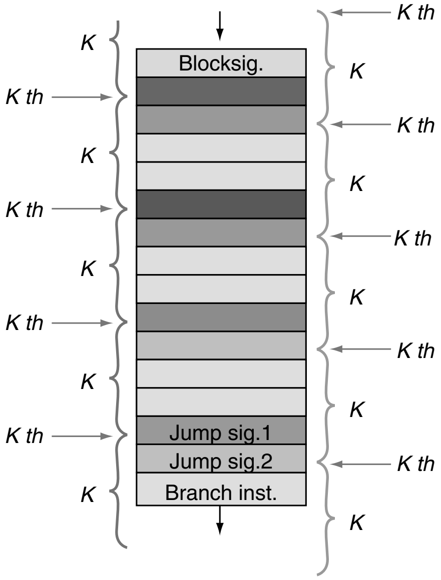

FIGURE 8.14 A Block with K Subsets of Instructions. Instructions in each subset are shaded the same, one of which is sent to the WD based on the alignment of the block on the instruction access pattern of the processor. Each subset has a potentially different derived signature. All K derived signatures are stored in the WD as reference information.

The method described in the previous paragraphs for performing a partial derived signature checking CFC (partial CFC, for brevity) was implemented for a processor system with an internal cache for a Motorola 68040 processor. The processor's initial VHDL description was obtained from (Heishman *et al.*). It was augmented greatly and various structural descriptions were added to the original behavioral description for CFC and partial CFC implementations (Rota, 2002; Trovo, 2002). A cache-less 68040 (or equivalently a 68040 with an external cache) was also simulated with the WD then being able to monitor the program flow completely and thus perform a full CFC. The two different WDs were also described in VHDL. Simulations performed show that the error coverage for $K = 2$ of the partial CFC scheme for an internal cache system is almost as good as that for full CFC. This result is shown in Figure 8.15 for two and four faults

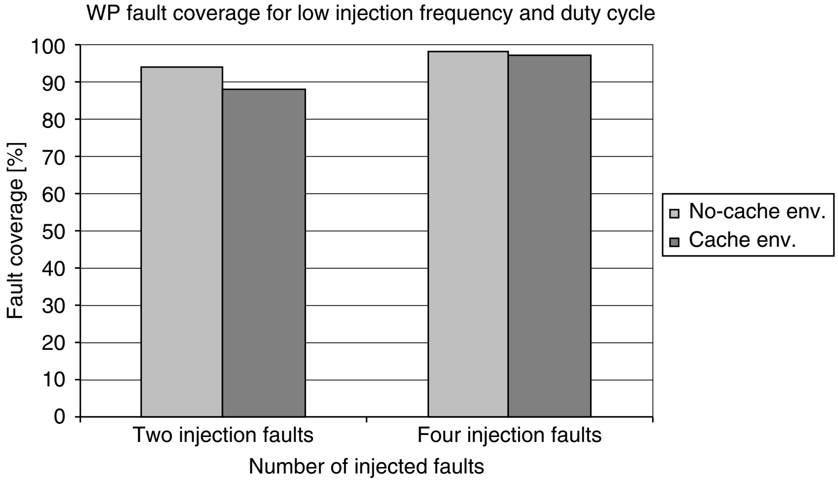

FIGURE 8.15 Fault Coverage Results for Full and Partial CFC Checking. The results are for external-cache/cache-less systems and in internal cache systems with partial CFC respectively, for $K = 2$, and for two and four faults, averaged over a number of patterns (random, semiclustered, fully clustered) for each number of faults.

injected in the memory data bus at a repeat frequency of 100 KHz and at 25% duty cycle.[4]

8.5 Microrollback—A Fault-Tolerance Mechanism for Processor Systems

Microrollback is a technique that is coupled with concurrent error detection mechanisms (such as FD arithmetic circuits [see Section 8.2] and program CFC [see Section 8.4]) and allows a processor system to recover from detected errors by going back to a state prior to the occurrence of these errors and restarting execution from that point. In general, to perform such a rollback to a previous state, it is necessary to have copies of all previous states of the system up to a certain time interval. Because a lot of memory is required to store this kind of information, it is necessary to consider the fact that only a reduced number of snapshots of previous states can be kept. Due to this limitation, it is necessary to determine critical points, called **checkpoints** at which we need to or it is appropriate to store the state of the system (Bowden and Pradhan, 1992; Chandy and Ramamoorthy). This decision process is important for software rollback, but is too complex for a completely hardware solution.

Hardware-based rollback techniques fall in one of two categories: (1) **full checkpointing** and (2) **incremental checkpointing** (Alewine *et al.*, 1992). Full checkpointing maintains snapshots of the entire state of the system (essentially all register, cache, and memory contents) at the checkpoints, whereas incremental checkpointing maintains only the changes to the state from the immediately preceding checkpoint (e.g., contents of registers written between the checkpoints). Rollback in full checkpointing schemes involves setting the current state to be the desired checkpointed state, while in incremental checkpointing, rollback involves undoing or backing out of the state changes made after the desired checkpointed state. We will focus on incremental checkpointing in the discussion of hardware microrollback in the rest of this section.

At the implementation detail level, there are two different approaches to hardware microrollback: clock *cycle microrollback* (state changes saved at every clock cycle), as described by Sparmann and Reddy (1994) and *instruction microrollback*: (state changes saved at the completion of every instruction execution, as described by Trovo (2002)).

Before presenting the hardware solution by Tamir and Tremblay (1990), we define rollback distance and rollback range.

- **Rollback distance** is the number of state change snapshots to be undone. This number is limited by the number of stored snapshots.
- **Rollback range** is the maximum rollback distance that the system can support. This value is determined by the maximum error detection latency of the system, thus allowing it to always roll back to a state prior to that in which the errors were generated.

We next describe the complete hardware solution for clock cycle microrollback discussed by Tamir and Tremblay (1990) for a Reduced Instruction Set Computer (RISC) processor.

[4] This work was done as part of an AFOSR MURI project for determining the effect of deliberate electromagnetic (EM) interference on digital and computer systems; the interference pattern is expected to be a train of EM pulses for some duration followed by a silent period, with this pattern repeating at some frequency that is dependent on the power capability of the interfering source. EM interference is also expected to cause multiple transient faults, especially on off-chip wiring like memory busses.

8.5.1 Support for Microrollback in the Register File

In a RISC processor, a write into a register may be performed every clock cycle. Incremental checkpointing is performed for the register file by using a delayed-write buffer (DWB) to store the written register values for up to *N* clock cycles to realize a rollback range of *N*. Figure 8.16 shows the DWB structure for supporting microrollback in the register file.

The address of the destination register and its new value are stored in the DWB, which is an *N*-level FIFO buffer. This storage structure is composed of an *N*-level data FIFO that contains the values of the registers that have been written and an *N*-level content associative memory (CAM) that stores the addresses of the written registers plus valid bits for the data FIFO entries. In each clock cycle, if a write register operation is executed, a new line of the DWB is filled; otherwise, the line is invalidated by resetting the corresponding valid bit in the CAM. This microrollback structure also accommodates the needed change in the read of the register file so that the latest value of the addressed register is read. During a read, the DWB checks the CAM to determine if the addressed register's content is stored in its data store. If so, a priority circuit chooses the most recent written value of the addressed register to be read out of the data FIFO. A microrollback of *d* clock cycles is implemented simply by invalidating the first (most recent) *d* locations of the DWB.

8.5.2 Support for Microrollback in Individual State Registers

Two different solutions were presented by Tamir and Tremblay (1990) for microrollback in a single-state register: the FIFO and RAM methods. The FIFO solution is shown in Figure 8.17. The storage data structure is a FIFO that contains all previous values of the register with associated valid bits up to *N* clock cycles. The *current register* is the register at the top of the FIFO structure and always has the most recent value of the register. In case of read or write (R/W) operations, the current register is accessed. After each clock cycle, the data contained in this register is pushed into the FIFO structure, and the corresponding valid bit is set to value 1. The priority circuit ensures that the pushing of an entry into this FIFO results in only the top consecutive sequence of valid entries being pushed down by one entry; entries following and including the first invalid entry do not move. To realize a microrollback of distance *d*, the *d*th valid entry from the top of the FIFO is moved to the current register, and the first *d* entries in the FIFO are invalidated.

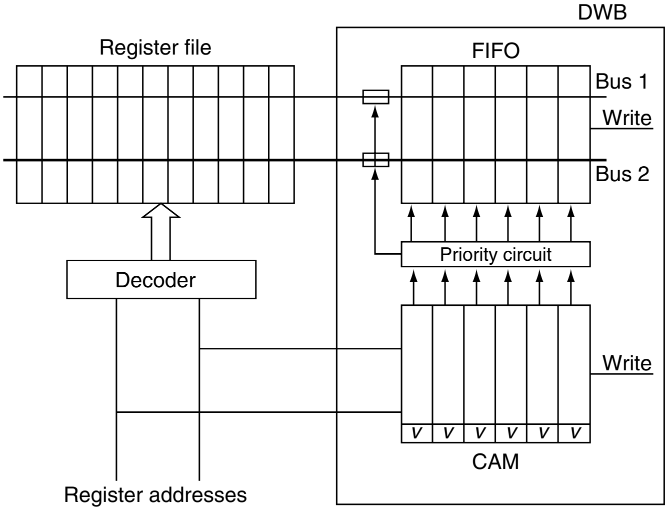

FIGURE 8.16 A Register File with Support for Microrollback

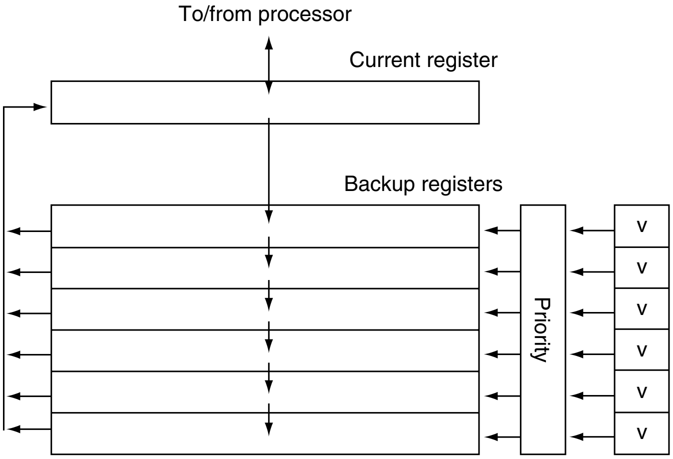

FIGURE 8.17 The FIFO Method for Microrollback in a State Register

The RAM method uses a small RAM and a pointer to the last stored value of the register to create a circular buffer. Like the previous solution, a R/W operation is performed on the current register (see Figure 8.18). During a write operation, the old value of the current register is written into the RAM location that immediately follows the pointer, and the pointer is then updated to point to this location. For microrollback, it is simply necessary to subtract the desired rollback distance from the pointer and move the value in the entry following the newly pointed location to the current register.

8.5.3 Support for Microrollback in Cache Memory

As in the register file, a DWB is used to support microrollback in cache memory. The only modification for a cache, presented by Tamir and Tremblay (1990), is the use of two CAMs instead of one. In this case, each CAM checks only one part of the address, and, thus, the response time of the DWB is smaller. This is done to achieve better performance on cache microrollback support. The cache CAMs' behavior for R/W operations and for rollback is exactly the same as that of the CAM for the register file.

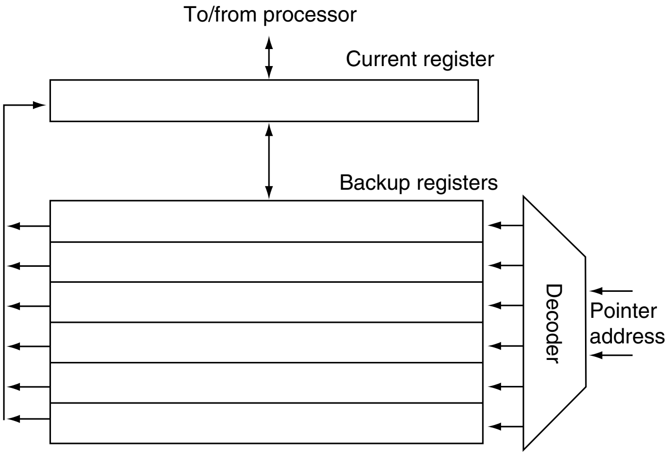

FIGURE 8.18 The RAM Solution for Microrollback of Individual State Registers

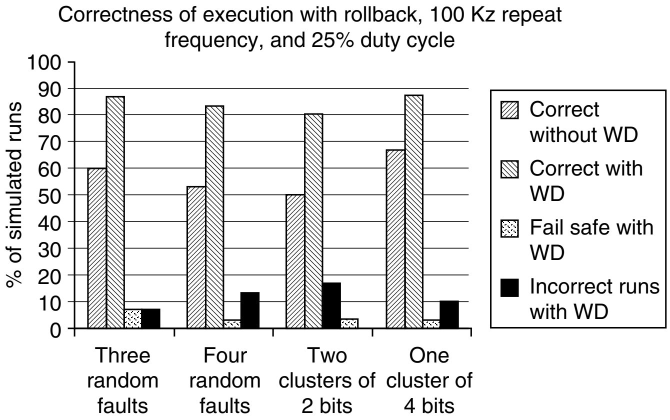

FIGURE 8.19 Execution Correctness of a Matrix Multiplication Program in a Simulated Motorola 68040. Using microrollback and Hamming code on memory and cache busses and WD-based CFC detection schemes for different number of faults and fault patterns.

8.5.4 Microrollback in a CISC Processor and Experimental Results

Trovo (2002) implemented microrollback in VHDL in the Motorola 68040 processor along with concurrent error detection via a watchdog (WD) processor-based control-flow checking (see Section 8.4) and a two-error detecting one-error correcting Hamming code (HC) implemented on the memory and cache data and address busses. Because the 68040 is a CISC processor, an instruction may not be executed every clock cycle, and an instruction microrollback scheme can be implemented for the register file, state registers, cache, and main memory (the main memory rollback support is similar to that of the cache) using hardware similar to that described in Sections 8.5.1–8.5.3.

In simulation experiments, multiple errors of different patterns were injected on the memory and cache busses at various repeat frequencies and duty cycles to simulate the effect of EM interference on a computer system (see footnote 4). These errors can be caught by the HC detector and/or the WD. The maximum error detection latency of the HC error detector is one instruction execution and that of the WD is $b_{\max}$ instruction executions, where $b_{\max}$ is the maximum block size of the program after CFC-based augmentation as described in Section 8.4 (note again that here the rollback distance unit is an instruction execution and not a clock cycle). Whenever either the HC or the WD detects an error, the microrollback unit is signaled and microrollback of the appropriate distance occurs (= error latency of the detector—one instruction execution for HC and b_i instruction executions for the WD if b_i is the size of the current block). When both the HC and WD detect errors simultaneously, the HC is given priority, and a rollback of one instruction is performed.

Sometimes the transient errors injected on the memory bus can become permanent errors if they are not detected by the HC and, if the corresponding instruction or data line fetched is stored in cache. Subsequently, when the instruction is fetched from cache, it will always be erroneous. If this error is subsequently detected by the WD monitoring the cache-processor bus or the HC on that bus, a microrollback occurs. After the microrollback occurs, the same instruction (with permanent errors) will be fetched again, and the microrollback and subsequent fetch will repeat ad infinitum. This type of infinite loop can be detected with high probability if the WD can be augmented to detect the number of microrollbacks of the same type (e.g., defined by just the microrollback distance) and then send a signal to the processor to terminate the program when 10 consecutive microrollbacks of the same type are detected. Such termination is a fail-safe termination of the program as its results are not deemed reliable.

Figure 8.19 shows the efficacy of this microrollback method, HC- and CFC-based error detection, and infinite loop detector at a fault injection repeat frequency of 125 KHz and duty cycle 25% for different patterns of three to four faults injected on the memory and cache busses. In all cases, the matrix multiplication program that was tested ended with incorrect results less than 10% of the time, thus achieving a safety probability of about 90%. This compares to a safety probability in the range of 50 to 68% for microrollback without using concurrent error detection via WD-based CFC, thus also demonstrating the usefulness of CFC.

8.6 Algorithm-Based Fault Tolerance

Algorithm-based fault tolerance (ABFT) refers to techniques that use the property of the algorithm or computation to check the correctness of output data. This is usually done by encoding the input data (e.g., by checksums) and verifying that the output also has a valid encoding. Huang and Abraham

(1984) presented the seminal work in ABFT in which methods of detecting and correcting errors in various matrix computations using checksum-encoded matrices were discussed. These methods use the linear transformation property of matrix computations to detect errors in the result matrix. Subsequently, a number of ABFT schemes were proposed for error detection in different computations like Fourier transforms (Malek and Choi, 1985) and matrix equation solvers (Luk and Park, 1988). Most ABFT schemes use a floating point (FP) checksum equality test that is susceptible to roundoff in FP computations of finite precision. This susceptibility arises from the difference in the sequence of operations used in computing the two sides of the equality test. Roundoff error analysis in Wilkinson (1963) indicates that upper bounds on the (roundoff) error in FP operations are dependent on the quantities involved, the order in which the intermediate operations are performed, and the precision used in the intermediate result's accumulation.

Banerjee *et al.* (1990) presented an evaluation of the error coverage of ABFT schemes for matrix operations on a hypercube multiprocessor. In this work, a threshold Δ was used for the equality test so that a difference of at most Δ between the two FP numbers being compared meant passing the test. The value of Δ was determined arbitrarily using averaging on certain input data sets and did not result in very good error coverage. Nair and Abraham (1990) proposed a generalization of the checksum test in the framework of real number codes. The performances of several weighted checksum schemes that correspond to different encoder vectors were examined. The checksum schemes and the numerical error involved again were found to be data dependent. Roy-Chowdhury and Banerjee (1993) developed a theoretical forward (roundoff) error bounds for some computations; the bounds are used as the threshold values. They found good error coverage for random dense problems. Although this is an innovative method, it has some drawbacks. Although, they have a theoretical basis for their thresholds, their experiments use tighter empirical thresholds to obtain a reasonable error coverage. Second, the inherent nature of threshold methods can miss errors in the low-order bits. Such errors in the low bits could become very large if the system of linear equations in **LU** decomposition is ill-conditioned (Wilkinson, 1965).

Luk and Park (1988) analyzed the effect of roundoff errors on various matrix decomposition methods. They also concluded that small roundoff errors are magnified in the final result, thus necessitating the use of a large threshold for the FP checksum test to prevent false alarms. As Boley and Luk (1991) determined, a good threshold depends on the condition number of the matrix of **checksum coefficients**. Thus, the selection of the threshold is generally a difficult issue. False alarms can occur when the threshold is too small, and relatively large roundoff errors can be mistaken as the presence of an error in the result, which can lead to unnecessary recomputation. On the other hand, a large threshold can cause an actual error to go undetected, and this can lead to substantial inaccuracies in the final result. In addition, if ABFT is being used as a detection mechanism for hardware faults, then transient and, more dangerously, intermittent and permanent faults can go undetected for a long time. Hence, the issue of acceptable accurate error detection of various matrix computations using equality test-based ABFT schemes needed to be satisfactorily solved.

ABFT methods using the mantissas of floating point quantities can potentially be used to check certain floating point operations, such as multiplication using checksums of the input mantissas treated as integers without being susceptible to the problem of roundoff errors (Assaad and Dutt, 1992, 1996). The only drawback to this approach is that it cannot be applied to all floating point operations (e.g., addition). However, a hybrid test was formulated that applies both the floating-point and integer mantissa checksum tests to appropriate parts of a computation (that is amenable to ABFT), thus covering all its operations. In this manner, much higher error coverages are obtained compared to using only the floating-point test.

The floating-point and mantissa-based integer checksum techniques are discussed next.

8.6.1 Floating-Point Checksum Test

Many previous approaches for error detection and correction of linear numerical computations were based on the use of checksum schemes (Banerjee *et al.*, 1990; Huang and Abraham, 1984; Jou and Abraham, 1986; Luk and Park, 1988). A function f is **linear** if $f(\boldsymbol{u}+\boldsymbol{v}) = f(\boldsymbol{u}) + f(\boldsymbol{v})$, where $\boldsymbol{u}$ and $\boldsymbol{v}$ are vectors. We discuss here a commonly used checksum technique for a frequently encountered computation: matrix multiplication.

The floating point checksum technique for matrix multiplication from Huang and Abraham (1984) is as follows. Consider an $n \times m$ matrix A with elements $a_{i,j}$, $1 \leq i \leq n$, $1 \leq j \leq m$. The **column checksum matrix** A_c of the matrix A is an $(n+1) \times m$ matrix, whose first n rows are identical to those of A and whose last row **rowsum** (A) consists of elements $a_{n+1,\,j} := \sum_{i=1}^{n} a_{i,j}$ for $1 \leq j \leq m$. Matrix A_c can also be defined as $A_c := [\frac{A}{e^T A}]$, where $\boldsymbol{e}^T$ is the $1 \times n$ row vector $(1, 1, \ldots, 1)$. Similarly, the **row checksum matrix** A_r of the matrix A is an $n \times (m+1)$ matrix, whose first m columns are identical to those of A and whose last column **colsum** (A) consists of elements $a_{i,\,n+1} := \sum_{j=1}^{n} a_{i,j}$ for $1 \leq i \leq n$. Matrix A_r can also be defined as $A_r := [A|A\boldsymbol{e}]$, where A$\boldsymbol{e}$ is the column summation vector. Finally, a *full checksum matrix* A_f of A is defined to be the $(n+1) \times (m+1)$ matrix, which is the column checksum matrix of the row checksum matrix A_r. Corresponding to the matrix multiplication $C := A \times B$, the relation $C_f := A_c \times B_r$ was established by Huang and Abraham (1984). This result leads to their ABFT scheme for error detection in matrix multiplication, which can be described as follows.

```
Algorithm: Mult_Float_Check(A, B)
/*A is an $n \times m$ matrix and B an $m \times l$ matrix. */
  1. Compute $A_c$ and $B_r$.
  2. Compute $C_f := A_c \times B_r$.
  3. Extract the $n \times l$ submatrix D of $C_f$ consisting of the
     first n rows and l columns. Compute $D_f$.
  4. Check if $\boldsymbol{c}_{n+1} \overset{?}{=} \boldsymbol{d}_{n+1}$, where $\boldsymbol{c}_{n+1}$ and $\boldsymbol{d}_{n+1}$ are the
     $(n+1)$th rows of $C_f$ and $D_f$, respectively.
  5. Check if $\boldsymbol{c}^{n+1} \overset{?}{=} \boldsymbol{d}^{n+1}$, where $\boldsymbol{c}^{n+1}$ and $\boldsymbol{d}^{n+1}$ are the
     $(n+1)$th columns of $C_f$ and $D_f$, respectively.
  6. If any of the above equality tests fail then return
     ("error") else return ("no error").
```

The following result was proved indirectly in Theorem 4.6 of work by Huang and Abraham (1984).

Theorem 1: At least three erroneous elements of any full checksum matrix can be detected, and any single erroneous element can be corrected.

Theorem 1 implies that Mult_Float_Check can detect at least three errors and correct a single error in the computation of $C_f = A_c \times B_r$ as long as all operations, especially floating point additions, have a large enough precision such that no roundoff inaccuracies are introduced. Of course, such an 'infinite' precision assumption is unrealistic, and the checksum scheme is susceptible to roundoff introduced by finite precision floating point arithmetic, as described previously. In particular, there can be false alarms in which the checksum test fails due to roundoff in spite of the absence of errors (that can occur due to hardware glitches or failures) in the computation. Alternatively, real errors could be masked or canceled by roundoff leading to nondetection of a potential problem in the hardware.

8.6.2 Integer Checksum Test

The susceptibility of the floating point checksum test to round off inaccuracies can be largely mitigated by applying integer checksums to various (linear) computations that are "mantissa preserving." This results in high error coverage and zero false alarms because integer checksums do not have to contend with the roundoff error problem of floating point checksums. The integers involved are derived from the mantissas of the intermediate floating point results of the floating point computation. To date, we have successfully applied integer checksums (hereafter also called mantissa checksums) to two important matrix computations: matrix–matrix multiplication and **LU** decomposition (using the **GE** algorithm) (Assaad and Dutt, 1992; Dutt and Assaad, 1996). We will briefly discuss the general theory of mantissa checksums and how they are applied to these two computations.

General Theory

In the following discussion, $\boldsymbol{u} = (u_1, \ldots, u_n)^T$ is used to represent column vectors and *a*,*b*,*c*, etc., for scalars. Unless otherwise specified, these variables will denote floating point quantities. The notation mant (a) is used to denote the mantissa of the floating point number *a* treated as an integers. For example, considering 4-bit mantissas and integers, if 1.100 is the mantissa portion of *a*, with its implicit binary point shown, then the value of the mantissa is 1.5 in decimal. However, mant $(a) = 1100$ and has value 12 in decimal. Furthermore, for a vector $\boldsymbol{v} := (v_1, \ldots, v_n)^T$, mant $(\boldsymbol{v}) := (\text{mant})(v_1), \ldots, \text{mant}(v_n))^T$, and for a matrix $A := [a_{i,j}]$, $A^{mant} :=$ mant $(A) := [\text{mant}\ (a_{i,j})\ ]$. The $:=$ symbol is used to denote equality by definition, $=$ to denote the standard (derived) equality, and $\overset{?}{=}$ to denote an equality test of two quantities that are theoretically supposed to be equal but may not be due to errors and/or round-off.

Let f be any linear function on vectors. The linearity of f allows us to apply the following floating point checksum test on the computation of f on a set S of vectors:

$$f\left(\sum_{\boldsymbol{v}\in S} \boldsymbol{v}\right) \overset{?}{=} \sum_{\boldsymbol{v}\in S} f(\boldsymbol{v}). \tag{8.4}$$

Ignoring the round-off problem, the LHS and RHS of the above equation should be equal if there are no errors in the following: (1) computing the $f(\boldsymbol{v})$ for all $\boldsymbol{v} \in S$ (which is the original computation), (2) summing up the $f(\boldsymbol{v})$ to get the RHS, (3) summing up the **v**, (4) and applying f to the sum to get the LHS. If the sums are not equal, then an error is detected. Unfortunately due to round-off, the test of equation 8.4 often fails to hold in the absence of computation errors. Therefore, an integer version of this test that is not susceptible to round-off problems was sought. Of course, this integer checksum test should involve integers derived from the floating point quantities.

Because f is a linear function, irrespective of whether the vectors are floating points or integers, the following checksum property also holds:

$$f\left(\sum_{\boldsymbol{v}\in S} \text{mant}(\boldsymbol{v})\right) = \sum_{\boldsymbol{v}\in S} f(\text{mant}(\boldsymbol{v})), \tag{8.5}$$

where the multiple mant (**v**) are integer quantities, as we saw previously. Note that equation 8.5 is not related to the original floating point computation and can be used to check it only if f is **mantissa preserving** [i.e., f (mant $(\boldsymbol{v})$) is equal to mant $(f(\boldsymbol{v})$]. Then equation 8.5 becomes:

$$f\left(\sum_{\boldsymbol{v}\in S} \text{mant}(\boldsymbol{v})\right) = \sum_{\boldsymbol{v}\in S} \text{mant}(f(\boldsymbol{v})). \tag{8.6}$$

Thus, if there are errors introduced in the mantissas of the $f(\mathbf{v})$, then those errors are also present in the mant $(f(\mathbf{v}))$, and these will be detected by the integer checksum test of equation 8.6. Furthermore, this test is not susceptible to roundoff. Hence, it will not cause any false alarms, and very few computation errors will go undetected vis-a-vis the floating point test of equation 8.4. In practice, since an integer word can store a finite range of numbers, integer arithmetic is effectively done in modulo q, where $q - 1$ is the largest integer that can be stored in the computer. Some higher order bits can be lost in a modulo summation. As established shortly, however, a single error on either side of equation 8.6 will always be detected even in the presence of overflow.

The crucial condition that must be satisfied to apply a mantissa-based integer checksum test on f is whether $f(\mathrm{mant}(\boldsymbol{v})) = \mathrm{mant}(f(\boldsymbol{v}))$. To check if f is mantissa preserving, we have to look at the basic floating point operations, such as multiplication, division, addition, subtraction, square-root, and others, that f is composed of and see if they are mantissa preserving. A binary operator $\odot$ is said to be mantissa preserving if mant (a) $\odot$ mant (b) = mant ($a \odot b$). Let a floating point number a be represented as $a_1 \times 2^{a_2}$, where a_1 is the mantissa and a_2 the exponent of a. Ignoring the position of the implicit binary point (i.e., in terms of just the bit pattern of numbers), floating point multiplication is mantissa preserving because:

$$\begin{aligned}\mathrm{mant}(a)\ \mathrm{mant}(b) &:= a_1 \cdot b_1, \text{ while } \mathrm{mant}(a \cdot b)\\ &= \mathrm{mant}(a_1 \cdot b_1 \times 2^{a_2+b_2}) := a_1 \cdot b_1.\end{aligned} \tag{8.7}$$

Note that sometimes the mantissa c_1 of the product $c = a \cdot b$ is "forcibly" normalized by the floating point hardware when the "natural" mantissa of the resulting product is not normalized (e.g., $1.100 \times 1.110 = 10.101000$; the product mantissa is not normalized and is normalized to 1.010100, assuming 6 bits of precision after the binary point, and the exponent is incremented by 1). In such a case, c_1 is either equal to $(a_1 \cdot b_1)/2$ as in the previous example or is equal to $(a_1 \cdot b_1)/2 - 1$ when the mantissa that is not normalized has a 1 in its least-significant bit. When normalization is performed, the exponent of c becomes $a_2 + b_2 + 1$. This normalization done by the floating point multiplication unit is easy to detect and reverse in c (a process called **denormalization**) so that the multiplication is effectively mantissa preserving. Similarly, floating point division is also mantissa preserving. Floating point addition and subtraction, however, are not mantissa preserving.

Thus, if f is composed of only floating point multiplications and/or divisions, it is mantissa preserving, and the integer checksum test can be applied to it. On the other hand, if f has floating point additions as well, and there is no guarantee that the exponents of all numbers involved are equal, then f is not mantissa preserving. All is not lost in such a case because it might be possible to formulate f as a composition $g \circ h[g \circ h(\boldsymbol{u}) := g(h(\boldsymbol{u}))]$ of two (or more) linear functions g and h, where, without loss of generality, h is mantissa preserving and g is not. In such a case, one can apply an integer checksum test to the h portion of f [i.e., after computing $h(\boldsymbol{u})$] and a floating point checksum test to f [i.e., after computing $g(h(\mathbf{u})) := f(\mathbf{u})$]. Since errors in $h(\boldsymbol{u})$ are caught precisely, the error coverage will still increase and the false alarm rate will reduce in checking f vis-a-vis just by applying the floating point checksum test to f. This type of a combined mantissa and floating point checksum is called a **hybrid** checksum.

Application to Matrix Multiplication

We discuss here the application of integer mantissa checksums to matrix multiplication; the description of this test for **LU** decomposition can be found in work by Dutt and Assaad (1996). Matrix multiplication is not mantissa preserving, since it contains floating point additions. However, matrix multiplication can be formulated as a composition of two functions, one mantissa-preserving and the other not, as shown below.

First of all, matrix multiplication can be thought of as a sequence of vector–matrix multiplications:

$$A_{n\times m} \cdot B_{m\times l} := \begin{pmatrix} \boldsymbol{a}_1^T \cdot B \\ \boldsymbol{a}_2^T \cdot B \\ \vdots \\ \boldsymbol{a}_n^T \cdot B \end{pmatrix}, \tag{8.8}$$

where $\boldsymbol{a}_i^T$ is the ith row of A, and $\boldsymbol{a}_i^T \cdot B$ is a vector–matrix multiplication. Note that $f_B(\boldsymbol{a}_i^T) := \boldsymbol{a}_i^T \cdot B$ is a linear function. This property leads to the **floating point row checksum test** for matrix multiplication. In terms of f_B, the row checksum test is:

$$f_B\left(\sum_{i=1}^{n} \boldsymbol{a}_i^T\right) \overset{?}{=} \sum_{i=1}^{n} f_B(\boldsymbol{a}_i^T). \tag{8.9}$$

Matrix multiplication can also be thought of as a sequence of matrix vector products $A \cdot B = (A \cdot \boldsymbol{b}_1, A \cdot \boldsymbol{b}_2, \ldots, A \cdot \boldsymbol{b}_l)$. This leads to a similar **column checksum test**.

A vector–vector component-wise product $\diamond$ for two vectors $\boldsymbol{u}$ and $\boldsymbol{v}$ is defined as the vector:

$$\boldsymbol{u} \diamond \boldsymbol{v} := (u_1 \cdot v_1,\ u_2 \cdot v_2, \ldots,\ u_n \cdot v_n)^T. \tag{8.10}$$

For a matrix $B_{m\times l}$, and a m-vector $\boldsymbol{u}$, $\boldsymbol{u}^T \diamond B$ is defined as:

$$\boldsymbol{u}^T \diamond B := (\boldsymbol{u}^T \diamond \boldsymbol{b}_1,\ \boldsymbol{u}^T \diamond \boldsymbol{b}_2, \ldots,\ \boldsymbol{u}^T \diamond \boldsymbol{b}_l), \tag{8.11}$$

where $\boldsymbol{b}_i$ denotes the ith column of B. Thus $\boldsymbol{u}^T \diamond B$ is an $m \times l$ matrix. For example:

$$(5, 2) \diamond \begin{pmatrix} 2 & 3 \\ 1 & 4 \end{pmatrix} := \left((5, 2) \diamond (2, 1)^T, (5, 2) \diamond (3, 4)^T\right) = \begin{pmatrix} 10 & 15 \\ 2 & 8 \end{pmatrix} \tag{8.12}$$

It is easy to see that h_B defined by $h_B(\boldsymbol{u}) := \boldsymbol{u}^T \diamond B$ is linear and mantissa preserving.

Finally, defining function rowsum (C) for a matrix $C = (c_1, \ldots, c_m)$ as rowsum $(C) := (\vec{+}(c_1), \ldots, \vec{+}(c_m))$ where $\vec{+}(v) := \sum_{j=1}^{m} v_i$, we obtain the decomposition of the vector–matrix product as stated in theorem 2 (Dutt and Assaad, 1996):

Theorem 2: The vector–matrix product $\boldsymbol{u}^T \cdot B := f_B(\boldsymbol{u}) =$ rowsum $\circ\, h_B(\boldsymbol{u})$.

Since matrix multiplication $A \cdot B$ is a sequence of $f_B(\boldsymbol{a}_i)$ computations, one for each row of A, one can apply a mantissa-based integer row checksum test to the $h_B(\boldsymbol{a}_i)$ components to precisely check for errors in the floating point multiplicant in $A \cdot B$. This integer row checksum test is as follows:

$$h_B^{\text{mant}}\left(\sum_{i=1}^{n} \text{mant}(a_i)\right) \overset{?}{=} \sum_{i=1}^{n} \text{mant}(h_B(\boldsymbol{a}_i)), \qquad (8.13)$$

or in other words

$$\text{rowsum}(\text{mant}(A)) \diamond \text{mant}(B) \overset{?}{=} \sum_{i=1}^{n} \text{mant}(\boldsymbol{a}_i^T \diamond B). \qquad (8.14)$$

Note that the RHS of (Banerjee, 1986) is obtained almost for free from the floating point computations $\boldsymbol{a}_i^T \diamond B$ that are computed as part of the entire floating point vector matrix product $\boldsymbol{a}_i^T \times B$. A similar derivation can be made for an integer column checksum test.

The floating point additions have to be tested by applying the floating point checksum tests to rowsum $\circ h_B(\boldsymbol{u}) := f_B(\boldsymbol{u})$ (i.e., to the final matrix product $A \cdot B$) to give rise to the hybrid test for matrix multiplication.

Error Coverage Results

Analytical Results

Two noteworthy results that have been obtained regarding the error coverage of the mantissa checksum method are given in the two theorems in this subsection.

Theorem 3: If either modulo or extended-precision integer arithmetic is used in a mantissa checksum test of the form of equation 8.6 shown again here:

$$f\left(\sum_{v \in s} \text{mant}(v)\right) \overset{?}{=} \sum_{v \in S} \text{mant}(f(v)),$$

then any single bit error in each of the scalar component of this test will be detected even in the presence of overflow in modulo (or single-precision) integer arithmetic (Dutt and Assaad, 1996).

In equation 8.6, scalars a_i and b_i are compared, where $a := (a_1, \ldots, a_n)^T$ and $b := (b_1, \ldots, b_n)^T$ are the LHS and RHS, respectively of equation 8.6. The above result means that single bit errors in either a_i or b_i can be detected for each i even when single-precision integer arithmetic is used. The following result is regarding the maximum number of arbitrarily distributed errors (i.e., not necessarily restricted to one error per scalar component of the check) that can be detected by the mantissa checksum test.

Theorem 4: The row and column mantissa checksums for matrix multiplication can detect errors in any three elements of the product matrix $C = A \cdot B$ that are due to errors in the floating point multiplications used to compute these elements (Assaad and Dutt, 1992).

The mantissa checksum test also implicitly detects errors in the exponents of the floating point products. This is done during the denormalization process by checking if $\exp(a) + \exp(b) = \exp(a \cdot b)$, which occurs when the floating point multiplier did not need to normalize the product $a \cdot b$, or if $\exp(a) + \exp(b) = \exp(a \cdot b + 1)$, meaning that a normalization was needed and the mantissa of $a \cdot b$ needs to be denormalized for use in the mantissa checksum test. If neither of these conditions hold, then an error is detected in the exponent of $a \cdot b$.

Empirical Results

A **dynamic range** of x means that the exponents of the input data lie in the interval $[-x, x]$. In Figure 8.20, the error coverage or the number of detection events (for single errors) is plotted against different dynamic ranges of the input data for the following tests.

(1) The **thresholded floating point checksum test** is used with the lower 24 bits masked in the checksum comparison for matrix multiplication and 12 bits for **LU** decomposition. The threshold of the floating point checksum test component of the hybrid checksum test was chosen to correspond to masking the lower 24 (12) bits, which guarantees almost zero false alarm in matrix multiplication (**LU** decomposition).

(2) The **mantissa checksum test** is used alone, as described previously.

(3) The **hybrid checksum test** uses both the thresholded floating point test and the mantissa checksum test—an error is detected in the hybrid test if an error is detected in its mantissa checksum test or in its floating point checksum test.

The plots in Figure 8.20 clearly show the significant improvements in coverage of the hybrid checksum test with respect to both the mantissa and the floating point checksum tests. For the low false alarm case, the mantissa checksum test has superior coverage compared to the floating point checksum test. An important point to be noted that is not apparent from the plots of Figure 8.20 is that the mantissa checksum test detects 100% of all multiplication errors for both matrix multiplication and **LU** decomposition.

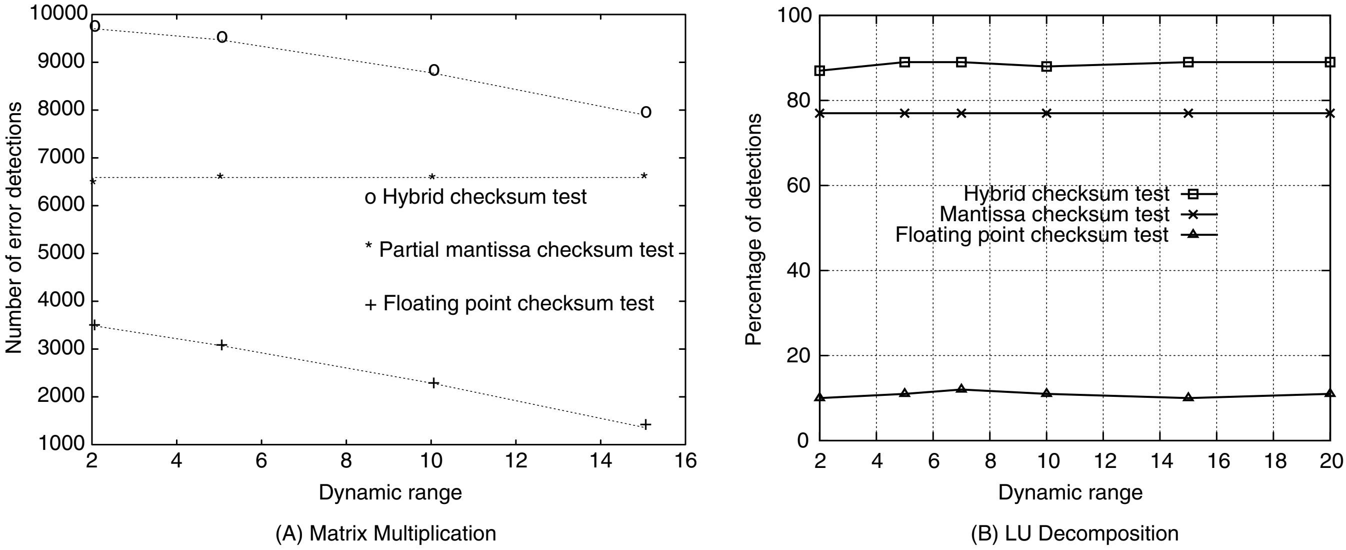

FIGURE 8.20 Error Coverage Versus Dynamic Range of Data. These data are for the mantissa checksum test, a properly thresholded floating point checksum test, and the hybrid checksum test.

Note that for matrix multiplication, the error coverage of the hybrid test is as high as 97% for a dynamic range of 2 and is 80% for a dynamic range of 15; this is a much higher error coverage than the technique of forward-error propagation used with the floating point checksum test in work by Roy-Chowdhury and Banerjee (1993). For **LU** decomposition, error coverage of 90% is obtained for a dynamic range of 7, which is similar to Roy-Chowdhury and Banerjee's results.

Timing Results

Note that part of the overhead of a mantissa checksum test is extracting the mantissas of the input matrices or vectors and also extracting and denormalizing the mantissas of the intermediate multiplications $a_{i,\,j} \cdot b_{j,\,k}$. The latter overhead can be eliminated by a very simple modification to the floating point multiplication unit that is shown in Figure 8.21. With this modification, the mantissa that is not normalized is also available (along with the normalized mantissa) as an output of the floating point multiplier. In many computers, the floating point product is also available in the form that is not normalized by using the appropriate multiply instruction—this requires tinkering with the compiler in such a machine to use the non-normalized multiply instruction where appropriate. No hardware modification is needed in this case to extract the mantissa for free.

Figure 8.22 shows the plots of the times of the fault-tolerant computations that use the hybrid checksum test and that use only the floating point checksum test. The average overhead of the hybrid checksum for matrix multiplication is 15%, whereas for **LU** decomposition, the overhead is only 9.5%. Thus, the significantly higher error coverages yielded by the mantissa checksum test are obtained at only nominal time overheads that are lower than those of previous techniques (such as by Roy-Chowdhury and Banerjee, 1993) developed for combatting the susceptibility of the floating point checksum test to round-off.

8.7 Conclusions

We have presented a summary of various fault-detection and fault-tolerance methods at various levels of a computing system: arithmetic circuit, FPGA, program control flow, processor system and algorithm. We have also presented some of our works in these areas. Results show that the techniques discussed produce significant increases in system reliability. As computer chips become more complex and denser, with smaller devices, they and systems incorporating them become more and more vulnerable to faults arising from a myriad of sources like fabrication errors, operation extremes, and external disturbances. Computer systems are also being increasingly used in various economic- and life-critical environments. It is thus hoped that microprocessor and computer manufacturing will undergo a paradigm shift whereby reliability becomes an important metric, and fault tolerance capabilities of different degrees such as those discussed here are explicitly designed in computer chips and systems to provide different levels of dependability and reliability needed in various application environments.

9.1 Introduction

Petri nets are an excellent formal model for studying concurrent and distributed systems and have been widely applied in many different areas of computer science and other disciplines (Murata, 1989). There have been over 8000 publications on Petri nets (refer to Website *http://www.daimi.au.dk/PetriNets/*). Since Carl Adam Petri originally developed Petri nets in 1962, Petri nets have evolved through four generations: the first-generation low-level Petri nets primarily used for modeling system control (Reisig, 1985a), the second-generation high-level Petri nets for describing both system data and control (Jensen and Rozenberg, 1991), the third-generation hierarchical Petri nets for abstracting system structures (He and Lee, 1991; He, 1996; Jensen, 1992), and the fourth-generation object-oriented Petri nets for supporting modern system development approaches (Agha, 2001). Petri nets have also been extended in many different ways to study specific system properties, such as performance, reliability, and schedulability. Well-known examples of extended Petri nets include timed Petri nets (Wang, 1998) and stochastic Petri nets (Marsan *et al.*, 1994; Haas, 2002). In this article, we present several extensions to Petri nets based on our own research work and provide analysis techniques for these extended Petri net models. We also discuss the intended applications of these extended Petri nets and their potential benefits.

9.2 High-Level Petri Nets

In the past few years, a concerted effort by the worldwide Petri net community has resulted in an international standard on defining high-level Petri nets (HLPN) (ISO/IEC, 2002) that will profoundly help to facilitate and promote the research and applications of these nets. In the following sections, we follow as closely as possible the notations, concepts, and definitions given in the standard documentation to introduce high-level Petri nets, which are used later to define our extensions.

9.2.1 The Syntax and Static Semantics of High-Level Petri Nets

An **HLPN** is a structure:

$$N = (NG, \mathrm{Sig}, V, H, Type, AN, M_0).$$

Where:

- $NG = (P, T; F)$ is a net graph, with:
  - P a finite set of nodes, called places;
  - T a finite set of nodes, called transitions, disjoint from P ($P \cap T = \varnothing$); and
  - $F \subseteq (P \times T) \cup (T \times P)$ a set of directed edges called arcs, known as the flow relation.
- $Sig = (S, O)$ is a Boolean signature, where S is a set of sorts and O is a set of operators defined in the Annex A of ISO/IEC (2002).
- V is an S-indexed set of variables, disjoint from O.
- $H = (S_{\mathrm{H}}, O_{\mathrm{H}})$ is a many-sorted algebra for the signature Sig, defined earlier in this list:
- $Type$: $P \rightarrow S_{\mathrm{H}}$ is a function that assigns types to places.
- $AN = (A, TC)$ is a pair of net annotations.
  - A: $F \rightarrow TERM(O \cup V)$ such that for all (p, t), $(t, p) \in F$ and all bindings α, $Val_\alpha(A(p, t))$, $Val_\alpha(A(t', p)) \in \mu Type(p)$. $TERM(O \cup V)$, α, Val_α and $\mu Type(p)$ are defined in Annex A of ISO/IEC (2002). A is a function that annotates each arc with a term that when evaluated (for some binding) results in a multiset over the associated place's type.
  - TC: $T \rightarrow TERM(O \cup V)_{\mathrm{Bool}}$ is a function that annotates transitions with Boolean expressions.
- $M_0 \colon P \rightarrow \cup_{p \in P} \ \mu Type(p)$ such that $\forall p \in P$, $M_0(p) \in \mu Type(p)$ is the initial marking function that associates a multiset of tokens (of the correct type) with each place.

The above definitions are directly from ISO/IEC 2002. Basically, an HLPN has three essential parts: (1) a net graph NG defining the syntax, (2) an underlying algebraic specification (Sig, V, H) defining the semantic domain, and (3) a net inscription ($Type$, AN, M_0) mapping syntactic entities to their semantic denotations. By restricting the underlying algebraic specification and/or the net inscription, different variations of high-level Petri nets can be obtained.

9.2.2 Dynamic Semantics

Marking

The marking M of the HLPN is defined in the same way as the initial marking:

$M \colon P \rightarrow \cup_{p \in P} \ \mu Type(p)$ such that $\forall p \in P$, $M(p) \in \mu Type(p)$.

Enabling

- **Enabling of a Single Transition Mode**

A transition $t \in T$ is enabled in a marking M for a particular assignment of α_t to its variables and satisfies the transition condition, $Val_{\mathrm{bool}}(TC(t)) = \mathrm{true}$, known as a **mode** of t, if:

$$\forall p \in P \ Val_{\alpha_t}(\overline{p,\ t}) \leq M(p),$$
$$\text{where for } (u, v) \in (P \times T) \cup (T \times P),$$
$$\overline{u,\ v} = A(u, v) \text{ for } (u, v) \in F, \text{ or } \overline{u,\ v} = \varnothing \text{ for } (u, v) \notin F.$$

- **Concurrent Enabling of Transition Modes**

Let α_t be an assignment for the variables of transition $t \in T$ that satisfies its transition condition, and then denote the set of all assignments for transition t, by Assign_t. Define the set of all transition modes to be $TM = \{(t, \alpha_t) | t \in T,\ \alpha_t \in \mathrm{Assign}_t\}$ and a step to be a finite nonempty multiset over TM.

A step X of transition modes is enabled in a marking, M, if:

$$\forall p \in P \sum_{(t, \alpha_t) \in X} Val_{\alpha_t}(\overline{p, t}) \leq M(p).$$

Thus, all of the transition modes in X are concurrently enabled if X is enabled. Enabling of a single transition mode is a special case of concurrent enabling of transition modes.

The enabling condition of a transition specifies that enough right tokens are available to make the transition fire.

Transition Rule

If $t \in T$ is enabled in mode α_t for marking M, t may occur in mode α_t. When t occurs in mode α_t, the marking of the net is transformed to a new marking M', denoted in $M[t, \alpha_t> M'$, according to the following rule:

$$\forall p \in P(M'(p) = M(p) - Val_{\alpha_t}(\overline{p,\ t}) + Val_{\alpha_t}(\overline{t,\ p})).$$

If a step X is enabled in marking M, then the step can occur, resulting in a new marking of M' denoted by $M[X> M'$, where M' is given by:

$$\forall p \in P(M'(p) = M(p) - \sum_{(t, \alpha_t) \in X} Val_{\alpha_t}(\overline{p, t}) + \sum_{(t, \alpha_t) \in X} Val_{\alpha_t}(\overline{t,\ p}))$$

The firing rule defines the effect of firing a transition, which consumes specific tokens according to the mode in the preset (input places) of the transition and generates new tokens in the postset (output places) of the transition.

Behavior of A HLPN N

An **execution sequence** $M_0[X_0> M_1[X_1> \ldots$ of N is either finite when the last marking is terminal (no more enabled transition in the last marking) or infinite, in which each X_i is a step. The **behavior** of N is the set of all execution sequences starting from the initial marking. The set of all reachable markings from the initial marking is denoted by $[M_0>$.

Although ISO/IEC (2002) has defined the concepts of markings, transition enabling, and firing rules, it stopped short in defining the dynamic semantics of an HLPN. In the existing Petri net literature, there have been several semantic models of Petri nets, such as interleaving, concurrent, and causal executions (Reisig, 1985b). From our own experience, we feel that the interleaving set semantics model defined above is adequate for studying many useful system behavioral properties.

9.3 Temporal Predicate Transition Nets

Petri nets are a model-oriented formal method and are well suited for modeling the dynamic behaviors of concurrent and distributed systems. Petri net specifications reveal system design structures and thus provide guidelines for system implementation. Furthermore, Petri net specifications are executable and support system simulation and testing in addition to formal analysis. It is not easy, however, to directly and explicitly express behavioral properties using Petri nets. On the other hand, property-oriented formal methods, such as temporal logic, are ideal for specifying and analyzing behavioral properties. It would be great to have a hybrid formal method by integrating the strengths of model-oriented and property-oriented formal methods. In recent years, integrating formal methods has become a major research area (Clarke and Wing, 1996). There have been several published results on integrating Petri nets and temporal logic (Anttila *et al.*, 1983; Diaz *et al.*, 1983; He and Lee, 1990; He, 1992; Mandrioli *et al.*, 1996; Suzuki and Lu, 1989). Most of the earlier work was either lacking a systematic approach or using a low-level Petri net model. In the following subsections, we describe our results on integrating predicate transition nets (Genrich and Lautenbach, 1981) and first-order linear time temporal logic (Manna and Pnueli, 1992).

9.3.1 Definition of Temporal Logic

In this section, we define a linear time first-order temporal logic (LTFOTL) in the style of Lamport (1994a) based on a given PrTN. Let $N = (NG, Sig, V, H, Type, AN, M_0)$ be a PrTN.

Values, State Variables, and States

The **set of values** is the multiset of tokens defined by the ground terms TERM(O) of N. Multisets can be viewed as partial functions. For example, multiset $\{3a, 2b\}$ can be represented as $\{a \mapsto 3, b \mapsto 2\}$.

The **set of state variables** is the set P of places of NG, which change their meanings during the executions of N. The arity of a place p is determined by its type $Type(p)$.

The **set of states *St*** is the set of all reachable markings $[M_0>$ of N. A marking is a mapping from the set of state variables into the set of values. We use $M[\![x]\!]$ to denote the value of x under state (marking) M.

Since state variables take partial functions as values, they are *flexible* function symbols. We can access a particular component value of a state variable. There is a problem, however, associated with partial functions (i.e., many values are undefined). The above problem can easily be solved by extending state variables into total functions in the following way: for any n-ary state variable p, any tuple $c \in$ TERM(O), and any state M, if $p(c)$ is undefined under M, then let $M[\![p(c)]\!] = 0$. The above extension is consistent with the semantics of PrTN. Furthermore we can consider the meaning $[\![p(c)]\!]$ of the function application $p(c)$ as a mapping from states to **Nat** using a postfix notation for function application $M[\![p(c)]\!]$.

Rigid Variables, Rigid Function, and Predicate Symbols

Rigid variables are individual variables that do not change their meanings during the executions of N. All rigid variables occurring in our temporal logic formulas are bound (quantified), and they are the only variables that can be quantified. Rigid variables are variables appearing in the label expressions and constraints of N.

Rigid function and **predicate symbols** do not change their meanings during the executions of N. The set of rigid function and predicate symbols is defined in V of N.

State Functions, Predicates, and Transitions

A **state function** is an expression built from values, state variables, rigid function, and predicate symbols. For example, $[\![p(c) + 1]\!]$ is a state function, where c and 1 are values, p is a state variable, and $+$ is a rigid function symbol. Since the meanings of rigid symbols are not affected by any state, for any given state M, $M[\![p(c) + 1]\!] = M[\![p(c)]\!] + 1$.

A **predicate** is a Boolean-valued state function. A predicate p is satisfied by a state M if and only if $M[\![p]\!]$ is true.

A **transition** is a particular kind of predicate that contains primed state variables (e.g., $[\![p'(c) = p(c) + 1]\!]$). A transition relates two states (an old state and a new state), where the unprimed state variables refer to the old state and where the primed state variables refer to the new state. Therefore, the meaning of a transition is a relation between states. The term **transition** used here is a temporal logic entity. Although it reflects the nature of a transition in a PrTN net N, it is not a transition in N. For example, given a pair of states M and M': $M[\![p'(c) = p(c) + 1]\!]M'$ is defined by $M'[\![p(c)]\!] = M[\![p(c)]\!] + 1$. Given a transition t, a pair of states M and M' is called a "transition step" if $M[\![p]\!]M'$ equals true.

We can easily generalize any predicate p without primed state variables into a relation between states by replacing all unprimed state variables with their primed versions such that $M[\![p]\!]M'$ equals $M'[\![p]\!]$ for any states M and M'.

Temporal Formulas

Temporal formulas are built from elementary formulas (predicates and transitions) using logical connectives $\neg$ and $\wedge$ (and derived logical connectives $\vee$, $\Rightarrow$, and $\Leftrightarrow$), universal quantifier $\forall$ (and derived existential quantifier $\exists$), and temporal operator **always** $\Box$ (and derived temporal operator sometimes $\Diamond$).

The semantics of temporal logic is defined on infinite sequences of states that are extracted from the execution sequences of PrTNs, where the last marking of a finite execution sequence is repeated infinitely many times at the end of the execution sequence. For example, for an execution sequence $M_0[X_0> M_1[X_1> \ldots M_n$, the following infinite sequence behavior $\sigma = << M_0 \ldots M_n, M_n, \ldots >>$ is obtained. We denote the set of all possible behaviors obtained from a given PrTN as St^{∞}. Let u and v be two arbitrary temporal formulas; p be an m-ary place; t be a transition; $x, x_1 \ldots, x_n$ be rigid variables; $\sigma = << M_0, M_1, \ldots >>$ be a behavior; and $\sigma^k = << M_k, M_{k+1}, \ldots >>$ be a k-step-shifted behavior sequence. We define the semantics of temporal formulas recursively as follows:

(1) $\sigma[\![p(x_1, \ldots, x_n)]\!] \;\equiv\; M_0[\![p(x_1, \ldots, x_n)]\!]$
(2) $\sigma[\![t]\!] \;\equiv\; M_0[\![t]\!]M_1$
(3) $\sigma[\![\neg u]\!] \;\equiv\; \neg\sigma[\![u]\!]$
(4) $\sigma[\![u \wedge v]\!] \;\equiv\; \sigma[\![u]\!] \wedge \sigma[\![v]\!]$
(5) $\sigma[\![\forall xu]\!] \;\equiv\; \forall x \cdot \sigma[\![u]\!]$
(6) $\sigma[\![\Box u]\!] \equiv\; \forall n \in \mathbf{Nat}\ \sigma^n[\![u]\!]$

Intuitively temporal operator always $\Box$ means every state in a state sequence, and its dual operator sometimes $\Diamond$ means some future state in a state sequence. The relationship between these two temporal operators is:

$$\neg\Box W\!\!\!\equiv \Diamond.$$

A temporal formula u is said to be **satisfiable** denoted as $\sigma \models u$, if there is an execution σ such that $\sigma[\![u]\!]$ is true (i.e., $\sigma \models u \Leftrightarrow \exists\sigma \in ST^{\infty} \cdot \sigma[\![u]\!]$). A temporal formula u is **valid** with regard to N, denoted as $N \models u$, if it is satisfied by all possible behaviors St^{∞} from N: $N \models u \Leftrightarrow \forall\sigma \in St^{\infty} \cdot \sigma[\![u]\!]$.

9.3.2 Temporal Predicate Transition Net

A temporal predicate transition net (TPrTN) is a tuple $TN = (NG, \mathrm{Sig}, V, H, \mathrm{Type}, AN, M_0, f)$, where $N = (NG, Sig, V, H, Type, AN, M_0)$ is a PrTN, and f is a LTFOTL formula that constrains the execution of TN. The semantics of TN are defined to be the set of execution sequences $\Sigma = \{\sigma | \sigma \in St^{\infty} \wedge \sigma[\![f]\!]\}$.

It is easy to see that a TPrTN TN is a PrTN N with a temporal logic formula f. The temporal logic formula is defined according to the net graph NG using logical connectives and operators, which can be viewed as a part of the underlying algebraic specification (Sig, V, H). The temporal logic formula f is evaluated using the dynamic behaviors of N. By incorporating a temporal formula into the definition of a PrTN, we are able to explicitly specify and verify many system properties such as fairness.

9.3.3 An Example of TPrTN

The **Five Dining Philosophers** problem is a classical example for studying behavioral properties of concurrent processes. There are five philosophers sitting around a round table, and there is one chopstick between two adjacent philosophers. Each philosopher is either thinking or eating. In order for a philosopher to eat, he needs to pick up two chopsticks next to him. There are several interesting issues with regard to a system model of this simple problem:

- Is the system deadlock free? A deadlock occurs when the system cannot progress anymore due to a formation of a waiting cycle.
- Has the system enforced mutual exclusion? Mutual exclusion ensures that no two neighboring philosophers can eat at the same time.
- Is the system live-lock free? A live lock occurs when some philosopher has no chance to eat anymore from a certain point and thus starves to death.

The following TPrTN models the Five Dining Philosophers problem, shown in Figure 9.1, in which five philosophers are denoted by five integer tokens 0 to 4 and five chopsticks are also denoted by five integer tokens 0 to 4. Places p_1 and p_3 stand for the **Thinking** and **Eating** states of philosophers, respectively. Place p_2 defines the availability of chopsticks. Transitions t_1 and t_2 stand for the actions of **Pick up** and **Put down** chopsticks, respectively.

The algebraic definition of the net $TN = (NG, Sig, V, H, Type, AN, M_0, f)$ is as follows:

$P = \{p_1, p_2, p_3\}$, $T = \{t_1, t_2\}$,
$F = \{(p_1, t_1), (p_2, t_1), (t_1, p_3), (p_3, t_2), (t_2, p_1), (t_2, p_2)\}$,
$\mathrm{Type}(p_1) = \mathrm{Type}(p_2) = \mathrm{Type}(p_3) = \mathrm{INT}$,
$A(p_1, t_1) = x, \quad A(p_2, t_1) = \{x, y\}, \quad A(t_1, p_3) = x,$

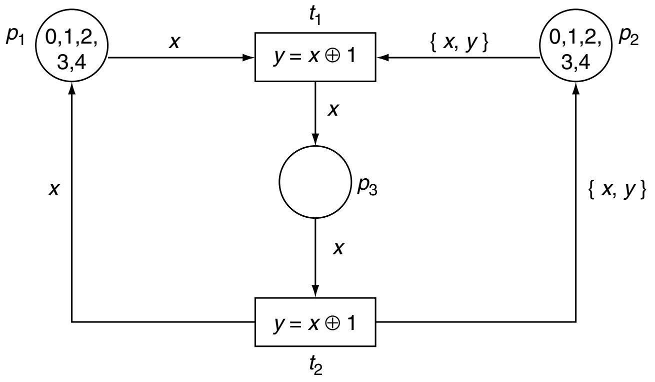

FIGURE 9.1 A TPrTN Specification of the Five Dining Philosophers Problem

where INT is a sort defined in *Sig*, x and y are variables in V, $\oplus$ is a modulo 5 addition operation given in *Sig* and defined in the algebra H, and $y = x \oplus 1$ is a term in algebra H.

Temporal formula f is defined as follows:

$$f = \forall x(\Box\Diamond(p_1(x) = 1 \wedge p_2(x) = 1 \wedge p_2(x \oplus 1) = 1)$$
$$\Rightarrow \Box\Diamond(p'_3(x) = 1 \wedge p'_1(x) = 0 \wedge p'_2(x) = 0 \wedge p'_2(x \oplus 1) = 0)).$$

Temporal formula f defines the strong fairness (Manna and Pnueli, 1992) that captures the enabling condition and the firing result of transition t_1 with every mode (defined by $\forall x$). Intuitively, it states that any philosopher who wants to eat **infinitely many times** (defined by the temporal operator sequence $\Box\Diamond$) will eat **infinitely many times**.

9.3.4 Analysis of TPrTNs

System behavioral properties can be divided into two major categories: **safety** properties and **liveness** properties (Manna and Pnueli, 1992). Widely accepted formal definitions of safety and liveness properties were given in (Alpern and Schneider, 1985). A safety property, which is different from the concept **safeness** in Petri net literature (Murata, 1999) needs to hold in every state and in every state sequence. The canonical form of a safety property is characterized by a temporal formula $\Box w$. A liveness property, which is different from the concept transition **liveness** in Petri net literature (Murata, 1989), needs to hold in some future state in every state sequence. The canonical form of a liveness property is characterized by a temporal formula $\Diamond w$.

In He and Lee (1990) and He and Ding (1992), we developed an axiomatic approach of using temporal logic to analyze PrTNs. The essential ideas are to derive system-dependent temporal inference rules from PrTN transitions. These inference rules capture the causal relationships of transition firings. Thus, executions of a PrTN become temporal logic deductions in the derived axiomatic system. We have proved that safety properties (Manna and Pnueli, 1992) can be effectively analyzed using this axiomatic approach. Furthermore, we have shown how to analyze liveness properties (Manna and Pnueli, 1992) using the above temporal formula (He, 1991).

Given $TN = (NG, Sig, V, H, Type, AN, M_0, f)$, we can obtain the following system-dependent temporal axiom system L:

(1) A system-dependent axiom captures the initial marking M_0: $\wedge_{p \in P}(IC_p)$, (IC),

where IC_p represents the initial condition of place p under M_0

(2) For each place p of arity k, let $y_1, \ldots, y_k$ be new variables not used in any label and t be any transition in the postset $p\bullet$ with label $L(p, t) = \{m_1(x_{11}, \ldots, x_{1k}), \ldots, m_n(x_{n1}, \ldots, x_{nk})\}$. We construct an inference rule as follows: $p(y_1, \ldots, y_k) > p'(y_1, \ldots, y_k)$ $| - \vee_{t \in p\bullet}((ET_t) \wedge (\vee_{1 \le i \le n}$ $(\wedge_{1 \le j \le k}(y_j = x_{ij})))), \quad (PR_p)$

where ET_t represents the causal relationship of firing transition t. Intuitively, each inference rule states if a place loses tokens from one marking to another, then some relevant transition must have fired (He and Ding, 1992). The variables are universally quantified and are omitted for simplicity. The above inference rules only reflect the local state changes. Together with system independent axioms and inference rules (Manna and Pnueli, 1992, 1995), we can use IC and PR_p to prove a variety of safety properties.

The following is the derived system-dependent temporal axiom system of the Five Dining Philosophers problem shown in Figure 9.1:

$$p_1(0) = 1 \wedge p_1(1) = 1 \wedge p_1(2) = 1 \wedge p_1(3) = 1 \wedge p_1(4) = 1 \wedge$$
$$p_2(0) = 1 \wedge p_2(1) = 1 \wedge p_2(2) = 1 \wedge p_2(3) = 1 \wedge p_2(4) = 1. \quad (IP)$$

$$p_1(x) > p'_1(x)| - p_1(x) \ge 1 \wedge p_2(x) \ge 1 \wedge p_2(y) \ge 1 \wedge$$
$$y = x \oplus 1 \wedge p'_1(x) = p_1(x) - 1 \wedge p'_2(x) =$$
$$p_2(x) - 1 \wedge p'_2(y) = p_2(y) - 1 \wedge p'_3(x) = p_3(x) + 1. \quad (PR_{p_t})$$

$$p_2(x) > p'_2(x)| - p_1(x) \ge 1 \wedge p_2(x) \ge 1 \wedge p_2(y) \ge 1 \wedge$$
$$y = x \oplus 1 \wedge p'_1(x) = p_1(x) - 1 \wedge p'_2(x) = p_2(x) - 1 \wedge$$
$$p'_2(y) = p_2(y) - 1p'_3(x) = p_3(x) + 1. \quad (PR_{p_2})$$

$$p_3(x) > p'_3(x)| - p_3(x) \ge 1 \wedge p'_1(x) = p_1(x) + 1 \wedge p'_2(x) = p_2(x) + 1 \wedge$$
$$p'_2(y) = p_2(y) + 1 \wedge p'_3(x) = p_3(x) - 1 \wedge y = x \oplus 1. \quad (PR_{p_3})$$

A TPrTN is **deadlock free** if and only if there is at least one transition being enabled in any reachable state or if a normal terminal state has been reached. Deadlock freedom is a safety property. The deadlock freedom property of the Five Dining Philosophers problem is formulated as follows:

$$\Box\exists x, y(p_3(x) \ge 1 \vee (p_1(x) \ge 1 \wedge p_2(x) \ge 1 \wedge p_2(y) \ge 1 \wedge$$
$$y = x \oplus 1)). \quad (*)$$

A TPrTN net is **live lock free** if and only if for any transition enabled infinitely often with a mode α, the same transition with mode α will fire infinitely often. Livelock freedom is a liveness property. One of the liveness properties of the Five Dining Philosophers problem is that every individual philosopher will eventually get a piece of a meal (starvation free), which can be expressed by the following temporal formula:

$$\forall x\Box\Diamond(p_3(x) = 1). \quad (**)$$

The proofs of the above formulas involve logical deductions using inference rules of ordinary first-order logic and temporal logic as well as system-dependent inference rules listed previously. Because logical deductions are machine-oriented and not suitable for human comprehension, we omit the proofs of the above properties (*) and (**). Interested readers can find the proofs of (*) and (**) in He (1991) and He and Ding (1992).

9.4 *PZ* Nets

A widely accepted formal notation for specifying the functionality of sequential systems is *Z* (Spivey, 1992). The *Z* is based on typed set theory and first-order logic and, thus, offers rich type definition facility and supports formal reasoning. However, *Z* does not support an effective definition of concurrent and distributed systems, and *Z* specifications do not have explicit operational semantics. Many researchers have attempted to combine *Z* with other concurrent models, including CSP (Benjamin, 1990), CCS (Taguchi and Araki, 1997), and temporal logic (Duke and Smith, 1989; Clarke and Wing, 1996; Evans, 1997; Lamport, 1994b) in recent years. Several works attempted to integrate Petri nets and *Z* (van Hee *et al.*, 1991; He, 2001). In van Hee *et al.* (1991), *Z* was used to specify (1) the metamodel of restricted hierarchical colored Petri nets (that allows super transitions but not super places) and (2) the transitions of specific colored Petri nets. A complete specification consists of a hierarchical net structure, one global state schema for defining all places, and one operation schema for each transition. Schemas of transitions are piped to obtain an operational semantics through the use of input and output variables. In He (2001), a formal method of integrating Petri nets with *Z* was presented with the objectives to extend Petri nets with data and function definition capabilities through an underlying *Z* specification and to extend *Z* with an explicit operational semantics and concurrency mechanisms through Petri nets. In the following subsections, we briefly describe the basics of *Z* notations and introduce the results given in He (2001).

9.4.1 A Brief Overview of *Z*

Besides elementary data types, *Z* allows the user to introduce other primitive types, called given types. Given types are in capital letters and enclosed by a pair of brackets that do not require further definitions. For example, [IDEN] introduces a given type IDEN.

Part of *Z* is an essential notation called *schema* from which new types and their properties can be defined. A *Z* schema has a boxed structure often consisting of two major parts: the **declaration part** and the **predicate part** (optional) as follows:

```
┌────────── Name ──────────
│ Declaration part
├──────────────────────
│ Predicate part
└──────────────────────────
```

The name of a schema is global and can be used in the declaration part of other schemas to reuse the variable definitions.

The declaration part defines local variables of the schema in the form: **var: Type** (the collection of these variable definitions forms the **signature** of the schema), and thus a reference of this variable in another schema needs to be prefixed by its schema name followed by a period (i.e., **Name.var**). A variable name can be a simple name (defining the old value), a name with a prime′ (defining the new value of the same name without the prime), a name with a question mark ? (an input from the external environment), or a name with an exclamation point ! (an output to the external environment). If a schema includes both the name of a schema *S* and its primed version S', the following notation is used: ΔS when the value of some variable defined in *S* has been changed by the required processing or ΞS when nothing in *S* is changed by the required processing.

The predicate part specifies the constraint (invariant) of a definition or the precondition (subformulas without dashed variables) and postcondition (subformulas containing dashed variables) of some processing in terms of first-order logic formulas. Subformulas on separate lines in the predicate part are conjoined by default. The predicate thus defines the **property** of the schema.

State Schemas and Operation Schemas

A schema can be used to define the abstract state of a system, called a **state schema** in the sequel, when the state machine model is used. The predicate part in this case defines the data invariant among involved variables.

Each state schema *S* needs an initial value that is defined by an initialization schema that enumerates the initial values of state variables in the predicate part.

A schema *SC* can be used to define an operation, called an **operation schema** in the sequel, which includes both a state schema name *S* and its version S' in its declaration part. However, ΔS or ΞS is often used instead of *S* and S'. The predicate part can be divided into the precondition part (denoted by pre-*SC* in the sequel) and the postcondition part (denoted by post-*SC* in the sequel).

Operations on Schemas

New schemas can be built using existing schemas, in addition to the inclusion mentioned in the previous paragraphs.

(1) **Schema disjunction**: Schema disjunction has the form $\mathrm{New} \mathrel{\hat{=}} \mathrm{Old1} \vee \mathrm{Old2}$, where New, Old1, and Old2 are schema names. The declaration part of new schema New is obtained by merging the declaration parts of Old1 and Old2, and the predicate part of New is obtained by making a disjunction of the predicate part of Old1 with that of Old2.

(2) **Schema conjunction**: Schema conjunction has the form $\mathrm{New} \mathrel{\hat{=}} \mathrm{Old1} \wedge \mathrm{Old2}$, where New, Old1, and Old2 are schema names. The declaration part of new schema New is obtained by merging the declaration parts of Old1 and Old2, and the predicate part of New is obtained by making a conjunction of the predicate part of Old1 with that of Old2.

(3) **Schema composition**: Let Old1 and Old2 be two schemas; a new schema of the form New $\widehat{=}$ Old1; Old2 can be defined and has the following meaning:
- The signature of New is the inputs and outputs of both Old1 and Old2, together with the nondashed variables in Old1 and dashed variables of Old2;
- The property of Old1 is included in New, but all the dashed names are redecorated with a decorator not used in either Old1 or Old2;
- The property of Old2 is included in New, but all the nondashed names are decorated with the same decorator as was used in Old1; and
- The newly decorated names are hidden with an existential quantifier.

Other operations related to schemas can be found in work by Spivey (1992), including using a schema as a type in the declaration part of other schemas, hiding declarations in a schema, and reusing the operations defined in one schema in other related schemas through promotion.

9.4.2 Definition of *PZ* Nets

Let $Z = (Z_P, Z_T, Z_I)$ be a collection of Z schemas. If we let z be a Z schema, we use **name**(z), **sig**(z), and **prop**(z) to denote the name, the signature part (as a typed set of mappings), and property part of z, respectively in the sequel. The Z schemas in Z satisfy the following conditions:

- $\forall z1, z2 \in Z_P \cdot (z1 \neq z2 \Rightarrow \mathbf{sig}(z1) \cap \mathbf{sig}(z2 = \emptyset)$;
- $\forall z1, z2 \in Z_I \cdot (z1 \neq z2 \Rightarrow \mathbf{sig}(z1) \cap \mathbf{sig}(z2) = \emptyset)$; and
- $|Z_P| = |Z_I|$.

The first two conditions state that the signatures of z schemas are pair-wise disjoint, and the last condition states that the number of z schemas in Z_P is the same as that in Z_I (i.e., one-to-one correspondence).

A *PZ* net is a tuple $ZN = (NG, Sig, V, H, Type, AN, M_0, Z)$. Here, Z is a collection of Z schemas satisfying the above conditions, $AN = (Type, A, TC)$, and:

- $Type$: $P \rightarrow Z_P$ is one-to-one mapping, giving the data definition of ZN. For each place $p \in P$, $Type$ maps p to a unique Z schema $z \in Z_P$ such that $p = \mathbf{name}(z)$. The type of p is defined by the signature of z.
- TC: $T \rightarrow Z_T$ is one-to-one mapping, providing the functionality definition of ZN. For each transition $t \in T$, C maps t to a Z schema $z \in Z_T$ such that $t = \mathbf{name}(z)$. The functional processing of t is defined by the property of z. Furthermore, the following constraint is satisfied. For any $p \in P$, $t \in T$:
  (1) If $(p, t) \in F$, then $\mathbf{sig}(Type\ (p)) \cap \mathbf{sig}(TC(t)) \neq \emptyset$.
  (2) If $(t, p) \in F$, then $\mathbf{sig}(Type\ (p)) \cap \mathbf{sig}(TC(t)) \neq \emptyset$.
- A: $F \rightarrow \mathcal{P}Var$ is the control flow definition of ZN, where Var is the set of all hidden variables (through quantification) in Z_T. Let $Var(t)$ denote the set of hidden variables in $TC(t)$ for any transition t, let $S(v)$ denote the sort (or type) of a variable v, and let $S(V)$ denote the set of the sorts of the variables in the sorted set V. Then, the following constraints are satisfied for any $p \in P$:
  (1) $\bar{A}(p, t) \subseteq Var(t)$ and $\bar{A}(t, p) \subseteq Var(t)$, where
  $$\bar{A}(x, y) = \begin{cases} A(x, y) & \text{if (x, y)} \in \text{F.} \\ \emptyset & \text{otherwise} \end{cases}$$
  (2) For any $x \in \bar{A}(p, t)(\text{or } \bar{A}(t, p)) \cdot S(x) \in S(\mathbf{sig}(Type\ (p)))$.
  (3) $\mathbf{prop}(TC(t)) \Rightarrow \mathbf{sig}(Type(p)') = \mathbf{sig}(Type(p)) - \bar{A}(p, t) \cup \bar{A}(t, p)$.
- M_0: $P \rightarrow Z_I$ is a $Type$-respecting (i.e., $\mathbf{sig}(Type(p)) = \mathbf{sig}(M_0(p))$ initial marking of ZN, where Z_I is a set of Z schemas defining the initial state of the system. $M_0(p)$ is the Z schema in Z_1, defining the initial marking of place p.

The following is a simple example of a *PZ* net specification of the familiar Five Dining Philosophers problem. The overall system structure is shown in Figure 9.2, which is the same as Figure 9.1 except for the renaming.

The Z schemas (Z_P, Z_T, Z_I) are the following:

9.4.3 *PZ* Net Analysis

In He (1995, 2001), a structural induction technique was proposed for analyzing safety properties of *PZ* nets, which is based on an invariance inference rule from work by Manna and Pnueli (1995). This technique is briefly discussed in the following subsections.

Formalizing Invariant Properties

Let $[M_0>^\omega$ denote the set of all valid marking sequences extracted from all execution sequences of a given *PZ* net, and let σ be a valid marking sequence with $|\sigma|$ as the length of the sequence and $\sigma(i)$ as the *i*th state (marking) in σ.*W* (a first order logic formula) is an invariant property if and only if the following holds: $\forall\sigma\colon \sigma \in [M_0>^\omega \cdot (\forall i\colon 0 \leq i \leq |\sigma| \cdot (\sigma(i) \models W))$, where $\sigma(i) \models W$ denotes that marking $\sigma(i)$ satisfies *W* (i.e., the evaluation of *W* under marking $\sigma(i)$ yields true). Thus, a safety property holds in every state (marking) of every valid marking sequence. The above formulation can be simplified to the following equivalent version in terms of the set of all reachable markings only:

$$\forall M\colon M \in [M_0> \cdot (M \models W).$$

Proving Invariant Properties

In Manna and Pnueli (1995), several temporal logic-based inference rules for invariance (or safety properties) were given. Among the rules, the following basic invariance rule (in its state validity form) is reformulated in terms of *PZ* nets and is essential.

The Basic Invariance Rule

B1. $M_0 \Rightarrow W$

B2. $$\frac{C(t)\colon \alpha \wedge W \Rightarrow W' \text{ for every } t \in T \text{ and occurrence } \alpha}{M \models W \text{ for every } M \in [M_0>}$$

In the basic invariance rule, premise B1 requires that the initial marking M_0 imply property *W*, and premise B2 requires that all transitions preserve *W*. $C(t)$ is the *Z* schema associated with *t* that defines the enabling condition (precondition) and the firing result (postcondition) of *t*. W' is obtained from *W* by changing the names of variables to their dashed version. Based on premises B1 and B2, we conclude that *W* is valid or is satisfied under any reachable marking from M_0.

We provide the following procedure to use the above inference rule:

Step 1. Prove the initial marking satisfies a system property formula.

Step 2. Assume the system property formula holds after *k* events in a state *M*.

Step 3. Prove the system property formula holds after $k+1$ events in any directly reachable state M' from *M*.

It is easy to see that steps 2 and 3 in the temporal induction proof technique fulfill premise B2 of the invariance rule.

Furthermore, we only need to consider the firing of a relevant transition and the associated *Z* schema with regard to the given property under the guidance of the net structure during step 3. For example, a system deadlock may occur when a particular place has a special marking. To show the system does not have the deadlock, we only need to show that transitions connected to this place cannot result in this special marking. Therefore, the proof is in general local in the sense that only a subset of transitions needs to be considered. Similar ideas have been also explored in other temporal analysis techniques (He and Lee, 1990; He and Ding, 1992). In general, logical, net structural, and net behavioral reasonings are needed to prove an invariant property. The above temporal induction technique is demonstrated in the following example.

The deadlock freedom property of the Five Dining Philosophers problem is formulated as follows:

$$\Box(\exists x \in \text{ephil} \cdot (p_3(x) \geq 1 \vee \exists x \in \text{tphil} \cdot (\text{right}(x) \in p_2 \cdot \wedge \text{left}(x) \in p_2)).$$

This problem explains that at any state, a philosopher is eating, which ensures the enabled condition of transition Put down, or a philosopher is thinking, which ensures the enabled condition transition Pick up.

The above formula can be rewritten as follows without using the temporal operator:

$$\forall M \in [M_0> \cdot (\exists x \in \text{ephil} \cdot (p_3(x) \geq 1 \vee \exists x \in \text{tphil}\ (\text{right}(x) \in p_2 \wedge \text{left}(x) \in p_2)).$$

Thus, we need to prove the following formula using the structural induction technique:

$$\exists x \in \text{ephil} \cdot (p_3(x) \geq 1 \vee \exists x \in \text{tphil} \cdot (\text{right}(x) \in p_2 \wedge \text{left}(x) \in p_2) \quad (*)$$

Here is the proof outline of the formula (*):

Step 1: Under the initial marking M_0, Init_Thinking, Init_Chopstick, and Init_Eating endures:

$$\exists x \in \text{tphil} \cdot (\text{right}(x) \in p_2 \wedge \text{left}(x) \in p_2) \text{ and thus } (*).$$

Step 2: Assume (*) holds after k transitions in a state M.

Step 3: Prove (*) holds after $k+1$ transitions in a state M' such that $M[t, \alpha >M'$.

Case 1: Firing transition Pick up with $\alpha = \{x/ph_1, y_1/ch_1, y_2/ch_2\}$ and from the postcondition of schema Pick up with $ch_1 \in \text{ephil}'$ in M'. Thus, $\exists x \in \text{ephil} \cdot (p_3(x) \geq 1)$ is true in M', and hence (*) holds in M'.

Case 2: Firing transition put down $\alpha = \{z/< ph_1, ch_1, ch_2 >\}$: From the precondition of put down with left $(ph_1) = ch_1$ and right $(ph_1) = ch_2$; from the postcondition of schema put down with $ph_1 \in \text{tphil}$, $ch_1 \in \text{chop}'$, and $ch_2 \in \text{chop}'$. Thus, $\exists x \in \text{tphil} \cdot (\text{right}(x) \in p_2 \wedge \text{left}(x) \in p_2)$ is true in M', and hence (*) holds in M'.

Therefore, (*) has been proven.

9.5 Hierarchical Predicate Transition Nets

The development of hierarchical predicate transition nets (HPrTNs) was motivated by the need to construct specifications for large systems using Petri nets (Reisig, 1987) and inspired by the development of modern high-level programming languages and other hierarchical and graphical notations, such as data flow diagrams (Yourdon, 1989) and statecharts (Harel, 1988). Similar work on introducing hierarchies into colored Petri nets was given in Jensen (1992, 1995). With the introduction of hierarchical structures into predicate transition nets, the resulting net specifications are more understandable, and the specification construction process becomes more manageable. HPrTNs were used in specifying several systems, including an elevator system (He and Lee, 1991), a library system (He and Yang, 1992), and a hurried dining philosophers system (He and Ding, 2001). HPrTNs can be analyzed directly by using a structural induction technique combining structural, behavioral, and logical reasoning (He, 2001) and can be translated into program skeletons in a concurrent and parallel object-oriented programming language CC++ (He, 2000c) and Java (Lewandowski and He, 1998, 2000). A complete formal definition of HPrTNs was given in He (1996). In the following subsections, basic concepts and notation of HPrTNs are briefly introduced.

9.5.1 Definition of HPrTNs

An HPrTN is a structure:

$$HN = (NG, Sig, V, H, Type, AN, M_0, \rho).$$

Where:

- $NG = (P, T, F)$ is a net graph. P and T are finite sets of places and transitions such that $P \cap T = \emptyset$. Elements in P are represented by solid and dotted circles. Similarly, elements in T are represented by solid and dotted boxes. Solid circles or boxes are elementary nodes, and dotted circles and boxes are super nodes. In particular, we identify two subsets $IN \subseteq P \cup T$ and $\text{OUT} \subseteq P \cup T$ such that IN contains the heads of all incoming **nonterminating arcs** (an arc inside a super node is a nonterminating arc if one of its ends is connected to the boundary of the super node) and OUT contains the tails of all outgoing nonterminating arcs. Nodes in IN ∪ OUT are called **interface** nodes. We use •IN to denote the set of the presets of all elements in IN (i.e., $\bullet\text{IN} = \{\bullet\, n | n \in \text{IN}\}$), and OUT• to denote the set of the postsets of all elements in OUT. F is the set of arcs and is called the **flow relation**, satisfying the conditions: $P \cap F = \emptyset$, $F \cap T = \emptyset$, and $F \subseteq (\bullet\, \text{IN} \times \text{IN} \cup P \times T \cup T \times P \cup \text{OUT} \times \text{OUT}\bullet)$. An arc f can be uniquely identified by a pair of nodes (n_1, n_2) denoting its source and sink, in which $n_1(n_2)$ may denote the preset (postset) of $n_2(n_1)$ when f is a nonterminating arc.

- *Sig*, *V*, *H*, *Type* are defined as in HLPN in Section 9.2.
- *AN* = (*A*, *TC*) is a pair of net annotations.

  A is a function that annotates each arc with a term that when evaluated (for some binding) results in a multiset over the associated place's type. Furthermore, all simple labels of a compound label must have distinct identifiers, and all simple labels of arcs connected to the same node must have distinct identifiers. Because compound labels define data flows as well as control flows, the following basic control flow patterns (He and Lee, 1991) must be correctly labeled: (1) data flowing into and out of an elementary transition must take place concurrently, and (2) data flowing into and out of an elementary predicate can occur at different times. Furthermore, data flows between different levels of hierarchies must be balanced (i.e., a simple label occurs in a nonterminating arc if and only if it also appears in an arc with the same direction connected to the enclosing super node).
- *TC* is a function that annotates transitions with Boolean expressions. A super transition is an abstraction of low-level actions, and its meaning is thus completely defined by the low-level refinement. Therefore, the constraint of a super transition is true by default (it is conceivable that a nontrivial constraint for a super transition might be useful; however, in general it is very difficult to define such a constraint and also very difficult to interpret the constraint with regard to the operational (dynamic) semantics of the super transition).
- M_0 is the initial marking function.
- ρ: $P \cup T \to \wp(P \cup T)$ is a hierarchical mapping that defines the hierarchical relationships among the nodes in *P* and *T*; this mapping also satisfies the constraint that the interface nodes ∈ IN ∪ OUT be all predicates if their parent node is a predicate or all transitions if their parent node is a transition. For any node *n*, ρ(*n*) defines the immediate descendant nodes of *n*. The ancestor and descendants of any node can be easily expressed by using well-known relations, such as transitive closure on ρ. A node in an HPrTN is local to its parent and can be uniquely identified by prefixing its ancesters' names separated with periods to its own name; however, often its own name is referred whenever a no name clash occurs.

The enabling condition of an elementary transition is defined exactly the same as that of an *HLPN*'s in Section 9.2. A super transition is enabled if at least one of its interface child transitions in IN is enabled and its firing is defined by an execution sequence of its child transitions; thus, its behavior is fully defined by its child transitions. The firing rule of a transition is formally defined in He (1996). Two transitions (including the same transition with two different occurrence modes) can fire concurrently if they are not in conflict (the firing of one of them disables the other). Conflicts are resolved nondeterministically. The firing of an elementary transition is atomic, and the firing of a super transition implies the firing of some elementary transition and may not be atomic. We define the behavior of an HPrTN to be the set of all possible maximal execution sequences containing only elementary transitions. Each execution sequence represents consecutively reachable markings from the initial marking in which a successor marking is obtained through a step (firing of some enabled transitions) from the predecessor marking.

9.5.2 System Modeling Using HPrTNs

HPrTNs can be used to model systems using the traditional structured approach (Yourdon, 1989) or modern object-oriented approach (Booch, 1994). He and Ding (2001) proposed an approach to realize various object-oriented (OO) concepts in HPrTNs. Furthermore, He (2000a, 2000b) and Dong and He (2001) applied HPrTNs to formalize several diagrams in the Unified Modeling Language (UML)—a software industry standard second-generation object-oriented modeling language. In the following sections, we briefly describe how to model several key OO concepts in HPrTNs.

Classes

One of the central ideas of OO paradigm is data encapsulation captured by the **class** concept. A class is essentially an abstract data type with a name, a set of related data fields (or attributes), and a set of operations on the data fields. It is straightforward to use a predicate to denote a data field (structure) and a transition to represent an operation in Petri nets. The current value of a data field is determined by the tokens of the denoting predicate under the current marking. The meaning or definition of an operation is specified by the constraint associated with the denoting transition.

HPrTNs were originally developed for structured analysis that provides separate mechanisms for data abstraction and processing abstraction through super predicates and super transitions, respectively. Therefore, we can use a super predicate and super transition pair in an HPrTN to capture the notion of a class although it is adequate to define a class by using a super predicate when there is no externally visible operation or using a super transition when there is no externally visible attribute. This view of class is a major improvement over the view in (He and Ding, 1996), where a class was represented by a super predicate only. In this view, the interface of the class is defined by the super predicate and the super transition. The super predicate defines data and internal operations of the class, while the super transition mainly defines the externally visible operations of the class. The corresponding subnets further define the internal structures of the data and the operations. The net inscription defines the meanings of net components through predicate types, token values, and transition constraints. When the resulting HPrTN is simple enough, there is no need to separate the super nodes from their subnets (i.e., the subnets are directly embedded inside the super nodes). An attribute or operation is externally visible if the corresponding denoting predicate or transition is an interface node (i.e., connected with a nonterminating arc). It should be noted, however, that not every super predicate or transition needs to be considered as a class. A super predicate or transition may simply denote a data abstraction or operation abstraction as originally intended; for example, a super predicate can be used to hide the internal states of an attribute that is defined by several related predicates, and a super transition can be used to define alternative implementations of an operation to realize operation overloading or overriding. Thus, our approach supports the coexistence of various modeling paradigms.

Based on the above analysis, we use the following C++-like class schema to document a class defined by the super node(s) in an HPrTN (it is worth noting that the class schema is only used for understanding purpose and does not add functionality to the given HPrTN:

```
class Name [:superclass(es)]
{   public:
            predicates and transitions
    [private:
            predicates and transitions],
}
```

where brackets [...] denote optional items. Predicates and transitions listed in both public and private sections are those contained in the super node(s). The name(s) of the super node(s) are used to form the class name.

In the HPrTN shown in Figure 9.3, both super transition Phil and super predicate Chop can be viewed as classes. Thus, the following class definitions can be obtained:

```
class Chop
{   public:
            Avail, Used
},
class Phil
{   public:
            Pick up, Put down
    private:
            Thinking, Eating
}.
```

Objects

An instance or object of a class has its own copy of data while sharing operations with other objects of the same class. To distinguish an object from other objects, a unique identifier is needed for each object.

In an HPrTN, an object is essentially defined by a set of tokens related through the same identifier; thus, the sort of any predicate p needs to contain a component sort of relevant identifiers (i.e., $\text{Type}(p) = \wp(ID \times \ldots)$. Different objects of a class share the same class data structure (i.e., tokens with different identifiers can reside in a predicate at the same time in an HPrTN). In general, however, objects of the same class cannot interact with each other directly. The above problem can be easily solved by defining a subexpression comparing token identifiers in the constraint of each transition. Movements of tokens and/or changes of token values while maintaining the object identifier indicate state changes of the object.

In the HPrTN shown in Figure 9.3, there are k philosopher objects with identifiers of sort PHIL, and there are k chopstick objects with identifiers of sort CHOP.

Class Reference Relation

Classes work together to fulfill the functionality of the underlying system. A class can use the operations and/or data provided by other classes.

In HPrTNs, the interface of a transition includes a box with a name and the labels of relevant arcs (the label identifiers determining the calling context and the flow expressions specifying parameters). The meaning of an elementary transition is defined by its constraint, and the meaning of a super transition is defined through its corresponding subnet.

It is easy to model a class reference by adding some arc when a class needs to access some public attribute of another class. For example, Figure 9.4 illustrates simple class reference relationships where some operation in class C_1 (p_1 and t_1) uses some public attributes defined in class C_2 (p_2 and t_2), and some operation in class C_2 uses some public attributes defined in class C_1. Figure 9.3 contains simple reference relationships between classes Phil and Chop.

To define an operation in one class using another operation in a different class, we cannot simply add an arc since Petri nets do not allow direct connections between transitions. As discussed earlier, there are two main ways to handle class reference relationships in the existing research works: (1) to fuse the two operations in two classes into one such that only synchronized communication is allowed (Biberstein and Buchs, 1995; Battison *et al.*, 1995; Lakos, 1995b) and (2) to create some places inside one class to hold parameters to simulate message passing and function calls (Bastida, 1995; Lakos, 1995b), which supports asynchronous communication. HPrTNs support both synchronous and asynchronous communications through **reference places** to model different communication protocols. These reference predicates do not belong to any class and can be viewed as connectors in software architecture languages (Shaw and Garlan, 1996). It is quite easy to model a function call through passing two messages by using one reference predicate to hold the input values and another to hold output results; another easy way to model a function call is by defining the calling operation (function) as a super transition whose subnet has at least two transitions to handle sending and receiving values.

Figure 9.5 shows the general pattern of a function call from class C_1 containing t_1 to class C_2 containing t_2, in which p_1 and p_2 are reference places. The above pattern defines a one-way **synchronized communication** (i.e., the caller must wait for the callee to continue its execution), whereas a simple message passing from an operation in one class to an operation in another class in general defines an **asynchronous communication**.

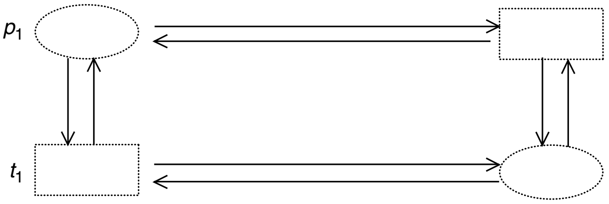

FIGURE 9.4 Simple Public Attributes Access

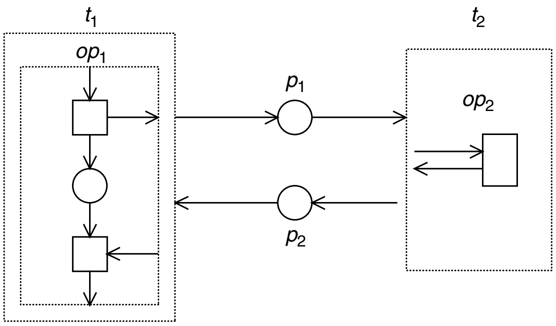

FIGURE 9.5 Reference Through Function Call

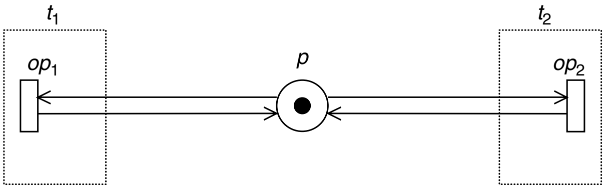

FIGURE 9.6 Synchronized Communication

Figure 9.6 defines a general synchronization pattern such that two operations in class C_1 containing t_1 and C_2 containing t_2 must execute mutual exclusivity, where p is a reference predicate with an initial dummy token.

It is quite natural and easy to define class reference relationships by using the decomposition and synthesis techniques of HPrTNs discussed in He and Lee (1991).

Class Inheritance Relation

Another major feature of the OO paradigm is **class inheritance relation** that captures the generalization–specialization relationships in the real world (Coad and Yourdon, 1991). A class inheritance relationship exists between a superclass and a subclass such that the subclass inherits data structures as well as operation definitions from the superclass without the need to define them again. Thus, class inheritance relation supports a flexible and manageable way to reuse existing data structures and operations.

A class inheritance relation is realized in HPrTNs through the reuse of the net structures of inherited super nodes and the net inscription of inherited elementary nodes (the sorts of predicates, the label expressions of relevant arcs, and the constraints of transitions) defined in an existing HPrTN denoting a class. The inherited predicates and transitions, however, are explicitly represented or embedded in the subclass to clearly define its role, the same convention was used by Lakos (1995b). An inherited element in a subclass has a name of the form super_node.element_name, where super_node is the partial name of the superclass and element_name is the internal name of the element in the superclass. Renaming of relevant arcs are also necessary to reflect the current context and to ensure flow balance. It is clear that inheritance does not reduce the size of an HPrTN specification since inherited elements are embedded; an alternative way to embedding is through delegation, as explained by Abadi and Cardelli (1996). However, the advantages are obvious since the meaning or structure (the most difficult part in writing an HPrTN specification) of an inherited element is already available and is obtained without any additional effort; furthermore, many known properties of the inherited element might be maintained through inheritance (structural properties are surely kept, but behavioral properties may need additional validation). It is worth noting that (1) only public components of a superclass can be inherited; (2) inheritances from multiple superclasses are supported, and an element can be inherited by multiple subclasses because no ambiguity will occur due to the naming convention; and (3) a redefined (overriding) operation is considered as a new operation in a subclass and is distinguished from an inherited operation such that an overriding operation in a subclass has the same name as the overriden operation in the superclass; this distinction between inheritance and overriding was also made by Abadi and Cardelli (1996).

Figure 9.7 shows a class inheritance relationship defined as follows:

```
class $p_1$ and $t_1$
{   public:
        $p_2$, $t_2$, $t_3$
};
class $p_3$ and $t_3$ : $p_1$ and $t_1$
{   public:
        $t_3$, $p_1 \cdot p_2$, $t_1 \cdot t_2$
    private:
        $p_4$, $p_5$, $t_6$
}.
```

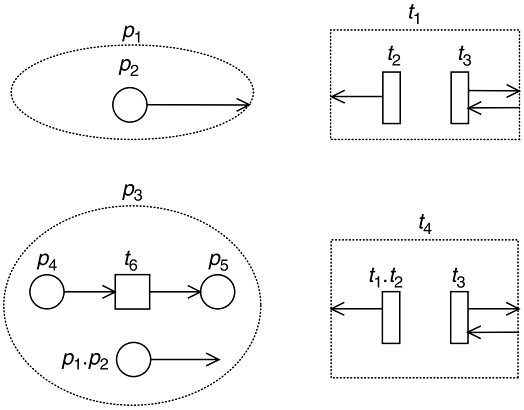

FIGURE 9.7 An Example of Class Inheritance Relation

Polymorphism

OO paradigm also supports **polymorphism** such that an operation's name (with possibly different signatures) may have different meanings or behaviors (implementations) through inheritance or overriding.

Polymorphism can be achieved in HPrTNs in two different yet related ways. First, polymorphism is a major feature of the underlying many-sorted algebra H of an HPrTN; detailed discussions of algebraic specifications and polymorphism can be found in work by Ehrig and Mahr (1985). The same operation symbol in H is used for many derived sorts. A simple example is the overloaded equality ($=$) operator when an algebraic specification H contains two elementary data types (or classes) INT and CHAR with a single parameterized definition of the equality ($=$). Second, polymorphism can be accomplished through net structure and inscription. An operation provides overriding capability if its constraint distinguishes a superclass object and a subclass object (or two objects from two different subclasses with the same superclass) and processes them differently. To realize polymorphism in an HPrTN, a shared predicate can be used to hold tokens of a superclass as well as tokens of subclasses, and the shared predicate is connected to the transition defined in the superclass and its inherited (or overriding) versions in the subclasses. The constraint of the original transition is only satisfied by the tokens of the superclass, and the constraint of each inherited (or overriding) transition is only satisfied with tokens of the subclass containing the transition.

Figure 9.8 shows the general pattern of realizing polymorphism through net structure in HPrTNs, in which p is a shared place, t_1 is a part of the superclass, and t_2 is a part of the subclass, and op_1^* is either an inherited or an overriding version of op_1, as shown in Figure 9.8.

Furthermore, operation overriding can be achieved through a super transition in an HPrTN such that the firing of a particular component transition is determined partly by the (dynamic) instantiation of an object identifier (and thus its sort). The use of the above case-like net structure in realizing polymorphism can be avoided in the implementation of an HPrTN.

9.6 Fuzzy-Timing High-Level Petri Nets

9.6.1 Definition of FTHN

A Fuzzy-timing high-level Petri net (FTHN) is a structure:

$$FN = (N,\ D,\ FT),$$

where N is an HLPN defined in Section 9.2; D is the set of all fuzzy delays, $\mathrm{d}_{tp}(\tau)$, associated with arcs (t, p) from each transition $t \in T$ to its output place p; and FT is the set of all **fuzzy time stamps**. A **fuzzy time stamp** $\pi(\tau) \in FT$ is associated with each token and each place. A fuzzy time stamp $\pi(\tau)$ is a **fuzzy time function** or **possibility distribution** giving the numerical estimate of the possibility that a particular token arrives at time τ in a particular place. Any type of possibility distribution can be represented or approximated by using a number of trapezoidal distributions. Thus, we use the trapezoidal **possibility distribution** specified by the five parameters, $h(a,\ b,\ c,\ d)$ as shown in Figure 9.9, where h is the height having the following properties: $0 \leq h \leq 1$, $h = 1$ for an event (arrival of a token) that has occurred or will occur and $h < 1$ for an event that will not necessarily occur. A so-called **fuzzy number** is represented by the triangular distribution $h(a,\ b,\ b,\ d)$, which is a special case of the trapezoidal form with $b = c$. A deterministic interval between a and d denoted $[a,\ d]$ can be represented by $(a,\ a,\ d,\ d)$, a special case of trapezoidal form with $a = b$, $c = d$, and $h = 1$. In addition, given an arbitrary-shaped possibility distribution, we can approximate it with the union of a number of trapezoidal distributions (Zhou and Murata, 1999).

In Zhou *et al.* (2000), *FTHN* is extended by adding a time interval with a possibility value p in the form of $p[\alpha,\ \beta]$ to each transition. That is, each transition is associated with a firing interval denoted $p[\alpha,\ \beta]$, where the default interval is $1[0,\ 0]$ (a transition definitely fires as soon as it is enabled). If a transition t is enabled at time instant τ, it may not fire before time instant $\tau + \alpha$ and must fire before or at time instant $\tau + \beta$. Possibility p is a value in the interval $[0,\ 1]$, where p is 1 if transition t is not in structural conflict with any other transition, and p can be less than 1 when we want to assign different chances to transitions in conflict. Here, **structural conflict** means that a transition t shares some input place with another transition that can be enabled simultaneously with transition t; firing one transition will disable the other transition.

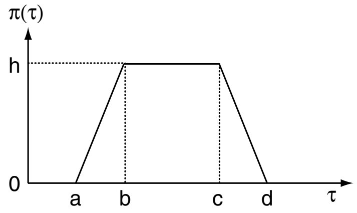

FIGURE 9.9 Trapezoidal Possibility Distribution

9.6.2 Computation for Updating Fuzzy Time Stamps

Suppose that a transition t is enabled by n tokens and the fuzzy enabling time $\mathrm{e}_t(\tau)$ of transition t is computed by $\mathrm{e_t}(\tau) = \text{latest}\ \{\pi_\mathrm{i}(\tau),\ \mathrm{i} = 1,\ 2, \ldots,\ n\}$, where **latest** is the operator that constructs the "latest-arrival-lowest-possibility distribution" from n distributions (Murata, 1996; Murata *et al.*, 1999). The $\pi_\mathrm{i}(\tau)$ is the fuzzy time stamp to which the enabling token arrives at the ith input place of transition t. When there are m transitions in structural conflict that are enabled with their fuzzy enabling times, $e_i(\tau)$, $\mathrm{i} = 1,\ 2, \ldots,\ t, \ldots,\ m$, and with their possibility intervals, $p_\mathrm{i}[\alpha_\mathrm{i},\ \beta_\mathrm{i}]$, we compute the fuzzy occurrence time $o_t(\tau)$ of transition t whose fuzzy enabling time is $\mathrm{e_t}(\tau)$ as follows:

$$\begin{aligned}\mathrm{o_t}(\tau) = \min\{&\mathrm{e_t}(\tau) \oplus p_i(\alpha_\mathrm{t},\ \alpha_\mathrm{t},\ \beta_\mathrm{t},\ \beta_\mathrm{t}),\\ &\text{earliest}\{\mathrm{e_i}(\tau) \oplus p_i(\alpha_\mathrm{i},\ \alpha_\mathrm{i},\ \beta_\mathrm{i}, \beta_\mathrm{i}),\ \mathrm{i} = 1,\ 2, \ldots,\ t, \ldots,\ m\}\},\end{aligned}$$

where **earliest** is the operator that constructs the "earliest-arrival-highest-possibility distribution" from m distributions, (Murata, 1996; Murata *et al.*, 1999), **min** denotes the minimum or intersection operation, and $\oplus$ is the extended addition (Dubois and Prade, 1989). We compute the fuzzy time stamp $\pi_{tp}(\tau)$, which is the fuzzy time distribution at which a token arrives at the transition t output place p, as follows:

$$\begin{aligned}\pi_{tp}(\tau) &= \mathrm{o_t}(\tau) \oplus d_{tp}(\tau) = h_1(o_1,\ o_2,\ o_3,\ o_4) \oplus h_2(d_1,\ d_2,\ d_3,\ d_4)\\ &= \min\{h_1,\ h_2\}(o_1 + d_1,\ o_2 + d_2,\ o_3 + d_3,\ o_4 + d_4),\end{aligned}$$

where $d_{tp}(\tau)$ is the fuzzy delay associated with the arc $(t,\ p)$ (Murata, 1996). When there are no transitions in conflict with transition t with its possibility interval $p_t[\alpha t,\ \beta_\mathrm{t}]$, the fuzzy occurrence time is given by $o_t(\tau) = e_t(\tau) \oplus (\alpha_\mathrm{t},\ \alpha_\mathrm{t},\ \beta_\mathrm{t},\ \beta_\mathrm{t})$, where we set $p_t = 1$ since no conflict exists. We use the following formulas as approximate computations of the earliest and latest operations:

$$\begin{aligned}\text{earliest}\{\mathrm{e_i}(\tau),\ i = 1,\ 2, \ldots,\ n\} &= \text{earliest}\{h_i(e_{i1},\ e_{i2},\ e_{i3},\ e_{i4}),\ i = 1,\ 2, \ldots,\ n\}\\ &= \max\{h_i\}(\min\{e_{i1}\},\ \min(e_{i2},\ \min\{e_{i3},\ \min\{e_{i4}\}),\ i = 1,\ 2, \ldots,\ n\end{aligned}$$

$$\begin{aligned}\text{latest}\{\pi_\mathrm{i}(\tau),\ i = 1,\ 2, \ldots,\ n\} &= \text{latest}\{h_i(\pi_{i1},\ \pi_{i2},\ \pi_{i3},\ \pi_{i4}),\ i = 1,\ 2, \ldots,\ n\}\\ &= \min\{h_i\}(\max\{\pi_{i1}\},\ \max\{\pi_{i2}\},\ \max\{\pi_{i3}\},\ \max\{\pi_{i4}\}),\ i = 1,\ 2, \ldots,\ n.\end{aligned}$$

Using the above procedure, we compute and update fuzzy time stamps $\pi(\tau)$, fuzzy enabling times $e(\tau)$, and fuzzy occurrence times $o(\tau)$ each time a transition firing (atomic action) occurs, starting from the initial (given) fuzzy time stamps of tokens in the initial marking M_0 and initially specified fuzzy delays. $d_{tp}(\tau)$. (See Zhou *et al.* [2000].)

9.6.3 Intended Application Areas and Application Examples of FTHNs

As seen in Subsections 9.6.1 and 9.6.2, the essence of FTHNs is the computation of updating fuzzy time stamps, and this computation involves only additions and comparisons of real numbers. Thus, computation can be done very fast, and FTHNs are suitable for performance analysis in real-time applications. The notion of fuzzy timing is highly flexible in that it can capture imprecise or incomplete knowledge regarding time behavior with specified or given possibility distributions, as well as the more conventional deterministic and probabilistic knowledge. However, it is expected that the traditional probabilistic approach and the FTHN method using possibility theory are complementary, rather than competitive, as possibility theory is considered to be complementary to probability theory (Zadeh, 1995). We expect that the FTHN method is more scalable than the traditional stochastic approaches because the FTHN computations are done using real arithmetic operations.

Some examples of FTHN applications include the following. A real-time network protocol used in local area networks (LANs) is modeled using FTHNs in (Murata, *et al.*, 1999). Here we are interested in evaluating the worst-case performance in a given network, where propagation delays, times for processing message frames, and other such processes are specified as trapezoidal fuzzy-time functions. The fuzziness is due to the uncertain length (thus uncertain delay) of each message. In addition, FTHN models are used for performance evaluation of manufacturing systems, where the abilities of machines and/or workers involved in a manufacturing process are fuzzily known (Watanuki, 1999). Another area in which FTHN models are applied is the synchronization of multimedia systems (Zhou and Murata, 1998, 2001). Multimedia systems integrate a variety of media with different temporal characteristics (e.g., time-dependent media, such as video, audio, or animation) and time-independent media (e.g., text, graphics, and images). Thus, synchronization is a critical issue in these systems. The temporal specification has to be properly represented for presentation reviewing and planning by the user as well as for storing purposes. Multimedia synchronization has a time-critical problem because it must guarantee the temporal constraints for presenting the media items. Thus, there is a benefit in using FTHN methods to specify and analyze the temporal relations and specifications. The FTHN method has been used to present a new fine-grained temporal FTHN model for distributed multimedia synchronization (Zhou and Murata, 2001). The FTHN method has also been applied to a video-on-demand (VOD) system, which is a continuous playback multimedia application in which constant real-time media data are required for smooth real-time presentation. Thus, timing is a critical issue, and the response time is the only timing that has direct interaction with the subscribers and also impacts the quality-of-service (QoS), as discussed by Murata and Chen (2000). A nontrivial example of FTHN application is found in Zhou *et al.* (2000), where the FTHN method has been used to model networked virtual-reality systems, such as Cave Automatic Virtual Environment (CAVE) and Narrative Immersive Constructionist/Collaborative Environments (NICE) projects at the University of Illinois at Chicago. Using the FTHN models, various simulations have been conducted to study real-time behaviors, network effects, and performance (latencies and jitters) of the NICE. The simulation results are consistent with data and measurements obtained experimentally. This study shows how powerful FTHN models are in specifying and analyzing performance and how helpful the performance analysis is in improving a real-time networked-virtual-environment system design process.

ELECTROMAGNETICS

Hung-Yu David Yang
Department of Electrical and
Computer Engineering,
University of Illinois at Chicago,
Chicago, Illinois, USA

Electromagnetics is fundamental in electrical and electronic engineering. Electromagnetic theory based on Maxwell's equations establishes the basic principle of electrical and electronic circuits over the entire frequency spectrum from dc to optics. It is the basis of Kirchhoff's current and voltage laws for low-frequency circuits and Snell's law of reflection in optics. For low-frequency applications, the physics of electricity and magnetism are uncoupled. Coulomb's law for electric field and potential and Ampere's law for magnetic field govern the physical principles. Infrared and optical applications are usually described in the content of photonics or optics as separate subjects. This section emphasizes the engineering applications of electromagnetic field theory that relate directly to the coupling of space and time-dependent vector electric and magnetic fields, and, therefore, most of the subjects focus on microwave and millimeter-wave regimes. The eleven chapters in this section cover a broad area of applied electromagnetics, including fundamental electromagnetic field theory, guided waves, antennas and radiation, microwave components, numerical methods, and radar and inverse scattering.

Chapter 1 discusses the basic theory of magnetostatics. Magnetic field and energy due to a direct current is defined based on Ampère's law and the Biot-Savart law. Macroscopic properties of magnetic material are described. In addition, domains and hysteresis are introduced. Inductance relating the magnetic flux to the current is defined. The concept of a magnetic circuit, which finds important applications in power transformers, is also introduced.

Chapter 2 is devoted to the fundamental theory of electrostatics. The concept of electric field and potential based on Coulomb's law and Gauss's law is introduced. Electric energy and force based on the field and potential are described. Boundary value problem based on the Poisson's equation and Laplace's equation for electric potential is formulated and canonical examples are given.

Waves propagating in a homogeneous isotropic region are usually in the form of plane-waves. Chapter 3 describes the basic properties of plane waves for both lossless and lossy media. These basic properties include the nature of the electric and magnetic fields, the properties of the wave number vector, and the power flow of the plane wave. Special attention is given to the specific case of a homogenous (uniform) plane wave, i.e., one having real direction angles because this case is most often met in practice. Properties such as wavelength, phase and group velocity, penetration depth, and polarization are discussed for these plane waves.

Chapter 4 describes the theory of transmission lines. Transmission equations for voltage and current are derived based on lumped-element circuit models. The propagation characteristics of both lossless and lossy lines are discussed with the latter emphasized on low-loss cases and cases lacking distortion. Useful parameters of a terminated transmission line, including impedance, reflection coefficient, voltage, and current, at various locations on the line are discussed in detail. The basic operation of the Smith chart to relate the reflection coefficient to the input impedance at the transmission line is explained and examples are given.

Distributing electromagnetic power from one point to another in a prescribed way usually requires transmission lines or waveguides. Chapter 5 discusses the properties of a class of guided wave structures. The emphasis is on non-TEM structures where the guided waves are dispersive. The mode characteristics of rectangular metallic waveguides, circular metallic waveguides, microstrip lines, slot lines, coplanar waveguides, and the circular dielectric waveguides are summarized.

In wireless communication systems, it is necessary to send signals in the form of electromagnetic waves through air, such as in radio or television broadcasting, or via point-to-point microwave links. An antenna is a device for transmission or reception of electromagnetic signals. Chapter 6 describes the basic theory of antennas and their arrays. This chapter presents the fundamental properties of electromagnetic waves emanating from any antenna as well as the antenna parameters, including polarization, radiation patterns, beam width, side lobe level, efficiency, gain, bandwidth, input impedance, directivity, and receiving cross section. Chapter 6 discusses the radiation/reception properties of selected antenna structures, including a dipole, a monopole, a wire-loop, a slot, and a microstrip. The theory of antenna arrays made of a number of individual antenna elements at different locations is also discussed.

Active and passive components are essential building blocks of microwave circuits and systems that have become increasingly important due to the booming of next-generation wireless communications. Chapter 7 describes the basic characteristics of a class of microwave passive components, including tuning stubs, lumped elements, impedance transformers and matching network, couplers, power dividers/combiners, resonators, and filters. Scattering parameters are usually used to characterize the frequency-dependent components. Examples are given mostly for rectangular metallic waveguides and microstrip circuits. Active microwave components will also be discussed in this chapter.

The engineering applications of electromagnetic fields and waves usually require accurate solutions of Maxwell's equations subject to proper boundary conditions. Due to the increasing capability of computers, many of the complicated electromagnetic problems are now becoming solvable. Numerical computation has become an indispensable subject in electromagnetics. The two most widely applied numerical methods are discussed in Chapter 8. Chapter 8 also describes a frequency-domain integral-equation based approach known as the method of moments. This method is particularly useful when the Green's function (the kernel) can be found analytically. This section also discusses the recent progress of using a fast algorithm to deal with large electromagnetic systems. Chapter 9 describes a time-domain differential equation-based approach known as the finite-difference time-domain (FDTD) method. This method is particularly useful for complicate noncanonical or nonlinear structures with impulsive sources. The volume of the structure usually dictates computer time and memory required. Perfect absorbing boundary facilitates fast computation with minimum required memory.

An early application of electromagnetics is on radio detection and ranging known as radar, which is an interdisciplinary subject involving communications, signal processing, and propagation. Chapter 10 discusses the principle of both pulsed and CW radar systems and radar parameters. Specialized radars for various applications are also addressed, including MTI radar, Doppler radar, tracking radar, high cross-range resolution radar, and synthetic aperture radar. An inverse scattering problem is to reconstruct or recover physical or geometric properties of an object from measured electromagnetic fields. The basic principles of inverse scattering are also discussed in this chapter. The approach based on an integral equation formulation in conjunction with an iterative scheme to solve the inverse scattering is also discussed.

Trends in compact communication systems to involve the integration of antenna (including matching network) and active circuits (such amplifiers) together as one component. Chapter 11 discusses the basic principles of active integrated circuit antennas. The basic operation of microwave transistors (both BJT and FET) is discussed. Active circuits of amplifiers, oscillators, and detectors/mixers are described. Active antennas using microstrip patches or printed slots are also described.

The section 5 editor would like to thank all the authors and reviewers for their volunteer effort and cooperation to make this chapter possible. It is our hope that this chapter will be valuable to electrical and electronic engineers who are interested in the subject of electromagnetics.

Magnetostatics

Keith W. Whites
Department of Electrical and Computer Engineering, South Dakota School of Mines and Technology, Rapid City, South Dakota, USA

1.1 Introduction

Magnetostatics involves the computation of magnetic forces and fields produced by direct (i.e., time-stationary) currents and from materials with permanent magnetization (**magnets**). Only magnetic forces and fields that do not change with time are **magnetostatic**.

There are many applications of magnetostatics and even a few industries that are almost wholly based upon it. The magnetic recording and electric power industries both apply principles from magnetostatics. Other applications include magnetic resonance imaging (MRI) (Inan and Inan, 1999), magnetic brush applicators in electrophotography (laser printers) (Schein, 1992), and aurora in the earth's atmosphere (Paul *et al.*, 1998), to name a few.

1.2 Direct Current

1.2.1 Current and Current Density

Current is the flow of charge. By convention, the direction of this flow is with the movement of positive charge. The amount of charge δQ flowing *through* (i.e., perpendicular) to a surface in time δt is defined as $\delta Q = I\delta t$, where I is the **current**. In the limit of infinitesimally small time increments, the current I through the surface can be defined as:

$$I = \frac{dQ}{dt}\,[\mathrm{A}], \tag{1.1}$$

where the units are coulombs per second [C/s] or amperes [A].

Magnetostatics is a field theory and, consequently, the quantities of interest are usually distributed throughout space. As such, the **volume current density**, $\boldsymbol{J}(x, y, z)$ is often employed. In terms of the charge carriers, the current density is given by

$$\boldsymbol{J} = Nq\boldsymbol{v}[\text{A/m}^2], \tag{1.2}$$

where N is the number of charge carriers per unit volume (i.e., the number density), q is the charge, and $\boldsymbol{v}$ is the average (or drift) velocity. In addition, a current density through an open surface S is related to the current as:

$$I = \int_s \boldsymbol{J} \cdot d\boldsymbol{s}[\text{A}]. \tag{1.3}$$

A **surface current density**, $\boldsymbol{J}_s[\text{A/m}]$, is an approximation for $\boldsymbol{J}$ in a very thin layer.

Example 1.1

One end of a copper wire (diameter = 2 mm) is attached to one end of an aluminum wire (diameter = 4 mm). A direct current $I = 10$ mA is passing through the wires. To determine the current density in each wire, equation 1.3 is applied assuming the current density is uniformly distributed over the cross-section:

$$J_{Cu} = \frac{I}{\text{Area}_{Cu}} = \frac{0.01\text{A}}{\pi(0.002)^2\text{m}^2} = 795.8\text{A/m}^2. \tag{1.4}$$

$$J_{Al} = \frac{I}{\text{Area}_{Al}} = \frac{0.01\text{A}}{\pi(0.004)^2\text{m}^2} = 198.9\text{A/m}^2. \tag{1.5}$$

The much smaller current density in Al is due solely to the larger diameter and not because of the material type.

The drift speed of the conduction electrons in each wire can be determined using equation 1.2 and by knowing that there are approximately 8.49×10^{28} conduction charges/m^3 in Cu and 6.02×10^{28} conduction charges/m^3 in Al (Halliday *et al.*, 2002). Therefore, the following two equations result:

$$v_{Cu} = \frac{J_{Cu}}{N_{Cu}e} = \frac{795.8 \text{ A/m}^2}{(8.49 \times 10^{28}/\text{m}^3)(1.6022 \times 10^{-19}\text{C})} = 5.850 \times 10^{-8}\text{m/s} \tag{1.6}$$

$$v_{Al} = \frac{J_{Al}}{N_{Cu}e} = \frac{198.9\text{A/m}^2}{(6.02 \times 10^{28}/\text{m}^3)(1.6022 \times 10^{-19}\text{C})} = 2.062 \times 10^{-8}\text{m/s}. \tag{1.7}$$

1.2.2 Ohm's Law

At each point in an ohmic material, such as in a conductor, the volume current density $\boldsymbol{J}$ and electric field $\boldsymbol{E}$ are related by **Ohm's law:**

$$\boldsymbol{J} = \sigma\boldsymbol{E} \ [\text{A/m}^2], \tag{1.8}$$

through the **electrical conductivity** σ of the material. The units of σ are siemens per meter [S/m]. The conductivities for various materials are listed in Table 1.1. It is apparent that σ varies enormously for different materials. The materials near the top of the table are called conductors, whereas those near the bottom are called insulators.

The electrical conductivity σ of metals varies with temperature. As a simple estimate of this variation, the conductivity can be assumed to change linearly with temperature (Halliday *et al.*, 2002):

$$\frac{1}{\sigma} - \frac{1}{\sigma_0} = \frac{\alpha}{\sigma_0}(T - T_0). \tag{1.9}$$

In this linear equation, σ_0 is the conductivity at temperature T_0, α is the temperature coefficient of the conductor (see Table 1.1), and σ is the conductivity at temperature T. For metals with a positive α, the conductivity decreases with increasing T (or resistivity $\equiv 1/\sigma$ increases with increasing T).

Example 1.2

From Table 1.1, the conductivity of copper at 20°C is $\sigma_0 = 5.8 \times 10^7$. We can use equation 1.9 to determine the temperature at which the conductivity is half that at 20°C. Solving for T in equation 1.9 using $T_0 = 20°\text{C}$, $\sigma = \sigma_0/2$, and $\alpha = 0.00393/°\text{C}$ gives the following:

$$T = T_0 + \frac{1}{\alpha} = 274.5°\text{C}. \tag{1.10}$$

1.2.3 Resistance

The ratio of the potential difference along a conductor to the current through the conductor is called the **resistance** R with units of ohms (Ω). Referring to an arbitrary conductor as in Figure 1.1, this ratio of voltage to current can be expressed as:

$$R = \frac{V}{I} = \frac{\int_c \boldsymbol{E} \cdot d\boldsymbol{l}}{\int_s \boldsymbol{J} \cdot d\boldsymbol{s}} = \frac{\int_c \boldsymbol{E} \cdot d\boldsymbol{l}}{\int_s \sigma \boldsymbol{E} \cdot d\boldsymbol{s}} [\Omega]. \tag{1.11}$$

To conform to the convention that $R \geq 0$ for passive conductors, the path of integration c is from the surfaces of higher to lower potential through the conductor, and $d\mathbf{s}$ is in the direction of current, as shown in Figure 1.1. If the conductor in this Figure is homogeneous with a cross-sectional area A, then from equation 1.11:

$$R = \frac{1}{\sigma} \frac{V}{A\left(\frac{V}{L}\right)} = \frac{L}{\sigma A} \ [\Omega]. \tag{1.12}$$

Equation 1.12 can be used to compute R for any straight, homogeneous conductor with a uniform cross-sectional area A at zero frequency. Conversely, if the conductor is inhomogeneous or has a nonuniform cross section, R must be computed using equation 1.11.

The resistance R and capacitance C of two perfect conductors (or, simply, two constant potential surfaces) at zero frequency are related as (Cheng, 1981):

$$RC = \frac{\varepsilon}{\sigma}, \tag{1.13}$$

where ε (permittivity) and σ are the material parameters of the otherwise homogeneous space between the perfect conductors.

Example 1.3

Suppose you wish to determine the resistance of a 1-m length of 12-gauge copper wire at 20°C and at a temperature of 274.5°C. At 20°C, using equation 1.12 and σ from Table 1.1, you get:

$$R = \frac{1}{5.8001 \times 10^7 \,\mathrm{S/m}(\pi \cdot 0.001025^2 \,\mathrm{m}^2)} = 5.224 \,\mathrm{m}\Omega. \tag{1.14}$$

As mentioned previously, the conductivity of copper decreases with increasing temperature. At $T = 274.5°\mathrm{C}$, $\sigma = 2.9001 \times 10^7 \,\mathrm{S/m}$ from equation 1.9. Hence, the following results

$$R = \frac{1}{2.9001 \times 10^7 \,\mathrm{S/m}(\pi \cdot 0.001025^2 \mathrm{m}^2)} = 10.45 \,\mathrm{m}\Omega. \tag{1.15}$$

This resistance is twice that at 20°C as expected, because the conductivity has decreased by half.

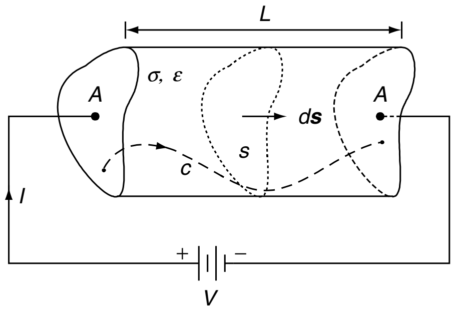

FIGURE 1.1 Conventions Used in the Computation of Resistance Using Equation 1.11

1.2.4 Power and Joule's Law

Ohm's law in equation 1.8 relates the conduction current $\boldsymbol{J}$ to the electric field $\boldsymbol{E}$ at every point in conductive material. Because of collisions between the charge carriers (electrons) comprising the current with the lattice of atoms forming the conductive material, there will be a loss of electrical energy. The **power** P delivered to electrical charges in a volume v is given by **Joule's law**:

$$P = \int_v \boldsymbol{E} \cdot \boldsymbol{J} dv [\mathrm{W}], \tag{1.16}$$

where P has units of joules per second [J/s] or watts [W]. This power is dissipated as heat in the conductive material through an irreversible process since P is unchanged when the direction of $\boldsymbol{E}$ in equation 1.16 is reversed with $\boldsymbol{J}$ given in equation 1.8.

Considering a conductor with a uniform cross section and a length L, if both $\boldsymbol{E}$ and $\boldsymbol{J}$ are directed along the conductor's length at all points, then from equation 1.16:

$$\begin{aligned} P &= \int_L E dl \int_s J ds \\ &= VI [\mathrm{W}]. \end{aligned} \tag{1.17}$$

This familiar expression for power in electrical circuits can be expressed in two alternative forms using Ohm's law for resistors (in equation 1.11) as:

$$P = \frac{V^2}{R} = I^2 R [\mathrm{W}]. \tag{1.18}$$

This power is dissipated in the resistor and transferred to its surroundings through **joule heating**.

Example 1.4

If a 75-W incandescent light bulb is connected to a 120-V electrical outlet, equation 1.18 can be used to compute the resistance of the light bulb provided V and I are root–mean–square values. In this case:

$$R = \frac{V_{RMS}^2}{P} = \frac{120^2}{75} = 19\Omega, \tag{1.19}$$

which is the resistance when the light bulb is turned on. If the cost of electricity is 5 ¢(kW·h), it would cost \$2.70 ($= 75 \times 24 \times 30 \times 0.05/1000$) to light this bulb continuously for 1 month. The resistance in equation 1.19 will likely be very different than when the light bulb is off and cold. From equation 1.9 using equation 1.12:

$$R - R_0 = \alpha R_0 (T - T_0) [\Omega] \tag{1.20}$$

Assuming the tungsten filament is approximately 3000°C when lit and using $\alpha = 0.0045/^\circ$C from Table 1.1, then using this last equation gives $R_0 \approx 13\ \Omega$ for the resistance of a room-temperature 75-W light bulb. This agrees closely with a measured value of 13.1 Ω even though using α at such a large temperature was not justified.

1.2.5 Conservation of Charge and Kirchhoff's Current Law

A basic postulate of physics is that electrical charge can neither be created nor destroyed. This fact is manifested in electromagnetics through the **continuity equation**:

$$\nabla \cdot \boldsymbol{J} = -\frac{\partial \rho}{\partial t}. \tag{1.21}$$

This equation relates the net outward flux of $\boldsymbol{J}$ per unit volume to the time rate of change of the **volume electric charge density** ρ at every point. When there is no time variation (which is the situation for magnetostatics), the conservation of charge equation 1.21 becomes:

$$\nabla \cdot \boldsymbol{J} = 0. \tag{1.22}$$

Physically, this equation tells us that the net outward flux of $\boldsymbol{J}$ per unit volume at every point must vanish. In other words, the electric current density $\boldsymbol{J}$ acts like an incompressible fluid.

Applying the divergence theorem (Paul *et al.*, 1998) to equation 1.22 gives the integral form of the static continuity equation as:

$$\oint_s \boldsymbol{J} \cdot d\boldsymbol{s} = 0. \tag{1.23}$$

This result is **Kirchhoff's current law** (KCL) expressed in integral form. Using equation 1.23 at a junction of N conducting wires in a nonconducting space (such as air), the currents I_j in all wires satisfy:

$$\sum_j I_j = 0, \tag{1.24}$$

which is the circuit form of KCL.

Example 1.5

Conductors are intrinsically charge neutral even if a current exists in the conductor. If an excess charge is somehow introduced into the conductor, it will redistribute itself until the electric field due to the excess charge is zero. For example, suppose an excess charge is introduced into an isolated conductor. Beginning with equation 1.21, substituting equation 1.8, and using Gauss's law $\nabla \cdot (\varepsilon \boldsymbol{E}) = \rho$, we can determine that the free volume charge ρ must satisfy the equation (Cheng, 1989):

$$\frac{\partial \rho}{\partial t} + \frac{\sigma}{\varepsilon}\rho = 0, \tag{1.25}$$

with solution

$$\rho = \rho_0 e^{-t/\tau} \quad [\mathrm{C/m^3}], \tag{1.26}$$

where

$$\tau = \frac{\varepsilon}{\sigma}\ [\mathrm{s}]. \tag{1.27}$$

In these results, ρ_0 is the charge density distribution at an initial time and τ is the **relaxation time constant**. For all practical purposes, the charge is redistributed in a time equal to 5τ. This time is very brief for metals and much longer for good dielectrics. At these two extremes, copper has a relaxation time $\tau \approx 1.5 \times 10^{-19}$ s, while for fused quartz, $\tau \approx 4$ days.

1.3 Governing Equations of Magnetostatics

1.3.1 Postulates of Magnetostatics

The natural phenomenon of magnetostatics is governed by a short and succinct set of equations. The circulation of the **magnetic field intensity** $\boldsymbol{H}$ [A/m] is governed by **Ampère's law**:

$$\nabla \times \boldsymbol{H} = \boldsymbol{J} \text{ (point form)}. \tag{1.28}$$

$$\oint_c \boldsymbol{H} \cdot d\boldsymbol{l} = I_{net} \text{ (integral form)}. \tag{1.29}$$

The I_{net} is the net current passing through the open surface bounded by the closed contour c (Cheng, 1989). Furthermore, the net outward flux of the **magnetic flux density** $\boldsymbol{B}$ [Wb/m^2 or T] is governed by **Gauss's law** for magnetic fields:

$$\nabla \cdot \boldsymbol{B} = 0 \text{ (point form)}. \tag{1.30}$$

$$\oint_s \boldsymbol{B} \cdot \boldsymbol{ds} = 0 \text{ (integral form).} \tag{1.31}$$

The $\boldsymbol{B}$ and $\boldsymbol{H}$ vector fields are related through the constitutive equation:

$$\boldsymbol{B} = \mu \boldsymbol{H}[\mathrm{T}], \tag{1.32}$$

where μ is the **permeability** [H/m] of the material.

All magnetostatic fields must satisfy the equations 1.28 through 1.31. Very few magnetostatic problems, however, have simple and analytical solutions for the vector fields $\boldsymbol{B}$ and $\boldsymbol{H}$. Table 1.2 contains a representative list of problems that do have simple analytical solutions. These problems all contain much symmetry, which is the key to arriving at these simple solutions.

Example 1.6

In rare instances, the integral forms of Ampère's law equation 1.29 and Gauss's law equation 1.31 can be used to *solve* for $\boldsymbol{H}$ and $\boldsymbol{B}$. This occurs when the problem contains sufficient symmetry so that $\boldsymbol{H}$ and $\boldsymbol{B}$ can be factored out of the integrals in these two equations (Paul *et al.*, 1998). As an example consider the toroid shown in Table 1.2. Assuming that the wire (carrying current I) is "tightly wound" on the toroid, then using Ampere's law around a circular contour inside the toroid gives:

$$\oint_c \boldsymbol{H} \cdot \boldsymbol{dl} = NI, \tag{1.42}$$

because the current pierces the open surface (bounded by contour c) N times. By symmetry and using a cylindrical coordinate system with $\boldsymbol{dl} = \hat{\boldsymbol{\varphi}} r d\phi$, in this case, gives:

$$2\pi r \, H_\phi = NI, \tag{1.43}$$

$$B_\phi = \frac{\mu NI}{2\pi r}[\mathrm{T}]. \tag{1.44}$$

Equation 1.44 is the solution given in Table 1.2. Outside the toroid, $I_{net} = 0$, and consequently $B_\phi = 0$.

1.3.2 Biot-Savart Law and Vector Magnetic Potential *A*

Ampère's law (equations 1.28 and 1.29) and Gauss's law (equations 1.30 and 1.31) are the rules that all magnetostatic fields must obey. Except in very limited situations, as discussed in the previous section, these laws cannot be used to directly compute $\boldsymbol{B}$ or $\boldsymbol{H}$. Instead, if a given current density $\boldsymbol{J}$ is prescribed at source coordinates $\boldsymbol{r}'$, the $\boldsymbol{B}$ field can be directly computed at any observation coordinate $\boldsymbol{r}$ using the **Biot-Savart law** (Paul *et al.*, 1998):

$$\boldsymbol{B}(\boldsymbol{r}) = \frac{\mu}{4\pi} \int_{r^1} \frac{\boldsymbol{J}(\boldsymbol{r}') \times \boldsymbol{R}}{R^3} dv' [\mathrm{T}]. \tag{1.45}$$

The vector $\boldsymbol{R} = \boldsymbol{r} - \boldsymbol{r}'$ points from the source point to the observation point. For a surface current density $\boldsymbol{J}_s$, the Biot-Savart law reads:

$$\boldsymbol{B}(\boldsymbol{r}) = \frac{\mu}{4\pi} \int_{s'} \frac{\boldsymbol{J}_s(\boldsymbol{r}') \times \boldsymbol{R}}{R^3} ds' \; [\mathrm{T}], \tag{1.46}$$

whereas for a filamentary current I (pointing in the direction of $\boldsymbol{dl}'$ at $\boldsymbol{r}'$), the Biot-Savart law is written as:

$$\boldsymbol{B}(\boldsymbol{r}) = \frac{\mu}{4\pi} \oint_{c'} \frac{I(\boldsymbol{r}') \boldsymbol{dl}' \times \boldsymbol{R}}{R^3} \; [\mathrm{T}]. \tag{1.47}$$

The $\boldsymbol{B}$ field can also be computed from the **magnetic vector potential** $\boldsymbol{A}$ as:

$$\boldsymbol{B} = \nabla \times \boldsymbol{A} \; [\mathrm{T}] \tag{1.48}$$

where for a volume current density $\boldsymbol{J}$ at source coordinates $\mathbf{r}'$:

$$\boldsymbol{A}(\boldsymbol{r}) = \frac{\mu}{4\pi} \int_{v'} \frac{\boldsymbol{J}(\boldsymbol{r}')}{R} dv' \; [\mathrm{Wb/m}]. \tag{1.49}$$

Expressions for $\boldsymbol{A}$ produced by $\boldsymbol{J}_s$ and I are similar to equations 1.46 and 1.47, respectively (Paul *et al.*, 1998). In rare instances, computation of $\boldsymbol{A}$ first and then $\boldsymbol{B}$ is simpler than computing $\boldsymbol{B}$ directly using the Biot-Savart law.

Example 1.7

A direct current I exists in the circular loop shown in Table 1.2. You can use the Biot-Savart law (equation 1.47) to find a simple analytical solution for $\boldsymbol{B}$ along the z-axis. (This is not true for observation points off the z-axis. Instead, numerical integration of (equation 1.47) would be required) (Whites, 1998, Example 4.10). For this geometry, referring to equation 1.47 and the circular loop figure in Table 1.2, $\boldsymbol{dl}' = \phi' a d\phi'$ and $\boldsymbol{R} = \boldsymbol{r} - \boldsymbol{r}' = \hat{\mathbf{z}} z - \hat{\mathbf{r}}' a$. Consequently, from equation 1.47:

$$\boldsymbol{B} = \frac{\mu I}{4\pi} \int_0^{2\pi} \frac{(\boldsymbol{\phi}' a d\phi') \times (\hat{\boldsymbol{z}} z - \hat{\boldsymbol{r}}' a)}{(a^2 + z^2)^{3/2}} = \frac{\mu I}{4\pi (a^2 + z^2)^{3/2}} \int_0^{2\pi} (\hat{\boldsymbol{r}}' az + \hat{\boldsymbol{z}} a^2) d\phi'$$
$$= \frac{\mu I}{4\pi (a^2 + z^2)^{3/2}} \left[\hat{\boldsymbol{x}} az \int_0^{2\pi} \cos\phi' d\phi' + \hat{\boldsymbol{y}} az \int_0^{2\pi} \sin\phi' d\phi' + \hat{\boldsymbol{z}} a^2 \int_0^{2\pi} d\phi' \right]. \tag{1.50}$$

TABLE 1.2 Examples of Problems with Simple Analytical Solutions for $\boldsymbol{B}$ [T]

Name	Geometry	Solution
Infinite sheet[1]		$\boldsymbol{B} = \pm\hat{\boldsymbol{z}}\frac{\mu J_s}{2}\, y \gtrless 0$ (1.33)
Straight wire[2]		Finite: $\boldsymbol{B} = \boldsymbol{\phi}\frac{\mu I}{4\pi r}(\cos\alpha_2 - \cos\alpha_1)$ (1.34) Infinite: $\boldsymbol{B} = \boldsymbol{\phi}\frac{\mu I}{2\pi r}(z = 0,\ L \to \infty)$ (1.35)
Circular loop (along z axis)[3]		$\boldsymbol{B} = \hat{\boldsymbol{z}}\frac{\mu I a^2}{2(a^2+z^2)^{3/2}}(x = y = 0)$ (1.36)
Magnetic dipole[1]		$\boldsymbol{B} = \frac{\mu m}{4\pi r^3}(\hat{\boldsymbol{r}}2\cos\theta + \hat{\boldsymbol{\theta}}\sin\theta)$ (1.37)

Therefore,

$$\boldsymbol{B}(z) = \hat{\boldsymbol{z}} \frac{\mu I a^2}{2(a^2 + z^2)^{3/2}} \text{ [T]}, \tag{1.51}$$

which is the result of equation 1.36 listed in Table 1.2.

1.3.3 Boundary Conditions for *B*, *H*, and *J*

The vector field quantities ***B*** and ***H*** behave in a prescribed manner at the interface between two different magnetic materials. The component of ***B*** perpendicular to the interface (in the direction of the unit vector $\hat{\boldsymbol{n}}$) is continuous across the interface. That is:

$$\hat{\boldsymbol{n}} \cdot (\boldsymbol{B}_2 - \boldsymbol{B}_1) = 0, \tag{1.52}$$

or equivalently,

$$B_{n2} = B_{n1}. \tag{1.53}$$

The $\boldsymbol{B}_1$ (or $\boldsymbol{B}_2$) is ***B*** at the interface but just inside material 1 (or 2) and $\hat{\boldsymbol{n}}$ is a unit vector pointing from region 1 toward region 2.

Conversely, the tangential components of ***H*** are discontinuous across a boundary that has a surface current density $\boldsymbol{J}_s$ as:

$$\hat{\boldsymbol{n}} \times (\boldsymbol{H}_2 - \boldsymbol{H}_1) = \boldsymbol{J}_s. \tag{1.54}$$

In scalar form, using the right-handed coordinate system $\{n, t, u\}$, the tangential components of $\boldsymbol{H}(H_{t2}$, and $H_{t1})$ are discontinuous across the material interface by an amount equal to $J_{s,u}$, which is the component of $\boldsymbol{J}_s$ perpendicular to H_{t2} and H_{t1}. That is:

$$H_{t2} - H_{t1} = J_{s,u}. \tag{1.55}$$

A surface current density $\boldsymbol{J}_s$ exists at an interface only in certain situations such as an impressed source layer, on the surface of superconductors, and, for time-varying fields, on the surface of perfect electrical conductors ($\sigma \rightarrow \infty$) (Paul *et al.*, 1998). When $\boldsymbol{J}_s$ does not exist at the interface, then from equation 1.55:

$$H_{t2} = H_{t1}, \tag{1.56}$$

so that the tangential components of ***H*** are continuous across the interface.

At the interface between two materials with conductivities σ_1 and σ_2, the components of ***J*** that are normal (i.e., perpendicular) to the interface are continuous across the interface:

$$J_{n2} = J_{n1}, \tag{1.57}$$

while the tangential components are discontinuous according to the relationship:

$$\frac{J_{t2}}{\sigma_2} = \frac{J_{t1}}{\sigma}. \tag{1.58}$$

1.4 Magnetic Force and Torque

1.4.1 Ampère's Force Law

One of the most fundamental principles in magnetostatics is that a current immersed in a magnetic field experiences a force. This magnetic force behaves very differently than the electrostatic force. Considering two closed loops of current shown in Figure 1.2, the total net magnetic force on the current in loop 1 due to the current in loop 2 is given by **Ampère's force law** (Paul *et al.*, 1998):

$$\boldsymbol{F}_{12} = \frac{\mu I_1 I_2}{4\pi} \oint_{c_1} \oint_{c_2} \frac{d\boldsymbol{l}_1 \times (d\boldsymbol{l}_2 \times \boldsymbol{R}_{12})}{R_{12}^3} \text{ [N]}. \tag{1.59}$$

This force law can also be expressed in the slightly different form:

$$\boldsymbol{F}_{12} = -\frac{\mu I_1 I_2}{4\pi} \oint_{c_1} \oint_{c_2} \frac{\boldsymbol{R}_{12}(d\boldsymbol{l}_1 \cdot d\boldsymbol{l}_2)}{R_{12}^3} \text{ [N]}. \tag{1.60}$$

By interchanging indices 1 and 2 in equation 1.60, it is easy to see that:

$$\boldsymbol{F}_{21} = -\boldsymbol{F}_{12}, \tag{1.61}$$

as required by Newton's third law (Whites, 1998).

Substituting equation 1.47 into equation 1.59, the net force on loop 1 can be expressed as:

$$\boldsymbol{F}_{12} = \oint_{c_1} I_1 d\boldsymbol{l}_1 \times \boldsymbol{B}_2(\boldsymbol{r}_1) \text{ [N]}. \tag{1.62}$$

It is very clear from this result that a current immersed in a magnetic field experiences a force. Specifically, the magnetic field is produced by the current in loop 2, and the force $\boldsymbol{F}_{12}$ in equation 1.62 is that experienced by the current in loop 1.

Example 1.8

Using equation 1.62 it can be shown that the net magnetic force on any closed loop of current immersed in a uniform ***B***

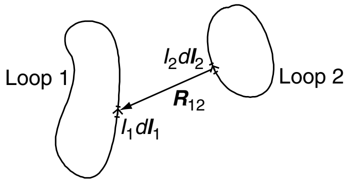

FIGURE 1.2 Differential Current Elements $I_1 d\boldsymbol{l}_1$ and $I_2 d\boldsymbol{l}_2$ Located in Two Current Loops

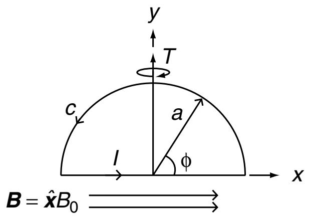

FIGURE 1.3 Closed Loop of Current I Immersed in a Uniform $\boldsymbol{B}$ Field

field is zero (Ulaby, 2001). When $\boldsymbol{B}$ is uniform, then from equation 1.62:

$$\boldsymbol{F} = I\oint_c d\boldsymbol{l} \times \boldsymbol{B} = I\underbrace{\left(\oint_c d\boldsymbol{l}\right)}_{=0} \times \boldsymbol{B} = 0. \tag{1.63}$$

This result is true regardless of the shape of the current loop so long as the $\boldsymbol{B}$ field is uniform. As an example, the net magnetic force on the loop in Figure 1.3 can be computed using equation 1.62 as:

$$\begin{aligned}\boldsymbol{F} = I\oint_c d\boldsymbol{l} \times \boldsymbol{B} &= I\left[\int_{-a}^{a} (\hat{\boldsymbol{x}}dx) \times (\hat{\boldsymbol{x}}B_0) + \int_0^{\pi} (\boldsymbol{\phi}ad\phi) \times (\hat{\boldsymbol{x}}B_0)\right] \\ &= I\int_0^{\pi} (-\hat{\boldsymbol{x}}\sin\phi + \hat{\boldsymbol{y}}\cos\phi)ad\phi \times (\hat{\boldsymbol{x}}B_0) = -\hat{\boldsymbol{z}}IaB_0\sin\phi|_0^{\pi} = 0,\end{aligned} \tag{1.64}$$

which is zero, as expected in light of equation 1.63.

1.4.2 Lorentz Force Equation

Moving charges in a magnetic field also experience a magnetic force, similar to current in the previous section. The total force experienced by a charge q moving with velocity $\boldsymbol{v}$ is given by the celebrated **Lorentz force equation**:

$$\boldsymbol{F} = q(\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B})\ [\mathrm{N}], \tag{1.65}$$

which is the sum of an electric force ($\boldsymbol{F}_e = q\boldsymbol{E}$) and a magnetic force ($\boldsymbol{F}_m = q\boldsymbol{v} \times \boldsymbol{B}$).

There are two important distinctions concerning the behavior of the electric and magnetic forces in the Lorentz force equation. First, it is apparent from equation 1.65 that the electric force $\boldsymbol{F}_e$ acts on both moving and stationary charges, whereas the magnetic force $\boldsymbol{F}_m$ acts only on moving charges. Second, energy is transferred from the electric field to the charged particle, whereas no energy is transferred from the magnetic field to a moving (or stationary) charged particle.

Because of this second fact, a magnetic force can only change the direction of a moving charge and not its speed. This can be easily understood by considering the differential work dW performed by the magnetic field when the particle is displaced a small distance $d\boldsymbol{l} = \boldsymbol{v}dt$ in time dt (Ulaby, 2001):

$$dW = \boldsymbol{F}_m \cdot d\boldsymbol{l} = (\boldsymbol{F}_m \cdot \boldsymbol{v})dt = 0, \tag{1.66}$$

since from equation 1.65, $\boldsymbol{F}_m \cdot \boldsymbol{v} = 0$.

Example 1.9

The Lorentz force equation can be applied to charged particle motion through solids and gases. An example of the former is the **Hall effect** in a conductor as illustrated in Figure 1.4. In steady-state, the force of equation 1.65 on an electron q_e passing through this material is zero such that:

$$\boldsymbol{E} = -\boldsymbol{v} \times \boldsymbol{B} = -\hat{\boldsymbol{y}}vB_0\ [\mathrm{V/m}]. \tag{1.67}$$

The difference in potentials at the $y = w$ and $y = 0$ faces of the material is as follows:

$$V_H = -\int_0^w E_y dy = vwB_0\ [\mathrm{V}], \tag{1.68}$$

because of the charge accumulation on these two faces. This V_H is called the **Hall voltage**.

From the sign of V_H, the polarity of the charge can be determined; from the magnitude of V_H, the number density of charge carriers can be computed. A Hall device can also be used to measure conductivities of materials and to measure magnetic field strengths (Inan and Inan, 1999; Halliday, 1992). Imagine that a copper foil of thickness $d = 100\,\mu\mathrm{m}$ with current $I = 20$ A is placed in magnetic field with $B_0 = 0.5\,\mathrm{T}$. Substituting equation 1.2 in equation 1.68 and rearranging gives the following:

$$\begin{aligned}V_H &= \frac{IB_0}{dNe} \\ &= \frac{(20\mathrm{A})(0.5\ \mathrm{T})}{(100\times10^{-6}\ \mathrm{m})(8.49\times10^{28}\ \mathrm{m}^{-3})(1.6022\times10^{-19}\ \mathrm{C})} = 7.35\,\mu\mathrm{V}.\end{aligned} \tag{1.69}$$

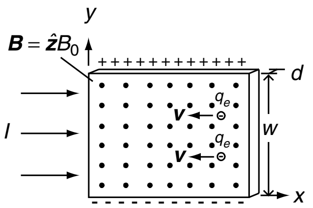

FIGURE 1.4 Hall Effect and a Conducting Material Placed in a Uniform $\boldsymbol{B}$ Field

1.4.3 Torque and Magnetic Dipole Moment

In example 1.8, it was mentioned that the net magnetic force on a closed loop of current in a uniform $\boldsymbol{B}$ field is zero. However, this closed loop of current does experience a torque and will rotate if it is free to do so. The **torque $\boldsymbol{T}$** exerted on any planar loop of current immersed in a uniform $\boldsymbol{B}$ field is given as (Cheng, 1989):

$$\boldsymbol{T} = \boldsymbol{m} \times \boldsymbol{B} \text{ [N-m]}, \tag{1.70}$$

where the **magnetic dipole moment $\boldsymbol{m}$** of a planar current loop of area A is as follows:

$$\boldsymbol{m} = \hat{\boldsymbol{n}} m = \hat{\boldsymbol{n}} IA \text{ [A-m}^2\text{]}. \tag{1.71}$$

The unit normal vector $\hat{\boldsymbol{n}}$ is determined using the right-hand rule. That is, with the fingers pointing in the direction of the current, the thumb points in the direction of $\hat{\boldsymbol{n}}$. The magnetic dipole moment $\boldsymbol{m}$ of any planar loop can be computed using equation 1.71. (Note, however, that the $\boldsymbol{B}$ field from equation 1.37 produced by $\boldsymbol{m}$ is valid only at distances "far" from the loop [White, 1998, Example 4.10].)

Example 1.10

The object shown in Figure 1.3 is an example of a planar current loop in a uniform $\boldsymbol{B}$ field that experiences a torque. The magnetic dipole moment of this loop can be found using equation 1.71:

$$\boldsymbol{m} = \hat{\boldsymbol{z}} \frac{I}{2} \pi a^2 \text{ [A-m}^2\text{]}, \tag{1.72}$$

and the torque can be determined from equation 1.70 as:

$$\boldsymbol{T} = \left(\hat{\boldsymbol{z}} \frac{I}{2} \pi a^2 \right) \times (\hat{\boldsymbol{x}} B_0) = \hat{\boldsymbol{y}} \frac{I}{2} B_0 \pi a^2 \text{ [N-m]}. \tag{1.73}$$

The directions of $\boldsymbol{T}$ and the loop rotation—if it were free to move—are both indicated in Figure 1.3. The direction of rotation is determined from $\boldsymbol{T}$ using the right-hand rule: With the thumb in the direction of $\boldsymbol{T}$, the fingers give the sense of rotation. The loop will not experience a torque when the unit normal vector $\hat{\boldsymbol{n}}$ is pointing in the direction of $\boldsymbol{B}$.

1.5 Magnetic Materials

1.5.1 Magnetization Vector and Permeability

When magnetic material is placed in an incident (or external) magnetic field, a secondary magnetic field is produced by the material. Similar to a dielectric material, the magnetic material is said to have become polarized by the alignment of microscopic magnetic dipole moments $\boldsymbol{m}$. These magnetic dipole moments can be used to develop a phenomenological model for the classical effects and many quantum mechanical aspects of magnetization (Paul *et al.*, 1998; Plonus, 1978).

The macroscopic effects of magnetization are described by a **magnetization vector** field $\boldsymbol{M}$ as a vector sum of $\boldsymbol{m}_i$ in a small volume $\Delta v'$:

$$\boldsymbol{M} = \lim_{\Delta v' \to 0} \frac{\sum_{i=1}^{N} \boldsymbol{m}_i}{\Delta v'} \text{ [A/m]}, \tag{1.74}$$

where N moments are assumed contained in $\Delta v'$. By definition, the **magnetic field intensity $\boldsymbol{H}$** is then given as:

$$\boldsymbol{H} = \frac{\boldsymbol{B}}{\mu_0} - \boldsymbol{M} \text{ [A/m]}. \tag{1.75}$$

The **permeability of free space**, μ_0, is identically equal to $4\pi \times 10^{-7}$ [H/m].

From experimentation, it has been found that for many materials, $\boldsymbol{M}$ and $\boldsymbol{H}$ are simply related as:

$$\boldsymbol{M} = \chi_m \boldsymbol{H} \text{ [A/m]}. \tag{1.76}$$

In this expression, χ_m is the **magnetic susceptibility** of the material and is a dimensionless quantity. The values of χ_m are typically found through experimental measurement.

Substituting equation 1.76 into 1.75 and rearranging gives the following equations:

$$\boldsymbol{B} = \mu_0 (1 + \chi_m) \boldsymbol{H} \text{ [T]} \tag{1.77}$$

or

$$\boldsymbol{B} = \mu \boldsymbol{H} \text{ [T]}, \tag{1.78}$$

where

$$\mu = \mu_0 \mu_r = \mu_0 (1 + \chi_m) \text{ [H/m]} \tag{1.79}$$

is the **permeability** and μ_r is the **relative permeability** of the material. For free space, $\mu_r = 1$. Equation 1.78 is the **constitutive relationship** for magnetic fields.

Example 1.11

A magnetic sphere of radius a and permeability μ is placed in a uniform incident field $\boldsymbol{H}^{\text{inc}} = \hat{\boldsymbol{z}} H_0$. It can be shown that the secondary field inside and outside the sphere is the following (Plonus, 1978; Ramo *et al.*, 1999):

$$\boldsymbol{H}^{\text{secondary}} = \begin{cases} -\hat{\boldsymbol{z}} \frac{\mu - \mu_0}{\mu + 2\mu_0} H_0 & r < a \\ \frac{\mu - \mu_0}{\mu + 2\mu_0} H_0 \frac{a^3}{r^3} \left(\hat{\boldsymbol{r}} 2 \cos\theta + \hat{\boldsymbol{\theta}} \sin\theta \right) & r > a \end{cases} \text{ [A/m]}. \tag{1.80}$$

The total ***H*** at any point is the sum $\boldsymbol{H} = \boldsymbol{H}^{\text{inc}} + \boldsymbol{H}^{\text{secondary}}$. A plot of the ***H*** field lines is shown in Figure 1.5. The magnetic sphere causes ***H*** to be disturbed from its original uniform nature. Inside the sphere, however, ***H*** is uniform and pointed along the same axis as the incident field, though its amplitude is now less than H_0 (and the amplitude of ***B*** is *greater* than B_0) when $\mu > \mu_0$. This disturbance in ***H*** is due to the secondary ***H*** produced by the induced magnetization ***M*** of the sphere. Using equation 1.76:

$$\boldsymbol{M} = \begin{cases} \hat{\boldsymbol{z}}\frac{3\chi_m\mu_0}{\mu+2\mu_0}H_0 = \hat{\boldsymbol{z}}\frac{3(\mu-\mu_0)}{\mu+2\mu_0}H_0 & r < a \\ 0 & r > a \end{cases} \text{[A/m]}, \qquad (1.81)$$

which is zero outside the sphere because there is nothing to magnetize in free space.

1.5.2 Magnetic Materials

There are five major classifications for magnetic materials as briefly discussed in this subsection (Inan and Inan, 1999; Paul *et al*., 1998; Halliday *et al*., 1992). Diamagnetic materials have $\chi_m < 1$, and the remaining four types all have $\chi_m > 1$. Because of this, diamagnetic materials are repelled by a strong magnet, whereas specimens of the other four categories are attracted to a strong magnet.

- **Diamagnetic** materials have a small negative χ_m so that $\mu_r \lesssim 1$ as shown in Table 1.3. All materials are diamagnetic to some extent although this behavior may be superceded by a more dominant effect, such as ferromagnetism. Diamagnetism is a classical (*versus* quantum mechanical) effect produced by moving charges. The induced magnetization ***M*** is opposed to the applied ***B***, thus reducing the total ***B*** in such a material sample. This effect is directly analogous to the polarization effects in ordinary dielectrics.
- **Paramagnetic** materials have a small positive χ_m so that $\mu_r \gtrsim 1$ as shown in Table 1.3. Paramagnetism is a quantum mechanical effect largely due to the spin magnetic moment of the electron. While these permanent magnetic moments are usually randomly oriented (so that $\boldsymbol{M} = 0$), they become partially aligned in an applied ***B***. In this latter state, the magnetization ***M*** is aligned with the applied ***B***, thus increasing the total ***B*** in the sample (and, consequently, decreasing ***H***).
- **Ferromagnetic** materials also have a positive χ_m, but the resulting μ_r is usually much greater than 1. There is a much stronger quantum mechanical interaction between neighboring spin moments than with paramagnetic materials that can also lead to magnetization ***M*** without an applied ***B***. Ferromagnetism is strongly temperature dependent. Only the elements iron, nickel, and cobalt are ferromagnetic at room temperature. Above the **Curie temperature** T_c, a ferromagnetic material becomes paramagnetic, and the magnetic susceptibility decreases with increasing temperature. The T_c of the room temperature ferromagnetic materials are 770°C for iron, 354°C for nickel, and 1115°C for cobalt.
- **Antiferromagnetic** materials are quite similar to ferromagnetic materials in that there is a strong quantum mechanical interaction between neighboring atomic molecules. However, this strong interaction causes an **antiparallel** alignment of magnetic moments yielding a zero

magnetization ***M***. The elements chromium and manganese are examples of antiferromagnetic materials. This effect is highly temperature dependent. Below the **Néel temperature** T_N, the magnetic susceptibility increases with increasing temperature but decreases for temperature greater than T_N (Kittel, 1996).

- **Ferrimagnetic** materials possess characteristics between those of ferromagnetic and antiferromagnetic materials. There is an incomplete antiparallel alignment of magnetic moments as in the antiferromagnetic materials, and, consequently, there is a net magnetization ***M***, though typically less than ferromagnetic materials. **Ferrites** are a special class of ferrimagnetic material that have a low conductivity at high frequencies. These ceramic-like materials are extremely useful in high-frequency applications due to their small conduction losses. Examples include MnZn with $\mu_{r,\,\max} \approx 2000$ and NiZn with $\mu_{r,\,\max} \approx 100$.

1.5.3 Domains and Hysteresis

The origin of the extremely large permeabilities of ferromagnetic materials is the existence of magnetized domains in these materials (Plonus, 1978; Kittel, 1996). A **magnetized domain** is a microscopic region (on the order of 0.1 to 1 mm^3) where the magnetization is uniform and saturated. Between adjacent domains are **domain walls**. Without an external field (at point O in Figure 1.6), these domains are randomly orientated so that the net magnetization of the material is zero. In the presence of external magnetic fields, these domains align and produce an enormous secondary ***B*** in the same direction as the applied field, thus giving a possibly enormous permeability.

If the applied fields become strong enough, the domains rotate and the material leaves the initial linear region of operation and enters the nonlinear and multivalued region indicated by the **hysteresis curve** in Figure 1.6. The ratio *B/H* at any point on the curves is the permeability μ. Around point O, the slope is nearly constant, whereas on the hysteresis curve it is not; this indicates that the ferromagnetic material has become nonlinear.

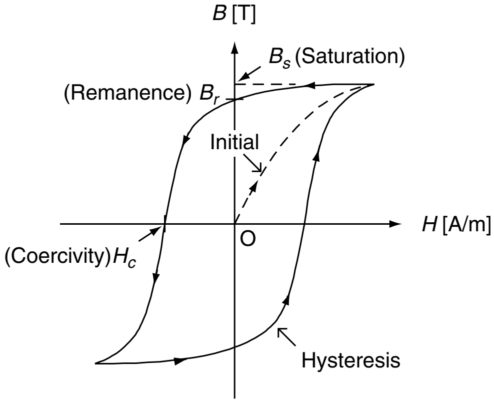

FIGURE 1.6 Magnetization Curves for a Typical Ferromagnetic Material. The initial magnetization curve is indicated by the dashed line, while the hysteresis curve is indicated by the solid line.

The maximum *B* that the material attains for any *H* is called the **saturated** *B*, B_s in Figure 1.6, corresponding to total alignment of domains. When *H* is then reduced from this point to zero, *B* reduces to B_r, which is the remanent *B* field or **remanance**. The negative (or antiparallel) *H* required to further reduce *B* to zero is H_c, the **coercivity**. Materials with a large H_c (called **hard ferromagnetic materials**) expend more energy per complete transversal of the hysteresis curve and consequently find applications as permanent magnets (see the next section). Conversely, materials with small H_c (called **soft ferromagnetic materials**) expend much less energy per hysteresis-curve cycle and find uses in transformers, relays, and generators.

The properties of a few selected soft ferromagnetic materials are listed in Table 1.4, including μ along the initial magnetization curve in Figure 1.6 and the maximum μ found anywhere along the hysteresis curve.

1.5.4 Permanent Magnets

Permanent magnets are materials that possess a magnetization ***M*** in the absence of an applied magnetic field. These magnets

can be constructed from ferromagnetic or other materials that are nonlinear with magnetization curves containing hysteresis, as shown in Figure 1.6. If the material has been properly magnetized, then a remanent B field B_r exists in the material even when $H = 0$. Consequently, this material acts as a **permanent magnet**.

In many applications of permanent magnets—such as in electrical motors, generators, and relays—the permanent magnet is part of a magnetic circuit containing an air gap. In these situations, as derived in example, 1.12, the permanent magnet generally operates in the second (or fourth) quadrant of the hysteresis curve (Bozorth, 1978). This second-quadrant portion of the hysteresis curve is called the **demagnetization curve** and is illustrated in Figure 1.7.

One quality measure of a permanent magnet is the "size" of this demagnetization curve. A large B_r and H_c in Figure 1.7 ensures that the intrinsic magnetization of the magnet is large and remains "permanent" even for large H. Another selection criterion used for permanent magnets is based on the **energy product** BH. This quantity is appropriately named since energy density is proportional to this product (see subsection 1.7.2), which is also plotted in Figure 1.7 by multiplying B and H at each point along the demagnetization curve. The **maximum energy product**$(BH)_{\max}$ is yet another measure of the quality of a permanent magnet since H in the air gap produced by the permanent magnet shown in Figure 1.8 is maximum (with $I = 0$) when the energy product is maximum. This maximum energy product $(BH)_{\max}$ for a selected number of steels, alloys, and other materials is listed in Table 1.5 together with the remanance B_r and coercivity H_c.

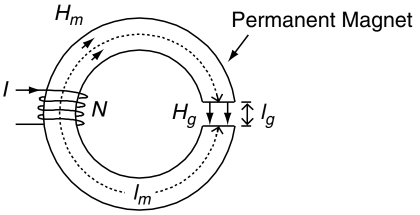

FIGURE 1.8 Ring of Permanent Magnet Material and Air Gap Excited by a Coil of Wire with N Turns and Current I

Example 1.12

The geometry shown in Figure 1.8 is an excellent canonical problem to illustrate the salient features of permanent magnet circuits. Assume a small cross-section and ignore all leakage flux. The first topic is to show the steps necessary to determine B in this problem, which is the same in the gap and the magnet because of the boundary condition shown in equation 1.52. To do this, two equations will be solved simultaneously. The first equation is the hysteresis curve for the permanent magnet, which is shown in Figure 1.9.

The second equation comes from an application of Ampère's law of equation 1.29 around the permanent magnet circuit in Figure 1.8:

$$\oint_c \boldsymbol{H} \cdot d\boldsymbol{l} = NI. \tag{1.82}$$

Assuming no "flux leakage" from the permanent magnet or "flux fringing" in the air gap (see Section 1.8), then:

$$H_m l_m + H_g l_g = NI, \tag{1.83}$$

where H_m and H_g are the magnetic fields in the magnet and air gap, respectively. In the air gap, $H_g = B/\mu_0$. Substituting this into equation 1.82 and rearranging gives:

$$B = -\mu_0 \frac{l_m}{l_g} H_m + \mu_0 \frac{NI}{l_g} [\mathrm{T}]. \tag{1.84}$$

This straight-line equation 1.84 is also drawn in Figure 1.9. The intersections of this "load line" (Bozorth, 1978, Ch. 9) with the hysteresis curve give the two possible solutions for B in the permanent-magnet circuit of Figure 1.8. The actual operating point depends on the previous time history because this is a nonlinear circuit. Nevertheless, note from this example that the second quadrant of the hysteresis curve (which is symmetrical with the fourth) is the important quadrant. This illustrates why the second quadrant is used as a measure of comparison for magnets, as shown in Figure 1.7.

The second topic considered in this example is the relationship between H_g in the air gap and the maximum energy product $(BH_m)_{\max}$ of the permanent magnet in Figure 1.8. With $I = 0$ in equation 1.82, then:

$$H_g = -\frac{l_m}{l_g} H_m [\mathrm{A/m}]. \tag{1.85}$$

Multiplying this result by H_g and using the constitutive relationship $B = \mu_0 H_g$ yields (Bozorth, 1978, Ch. 9):

$$H_g^2 = -\frac{l_m}{l_g} \frac{BH_m}{\mu_0}. \tag{1.86}$$

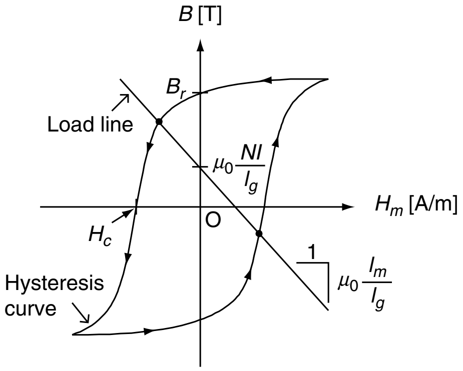

FIGURE 1.9 Solution for B in the Permanent-Magnet Circuit of Figure 1.8

That is, the square of the magnetic field in the air gap is directly proportional to the maximum energy product of the magnet. In other words, choosing a magnet with a larger maximum energy product will produce a larger magnetic field in the air gap shown in Figure 1.8.

1.6 Inductance

1.6.1 Magnetic Flux and Flux Linkage

Magnetic flux and flux linkage are two qualities of a spatially distributed magnetic field that are closely related to inductance. The flux of the ***B*** field, ψ_m, through a loop is the integral of the component of ***B*** normal to the loop over the loop cross-section. Mathematically, the **magnetic flux** through loop i produced by current in loop j is defined as (Paul *et al.*, 1998):

$$\psi_{m,\,ij} = \int_{s_i} \mathbf{B}_j \cdot d\mathbf{s}_i \text{ [Wb]}. \tag{1.87}$$

In the case that $i = 1$ and $j = 2$, for example, then $\psi_{m,12}$ is the magnetic flux through loop 1 produced by the current in loop 2. Alternatively, magnetic flux can also be computed as (Paul *et al.*, 1998):

$$\psi_{m,\,ij} = \oint_{c_i} \boldsymbol{A}_j \cdot d\boldsymbol{l}_i \text{ [Wb]}, \tag{1.88}$$

where $\boldsymbol{A}_j$ is the magnetic vector potential of current loop j.

Inductors are commonly constructed by wrapping many turns of wire around a core. This is an efficient method of increasing the inductance since for the same amount of current, the flux through (or "linking") the open surface bounded by the contour is approximately proportional to the number of wire turns. Accordingly, for loop i with N_i identical and "tightly wound" turns, the **flux linkage** is defined as:

$$\Lambda_{ij} = N_i \psi_{m,\,ij} [\text{Wb}]. \tag{1.89}$$

This flux linkage represents the total magnetic flux that passes through (or is "linked" by) the open surface bounded by the multiturn contour.

Example 1.13

The toroid in Figure 1.10 will be used to illustrate the computation of magnetic flux and flux linkage. Assume that μ is so large that all of the magnetic field is trapped in the toroid. In other words, ignore all "flux leakage." With a current I_1 in coil 1, applying Ampère's law of equation 1.29 along a closed contour in the toroid yields:

$$B_{\phi,1} = \mu \frac{N_1 I_1}{2\pi r} \ [\text{T}]. \tag{1.90}$$

Using the definition in equation 1.87, the magnetic flux through coil 1 due to I_1 (the "self flux") is as follows:

$$\psi_{m,\,11} = \int_{s_1} \boldsymbol{B}_1 \cdot d\boldsymbol{s}_1 = \int_{-h/2}^{h/2} \int_{a}^{b} \boldsymbol{\phi} \frac{\mu N_1 I_1}{2\pi_r} \cdot \boldsymbol{\phi} dr dz = \frac{\mu N_1 I_1 h}{2\pi} \ln\left(\frac{b}{a}\right) \ [\text{Wb}], \tag{1.91}$$

which is also equal to $\psi_{m,21}$ (the "mutual flux") since the cross sections of the two coils are identical.

The flux linkage through coil 1 is from equations 1.89 and 1.91:

$$\Lambda_{11} = N \psi_{m,\,11} = \frac{\mu N_1^2 I_1 h}{2\pi} \ln\left(\frac{b}{a}\right) \ [\text{Wb}], \tag{1.92}$$

whereas the flux linkage through coil 2 is as written here:

$$\Lambda_{21} = N_2 \psi_{m,21} = \frac{\mu N_2 N_1 I_1 h}{2\pi} \ln\left(\frac{b}{a}\right) \ [\text{Wb}]. \tag{1.93}$$

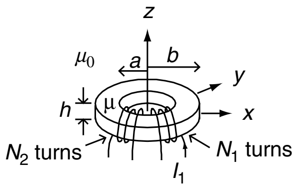

FIGURE 1.10 Two Wire Coils Wrapped Around a Toroid with Large μ

1.6.2 Definition of Inductance

An inductor is a device that can store energy in a magnetic field. Coils, solenoids, and toroids are all examples of inductors. For an ideal two-terminal inductor with inductance L, the voltage–current relationship is:

$$v_L(t) = L \frac{di_L(t)}{dt} \ [\text{V}]. \tag{1.94}$$

For practical inductors, however, nonideal effects may alter this voltage–current relationship through an additional series resistance and possible lead capacitance and inductance (Paul, 1992, Ch. 6).

Assuming an ideal inductor, the computation of inductance becomes a strictly magnetostatic problem.

Considering one or more loops of current in space, it can be shown that the magnetic flux through a loop is proportional to the current that produces the magnetic flux (Paul *et al.*, 1998). (This behavior is evident in equation 1.91 for the toroid.) The constant of proportionality is called **inductance** with units of henry (H). Specifically, inductance is defined in terms of the flux linkage and current as:

$$L_{ij} = \frac{\text{flux linkage through } ith \text{ coil due to current in } jth \text{ coil}}{\text{current in } jth \text{ coil}} \ [\text{H}] \tag{1.95}$$

or

$$L_{ij} = \frac{\Lambda_{ij}}{I_j} = \frac{N_i \psi_{m,ij}}{I_j} \ [\text{H}], \tag{1.96}$$

assuming from equation 1.89 that all N_i turns of the inductor are identical. The **Neumann formula** (Cheng, 1989):

$$L_{ij} = \frac{\mu}{4\pi} \oint_{c_i} \oint_{c_j} \frac{d\boldsymbol{l}_i \cdot d\boldsymbol{l}_j}{R_{ij}} \ [\text{H}] \tag{1.97}$$

is a useful alternative form to equation 1.96, especially for filamentary currents.

If $i = j$, $L_{ii} (= L)$ is called a **self-inductance**, whereas if $i \neq j$, L_{ij} is called a **mutual inductance**. A list of self-inductances for a few selected geometries is shown in Table 1.6. Inductance will not depend on current if the inductor is constructed from linear materials. Conversely, if ferromagnetic materials are used to fabricate the inductor, the inductance may be dependent on current since, as discussed previously, ferromagnetic materials can behave nonlinearly.

Other than for very simple and ideal geometries, neither equations 1.96 and 1.97 can be analytically evaluated to give
