Two-wire line[2]		$L \approx \frac{\mu h}{\pi} \ln\left(\frac{d}{r_w}\right)$ (1.102)

[1] Paul *et al.* (1998). [2] Plonus (1978). [3] Ramo *et al.* (1994).

simple formulas for inductance. This is only possible for inductors with high degrees of symmetry, such as the toroid or infinitely long coaxial cable shown in Table 1.6. Alternatively, numerical integration can be used instead to evaluate equations 1.96 and 1.97; the latter is particularly suited for coil-type inductors (Whites, 1998, Example 4.15).

Example 1.14

The self- and mutual inductances of the wire coils on the toroid in Example 1.13 can be computed using equation 1.96 together with the flux linkages in equations 1.92 and 1.93. For coil 1, the self-inductance is the following:

$$L_{11} = \frac{\Lambda_{11}}{I_1} = \frac{\mu N_1^2 h}{2\pi} \ln\left(\frac{b}{a}\right) \text{ [H]}, \tag{1.103}$$

which is the first entry in Table 1.6, while the mutual inductance is the following:

$$L_{21} = \frac{\Lambda_{21}}{I_1} = \frac{\mu N_2 N_1 h}{2\pi} \ln\left(\frac{b}{a}\right) \text{ [H]}. \tag{1.104}$$

In both cases, the inductance is proportional to the square of the number of wire turns. This behavior is common to all coil-type inductors.

The self-inductance for coil 2 and the mutual inductance L_{12} can also be computed using equation 1.96. A current I_2 is assumed to exist in coil 2 for the purposes of these inductance calculations. Since the inductance of inductors formed from linear materials does not depend on the current in the wire, assuming this current I_2 is only a construction step. From equation 1.96:

$$L_{22} = \frac{\Lambda_{22}}{I_2} = \frac{\mu N_2^2 h}{2\pi} \ln\left(\frac{b}{a}\right) \text{ [H]}, \tag{1.105}$$

and the mutual inductance is

$$L_{12} = \frac{\Lambda_{12}}{I_2} = \frac{\mu N_1 N_2 h}{2\pi} \ln\left(\frac{b}{a}\right) \text{ [H]}. \qquad (1.106)$$

Comparing equations 104 and 106, it is apparent that $L_{12} = L_{21}$. This is a general result. In particular, by interchanging indices i and j in equation 1.97 it can be shown that:

$$L_{ij} = L_{ji} \quad i \neq j \qquad (1.107)$$

1.7 Stored Energy

1.7.1 Energy Stored in a Magnetic Field

As described by Ampère's force law discussed in Section 1.4.1, a magnetic force exists between loops of constant current. Were the loops free to move, they would migrate toward or away from each other depending on their orientations. The work done to keep the current loops stationary is stored as energy in the magnetic field around the loops (Halliday *et al.*, 2002). Energy is also stored in the magnetic field of a single current loop as well as other situations where a magnetic field exists.

Magnetic energy W_m can be computed by integrating the dot product of $\boldsymbol{B}$ and $\boldsymbol{H}$ through space as (Cheng, 1989):

$$W_m = \frac{1}{2} \int\limits_{\text{all space}} \boldsymbol{B} \cdot \boldsymbol{H} dv \quad \text{[J]}. \qquad (1.108)$$

Any *change* to this stored magnetic energy occurs when the magnetic field changes with time according to Faraday's law. Once $\boldsymbol{B}$ and $\boldsymbol{H}$ have reached a steady-state, equation 1.108 provides a method to compute the time-stationary stored magnetic energy.

A **magnetic energy density** w_m can be defined at every point $\boldsymbol{r}$ in space from the integrand of equation 1.108 as:

$$w_m(\boldsymbol{r}) = \frac{1}{2} \boldsymbol{B}(\boldsymbol{r}) \cdot \boldsymbol{H}(\boldsymbol{r}) \quad [\text{J/m}^3]. \qquad (1.109)$$

The total stored magnetic energy can be computed by integrating w_m throughout space as:

$$W_m = \int\limits_{\text{all space}} w_m(\boldsymbol{r}) dv \quad \text{[J]}. \qquad (1.110)$$

Example 1.15

We will compute the magnetic energy stored in a 1-m section of a long coaxial cable shown in Figure 1.11. Using Ampère's law, the magnetic field inside and outside the center conductor are, respectively, (Whites, 1998, Example 4.2):

$$\boldsymbol{H}_{\text{in}} = \boldsymbol{\phi} \frac{Ir}{2\pi r_w^2} \; r < r_w \text{ [A/m]} \qquad (1.111)$$

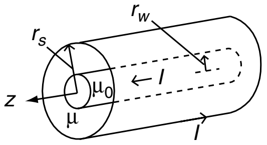

FIGURE 1.11 Coaxial Cable with a Nonmagnetic Center Conductor. All current I in the center conductor is assumed to return on the outer conductor.

and

$$\boldsymbol{H}_{\text{out}} = \boldsymbol{\phi} \frac{I}{2\pi r} \; r_w < r < r_s \text{ [A/m]}. \qquad (1.112)$$

From equations 1.108 and 1.78:

$$\begin{aligned} W_m &= \frac{1}{2} \int\limits_{\text{coax}} \mu |\boldsymbol{H}|^2 dv = \frac{1}{2} \int\limits_{z_0}^{z_0+1} \int\limits_0^{2\pi} \int\limits_0^{r_s} \mu H_\phi^2 r dr d\phi dz \\ &= \pi \left\{ \mu_0 \int\limits_0^{r_s} H_{\phi,\text{in}}^2 r dr + \mu \int\limits_{r_w}^{r_s} H_{\phi,\text{out}}^2 r dr \right\} \text{[J]}. \end{aligned} \qquad (1.113)$$

Substituting H_ϕ inside and outside the center conductor from equations 1.111 and 1.112, respectively, and integrating gives

$$W_m = I^2 \left[\frac{\mu_0}{16\pi} + \frac{\mu}{4\pi} \ln\left(\frac{r_s}{r_w}\right) \right] \text{ [J]}, \qquad (1.114)$$

for the 1-m section of coax.

1.7.2 Energy Stored in an Inductor

Inductors are the primary circuit elements for storage of magnetic energy. Ideally, they are the only circuit elements with this property. The **magnetic energy** W_m stored by an inductor with current I is as follows:

$$W_m = \frac{1}{2} L I^2 \text{ [J]}. \qquad (1.115)$$

In this expression, L is the self-inductance of the inductor as discussed in Subsection 1.6.2.

With coupled inductors—such as when two or more coils are wrapped around a common high permeability core—the energy expression becomes more complicated. In the case of two coupled inductors with currents I_1 and I_2 in coils 1 and 2, respectively, the energy stored in the magnetic field is (Paul *et al.*, 1998):

$$W_m = \frac{1}{2} L_{11} I_1^2 + \frac{1}{2} L_{22} I_2^2 + L_{12} I_1 I_2 \text{ [J]}, \qquad (1.116)$$

where L_{11} and L_{22} are the self-inductances of coils 1 and 2, respectively, and $L_{12}(=L_{21})$ is the mutual inductance between the two coils. As expected, the first two terms in equation 1.116 represent the magnetic energies stored in coils 1 and 2, respectively, while the last term is the energy stored in the mutual inductances of the two-coil system. One potential subtlety is that these self-inductances in equation 1.116 are those computed for a coil with the other one present but having a current equal to zero (Paul *et al.*, 1998).

Example 1.16

The energy stored in a 1-m section of the long coaxial cable in Figure 1.11 was computed to be equation 1.114 in example 1.15. This magnetic energy calculation will be repeated here but using the inductance expression of equation 1.115. The inductance for a 1-m section of coaxial cable is given from the third entry in Table 1.6 as:

$$L = \frac{\mu}{2\pi}\ln\left(\frac{r_s}{r_w}\right) + \frac{\mu_0}{8\pi}\ [\mathrm{H}]. \tag{1.117}$$

Using this inductance in equation 1.115 with a current I in the coaxial cable gives:

$$W_m = \frac{1}{2}\left[\frac{\mu}{2\pi}\ln\left(\frac{r_s}{r_w}\right) + \frac{\mu_0}{8\pi}\right] I^2\ [\mathrm{J}], \tag{1.118}$$

which is identical to equation 1.114 as expected.

In some situations, applying this procedure in reverse can be a convenient method for computing inductance. That is, the stored magnetic energy is computed first, and from this, the inductance is determined using equation 1.115.

1.8 Magnetic Circuits

Magnetic circuit analysis is a technique that can be applied to certain magnetic field problems to greatly simplify the solution. In short, this technique is a lumped-element approximation used to solve for magnetic fields and magnetic fluxes (Cheng, 1989; Paul *et al.*, 1998; Planus, 1978). Applications for this method include the design of electrical generators, motors, transformers, and actuators. Magnetic circuit analysis is quite similar to electrical circuit analysis. Quantities that serve analogous purposes in both types of circuit analyses are listed side by side in Table 1.7.

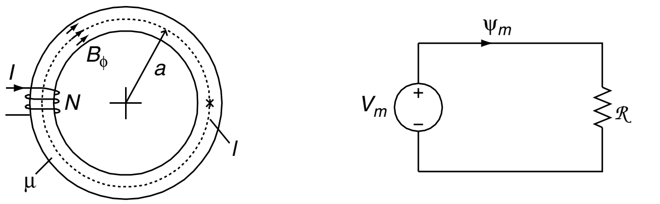
Magnetic circuit analysis is illustrated with the specific example of the toroid shown in Figure 1.12(A). There are two primary assumptions made in magnetic circuit analysis (Paul *et al.*, 1998). First, it is assumed that the permeability of the structure is very large ($\mu \gg \mu_0$). Second, since $\mu \gg \mu_0$, it is further assumed that all of the magnetic field lines flow along the magnetic core and do not deviate outside of the structure; that is, it is assumed there is no **flux leakage** out of the toroid in Figure 1.12(A). Applying Ampère's law of equation 1.29 gives:

$$\oint_c \boldsymbol{H}\cdot d\boldsymbol{l} = NI, \tag{1.119}$$

such that inside a linear magnetic core:

$$B_\phi = \frac{\mu NI}{2\pi}\ [\mathrm{T}]. \tag{1.120}$$

Another common assumption in magnetic circuit analysis – though not required – is that the cross-sectional dimensions



(A) Physical Geometry

(B) Equivalent Magnetic Circuit

FIGURE 1.12 Toroid with High Permeability Core of Circular Cross-Sectional Area *A*

TABLE 1.7 Analogous Quantities in Electrical and Magnetic Circuit Analysis[1]

Electrical circuits		Magnetic circuits	
Conductivity [S/m]	σ	Permeability [H/m]	μ
EMF [V]	V	MMF [A]	V_m
Current [A]	I	Magnetic flux [Wb]	ψ_m
Resistance [Ω]	$R = \frac{l}{\sigma A}$	Reluctance [H^{-1}]	$\mathcal{R} = \frac{l}{\mu A}$
Ohm's law	$V = IR$	—	$V_m = \psi_m \mathcal{R}$
KVL (around a loop)	$\sum_i V_i = \sum_j R_j I_j$	—	$\sum_i V_{m,i} = \sum_j \mathcal{R}_j \psi_{m,j}$
KCL (at a junction)	$\sum_j I_j = 0$	—	$\sum_j \psi_{m,j} = 0$

[1] Paul *et al.*, (1998); Cheng (1989).

are small with respect to the length (the "large aspect ratio" assumption). In these situations, ***B*** will be approximately uniform over the cross section. Assuming that is the case here, then from equation 1.120:

$$B_\phi \approx \frac{\mu NI}{2\pi a} \equiv B \ [\mathrm{T}]. \tag{1.121}$$

Consequently, the magnetic flux ψ_m in a core with cross-sectional area A will be approximately

$$\psi_m \approx BA = \frac{\mu ANI}{2\pi a} [\mathrm{Wb}], \tag{1.122}$$

and the flux will have this value all around the toroid.

The equivalent magnetic circuit for the toroid in Fig. 1.12(A) is developed by expressing equation 1.122 as the ratio of two quantities:

$$\psi_m = \frac{NI}{\left(\frac{2\pi a}{\mu A}\right)} \equiv \frac{V_m}{\mathcal{R}} \quad [\mathrm{Wb}]. \tag{1.123}$$

In the numerator,

$$V_m = NI \quad [\mathrm{A}]. \tag{1.124}$$

Equation 1.124 shows what is called the **magnetomotive force (MMF)** that serves an analogous function in this circuit as a **voltage source (EMF)** in an electrical circuit. In the denominator of equation 1.123:

$$\mathcal{R} = \frac{l}{\mu A} \quad [\mathrm{H}^{-1}]. \tag{1.125}$$

Equation 1.125 shows the **reluctance** of the core (with mean length l), which is analogous to resistance as shown in Table 1.7. The equivalent magnetic circuit for the toroid is shown in Figure 1.12(B).

Other magnetic field problems can be solved using this magnetic circuit analysis by dividing the geometry into different magnetic flux paths, as appropriate, then computing the reluctances of the paths using equation 1.125. The last two entries in Table 1.7 list the laws used to solve magnetic circuit problems. In particular, the sum of mmfs around a closed loop is equal to the sum of "reluctance drops" (KVL analogy), while the sum of magnetic fluxes into a junction equals zero (KCL analogy) (Cheng, 1989; Paul *et al.*, 1998)

Example 1.17

The geometry shown in Figure 1.13(A) is used to illustrate the solution of magnetic field problems using magnetic circuit analysis. The structure is assumed to have a square cross section of area $10^{-6}\ \mathrm{m}^2$, a core with $\mu_r = 1{,}000$, and dimensions $l_1 = 1\ \mathrm{cm}$, $l_3 = 3\ \mathrm{cm}$, and $l_4 = 2\ \mathrm{cm}$.

One distinguishing characteristic of this structure is the **air gap** at the bottom of the center section shown in Figure 1.13(A). If the length of the air gap is small with respect to the cross-sectional dimensions, we can ignore **flux fringing** (or "spreading out" of the ***B*** field lines) in the air gap (Plonus, 1978). Consequently, this gap can be simply modeled as another reluctance as indicated by $\mathcal{R}_g$ in the equivalent magnetic circuit of Figure 1.13(B).

The goal here will be to solve for the magnetic flux density in the air gap. Using equation 1.125 the four reluctances in Figure 1.13(B) can be calculated as:

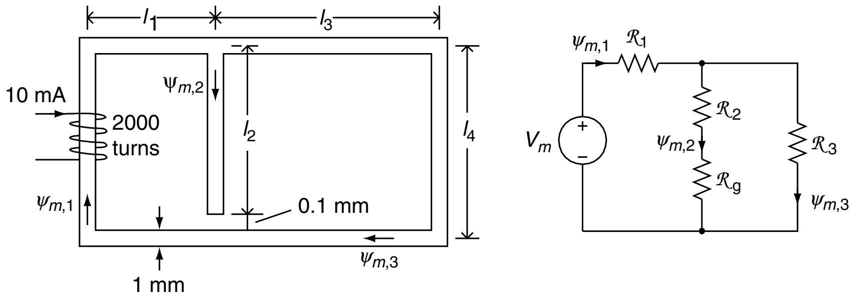
$$\mathcal{R}_1 = \frac{2l_1 + l_4}{1000\mu_0 A} = 31.83 \times 10^6 \quad [\mathrm{H}^{-1}]. \tag{1.126}$$

$$\mathcal{R}_2 = \frac{l_4 - l_g - 0.001/2}{1000\mu_0 A} = 15.44 \times 10^6 \quad [\mathrm{H}^{-1}]. \tag{1.127}$$

$$\mathcal{R}_3 = \frac{2l_3 + l_4}{1000\mu_0 A} = 63.66 \times 10^6 \quad [\mathrm{H}^{-1}]. \tag{1.128}$$

$$\mathcal{R}_g = \frac{l_g}{\mu_0 A} = 79.58 \times 10^6 \quad [\mathrm{H}^{-1}]. \tag{1.129}$$

The magnetic flux through the source coil, $\psi_{m,1}$, can be calculated as the source mmf divided by the total reluctance seen by the source as:



(A) Physical Geometry (B) Equivalent Magnetic Circuit

FIGURE 1.13 Magnetic Circuit Geometry with a Small Air Gap

$$\psi_{m,1} = \frac{V_m}{\mathcal{R}_{\text{total}}} = \frac{NI}{\mathcal{R}_1 + (\mathcal{R}_2 + \mathcal{R}_g)\|\mathcal{R}_3} = 0.286 \times 10^{-6}[\text{Wb}]. \tag{1.130}$$

Using "flux division" (which is analogous to current division in electrical circuits), the magnetic flux through the air gap is then:

$$\psi_{m,2} = \frac{\mathcal{R}_3}{\mathcal{R}_3 + \mathcal{R}_2 + \mathcal{R}_g}\psi_{m,1} = 0.115 \times 10^{-6}[\text{Wb}]. \tag{1.131}$$

Electrostatics

Rodolfo E. Diaz
Department of Electrical Engineering, Ira A. Fulton School of Engineering, Arizona State University, Tempe, Arizona, USA

2.1 Introduction

Electrostatics in its most restrictive sense is the specialization of Maxwell's equations to a system whose sources are steady-state, time-invariant electric charges. Because the conservation of charge is implicit in this definition, the unifying principle of all the equations is the conservation of total **electric flux**. Therefore, electrostatics also properly includes steady-state conduction current problems.

In this chapter, the fundamental relationship between source and field is between the **electric charge q** (measured in coulombs) and the **electric flux density D** (measured in coulombs per meter squared) because that relationship has the form of a conservation law. The **electric field E** (measured in volts per meter) is introduced with the concept of the **electrostatic potential** Φ (measured in volts) as the quantity involved in the dynamics of electrostatic systems (i.e., their interaction forces and energies). In this way, ε (measured in farads per meter), the permittivity of the material medium through which the flux traverses, appears as a proportionality constant that gauges the amount of energy stored in a given electrostatic system. Capacitance *C* (measured in farads) is then a purely geometric expression of the arrangement of that energy inside the system. The concepts of electrostatics are extended to the case of current flow in resistive environments by the recognition of the formal analogy between the electrostatic flux and the current density flux *J* (in amperes per meter^2). Wherever possible, the method of derivation of the important results is indicated.

2.1.1 Conventions

Although the presentation in this chapter will follow the steps outlined above, many other methods of exposition are possible. The reader should be aware of this whenever consulting the various textbooks available on electromagnetic theory. It must be emphasized that apart from the fundamental governing Maxwell equations and the constitutive relations connecting the various field quantities, almost anything that the author of this chapter adds is a matter of opinion or philosophy. This is most evident when the issue of the "fundamentality" of a field is brought up. The viewpoint adopted here is that electrostatics is the specialization of Maxwell's equations to elucidate the behavior of the electric fields in the case of no time variation or zero frequency. This idea is exemplified when equations 2.1 (written in their most conventional form and using the Lorentz Gauge) become equations 2.2.

$$\begin{aligned}
&\nabla \times \vec{E} = -\frac{\partial \vec{B}}{\partial t}. \quad \nabla \times \vec{H} = \frac{\partial \vec{D}}{\partial t} + \vec{J}. && \text{(a) The curl equations} \\
&\vec{B} = \mu(t)\vec{H}. \quad \vec{D} = \varepsilon(t)\vec{E}. && \text{(b) The constitutive relations} \quad (2.1) \\
&\nabla \cdot \vec{D} = \rho. \quad \nabla \cdot \vec{B} = 0. \quad \nabla \cdot \vec{J} = -\frac{\partial \rho}{\partial t}. && \text{(c) The divergence equations}
\end{aligned}$$

$$\begin{aligned}
&\nabla \times \vec{E} = 0. && \text{(a) The irrotational nature of the electric field} \\
&\vec{D} = \varepsilon\vec{E}. && \text{(b) The constitutive relation} \quad (2.2) \\
&\nabla \cdot \vec{D} = \rho. && \text{(c) The divergence equation}
\end{aligned}$$

No field in equations 2.1 and 2.2 can be considered more "fundamental" than the others; each plays a unique part in the dynamics of electromagnetic and electrostatic systems. In particular, when dealing with electrostatics, the distinction between D and E should never be blurred. The practical fact that the constitutive properties of dielectric matter vary in space prevents the moving of the permittivity function, ε, through the vector differential operators of equations 2.2a and 2.2c as if it were a constant. Therefore, the following two expressions are, in general, inequalities. They only become equalities **inside homogeneous regions of space**.

$$\frac{\nabla \times \vec{D}}{\varepsilon} \neq 0, \; \nabla \cdot \vec{E} \neq \frac{\rho}{\varepsilon}. \qquad (2.3)$$

Equation 2.2c defines the D field as the flux produced in space by its source, the charge density ρ, a quantity that is always conserved. Because of equation 2.2a, the E field is shown as the gradient of a potential function; therefore, it is a measure of the force exerted on charges by a given electrostatic field. Equation 2.2b then shows that the strength of this force depends on the environment in which the charges in question are located. The interested reader is referred to the book by Hammond (1981) for an illuminating proof that neither D nor E is more fundamental.

2.2 Sources and Fields

Electric charges are the sources of a vector field called the **electric flux density**. The relationship between a source and its flux is always expressed in the form of a conservation law as in equation 2.2c. The fundamental analysis problem of electrostatics is to calculate the vector fields resulting from a specific charge distribution. In the following section, this is done directly from equation 2.2c by exploiting symmetry. To solve for the fields due to more general asymmetric charge distributions requires a source-field relationship, as derived in Subsection 2.2.2. Finally, a simplification of the problem can be obtained by considering the vector fields to be derivable from potential functions. This is presented in Section 2.2.3.

2.2.1 *D* Fields of Charge Distributions Using Gauss's Law

The following derivations require the calculus of vector differential operators. Most textbooks in electromagnetic theory contain the relevant theorems and their application to electromagnetic fields. A particularly complete and concise presentation of the same can be found in Chapter 2 of the textbook by Jefimenko (1996). The book by Schey (1996) is also recommended. Helmholtz's theorem states that any vector field that is continuous and regular at infinity can be completely specified by its divergence and curl. Thus, including the mediation of the permittivity function, it is clear that the electrostatic field is completely defined by equations 2.2. Integrating both sides of equation 2.2c over all of space and applying the divergence theorem yields for the left-hand side:

$$\int_v \nabla \cdot \vec{D} dv = \oint_s \vec{D} \cdot d\vec{S} \qquad (2.4)$$

Integration of the right-hand side over all of space encompasses the volume containing the charge density and simply gives the total charge enclosed. The result is **Gauss's Law** stating that the total electric flux crossing any surface bounding the charge is equal to the total charge enclosed in that surface, clearly a conservation law:

$$\oint \vec{D} \cdot d\vec{S} = \int \rho dv = Q_{\text{enclosed}}, \quad \text{(Gauss's law)} \qquad (2.5)$$

where S is the bounding surface of the integration volume V and where the vector differential surface element is given by the differential surface element, dS, multiplied by the unit vector normal, $\hat{n}$, to the surface at the point of integration as Figure 2.1 illustrates.

With equation 2.5, the electric flux density, or D field, from **highly symmetric charge distributions** can be obtained. The method of approach is to guess at the form of the field and pick a bounding surface over which the D field is constant and

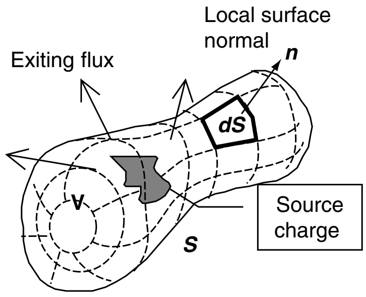

FIGURE 2.1 Gauss's Law Connects the Total Source of Flux Contained Inside the Volume V to the Flux Density that Exits its Bounding Surface S.

perpendicular to the surface, thus allowing it to be pulled out of the integral on the left-hand side of equation 2.5. The bounding surface is known as a **Gaussian surface**.

For instance, assume $\vec{D} = \hat{r} f(r)$. The left-hand side of equation 2.5 in spherical coordinates becomes $4\pi D(r_0) r_0^2$, where r_0 is the radius of the spherical surface of integration enclosing the charge distribution. This result must equal Q, the total charge enclosed. In particular, if r_0 is arbitrarily small, the field surrounding a **point charge** is obtained.

$$\vec{D}(r) = \frac{Q}{4\pi r^2}\hat{r}. \quad \text{(Point source)} \qquad (2.6)$$

This result holds in general *outside* any spherically symmetric charge distribution. By considering such distributions and evaluating the integral on the right-hand side of equation 2.5 for each one, the following classic cases are obtained:

(a) The infinitesimally thin spherical shell of **surface charge density** σ_0

(b) The uniformly charged spherical region of **volumetric charge density** ρ_0

(c) Concentric shells of radii b and a, $b > a$ carrying equal and opposite charges

The results are shown in the left-hand column of Table 2.1. Similarly, by looking for charge distributions that yield a purely radial D field in **two dimensions** the solutions for cylindrically symmetric charge distributions are obtained. The field of the line charge equivalent to equation 2.6 is:

$$\vec{D}(r) = \frac{\lambda}{2\pi r_c}\hat{r}, \quad \text{(Line source)} \qquad (2.7)$$

where λ is the lineal charge density in coulombs per meter. When the charge distribution is symmetrically spread in a

TABLE 2.1 Common Symmetric Charge Distributions with Exact Solutions Via Gauss's Law

Spherical coordinates		Cylindrical coordinates
$\vec{D}(r) = \frac{Q}{4\pi r^2}\hat{r}$	Arbitrarily small source  	$\vec{D}(r) = \frac{\lambda}{2\pi r}\hat{r}$
$\rho_0 \cdot \delta r = \sigma_0$, where $\sigma_0 =$ surface charge density in coulombs per meter squared. Total charge $Q = 4\pi a^2 \sigma_0$. $D(r) = \sigma_0 \frac{a^2}{r^2}$ for $r \geq a$. $D(r) = 0$ for $r < a$.	The infinitesimally thin shell  	$\sigma_0 \cdot 2\pi a = \lambda_0$, where $\sigma_0 =$ surface charge density in coulombs per meter squared. Total lineal charge density is $\lambda_0 = 2\pi a \sigma_0$. $D(r_c) = \frac{\lambda_0}{2\pi r_c}$ for $r_c \geq a$. $D(r_c) = 0$ for $r_c < a$.
$\rho_0 =$ volumetric charge density in coulombs per meter squared. Total charge $Q = \rho_0 4\pi a^3/3$. $D(r) = \rho_0 \frac{a^3}{3r^2}$ for $r \geq a$. $D(r) = \rho_0 \frac{r}{3}$ for $r < a$.	The uniformly charged region  	Total lineal charge density is $\lambda_0 = \rho_0 \pi a^2$. $D(r_c) = \frac{\lambda_0}{2\pi r_c}$ for $r_c \geq a$. $D(r_c) = \frac{\lambda_0}{2\pi a}\left(\frac{r_c}{a}\right)$ for $r_c < a$.
$-\sigma = -Q/4\pi b^2$, $+\sigma = +Q/4\pi a^2$. $D(r) = \frac{Q}{4\pi r^2}$ for $a < r < b$. $D(r) = 0$ for $r < a$ and $r > b$.	Concentric shells of radii b and a, $b > a$ carrying equal and opposite charges  	$-\sigma = -\lambda/2\pi b$, $+\sigma = +\lambda/2\pi a$. $D(r_c) = \frac{\lambda_0}{2\pi r_c}$ for $a < r_c < b$. $D(r_c) = 0$ for $r_c < a$ and $r_c > b$.
Rectangular coordinates $\vec{D} = +\hat{z}\frac{\sigma_0}{2}$ for $z > 0$. $\vec{D} = -\hat{z}\frac{\sigma_0}{2}$ for $z < 0$.	 	

two-dimensional space, cases corresponding to those of the spherical distribution are obtained. Table 2.2 summarizes these results along the right-hand column. Note that in the right-hand column of Table 2.1, the variable r_c is the radial variable in cylindrical coordinates and, by the definition of a two-dimensional field, the solution is for an infinitely long line charge. In all these cases, the field vanishes identically in those regions where the Gaussian surfaces surround zero net charge, and it becomes identical to the field of a point (line) source when the Gaussian surface surrounds a region with nonzero net charge. When the field inside a charge-filled region is being calculated, the Gaussian surface penetrates the region, as suggested in Figure 2.2. As long as flux is perpendicular to the surface, which is known from symmetry, Gauss's law always applies.

Apart from linear combinations of the above cases (such as the shell of finite thickness), the last case that can be derived with ease from Gauss's law is the case of the infinite charged plane. If a Gaussian surface in the form of a pillbox is drawn cutting through the surface of a plane of charge, symmetry dictates that equal amounts of flux must exit the pillbox above and below the plane. Thus, the result at the bottom of Table 2.1 is obtained.

This last example of the charged plane highlights a very important restatement of Gauss's law, relating the charge density on a surface to the total flux density cutting through that surface: Because the electric flux is conserved, the electric flux density normal to a surface is expected to be continuous across that surface. Any discontinuity of that normal flux implies that there is a net surface charge density stored on that surface numerically equal to that discontinuity. As the surface $z = 0$ is crossed in the last case of Table 2.1, the D field changes from $-\hat{z}\sigma_0/2$ to $+\hat{z}\sigma_0/2$, for a total jump discontinuity of magnitude σ_0. This is an example of the fundamental boundary condition on the D field as it crosses any (material) boundary surface:

$$D_{n1} - D_{n2} = \sigma_f, \quad \text{(Boundary condition on normal } D\text{)} \quad (2.8)$$

where D_{n1} is the normal component of the D field on side 1 of the surface, D_{n2} is the normal component of the D field on the other side of the boundary, and σ_f is the **free** surface charge on that boundary.

The simply symmetric charge distributions examined here are the only type of source distributions that can be solved by direct application of Gauss's law, equation 2.5. To find the field of more general (and realistic) charge distributions, a connection between a source charge and the D field it produces is needed.

2.2.2 First Alternative to Gauss's Law: Integration over Charge Distributions

From the result of equation 2.6 and the principle of linear superposition, it follows that an arbitrary charge distribution can be built up from individual differential (or point) charges and yield a total D field given by:

$$\vec{D} = \frac{1}{4\pi}\int \frac{dq}{r^2}\hat{r}. \quad (2.9)$$

In this equation, the vector $\vec{r}$ (and therefore $\hat{r}$ and r^2) is measured from the particular elementary charge being integrated, dq, to the **observation point**. Equation 2.9 can be proven as a consequence of Poisson's theorem for the field vector D in an infinite homogeneous space. Denoting the charge distribution by $\rho(x', y', z')$ and the differential volume element by dv', equation 2.9 is rewritten in the more common form:

$$\vec{D}(\vec{r}) = \int\limits_{\text{all}-\text{space}} \frac{\rho(r')dv'(\vec{r} - \vec{r}')}{4\pi|\vec{r} - \vec{r}'|^3}, \quad \text{(The source} - \text{field relationship)} \quad (2.10)$$

where the primed coordinates refer to the position of the differential element of charge being integrated, and the unprimed coordinates refer to the position of the observation point, as suggested in Figure 2.3.

When the charge distribution is volumetric, the elementary differential element of charge is $dq = \rho dv'$. For surface charge distributions, $dq = \sigma dS'$; for lineal charge distributions, the element is $\lambda dl'$. The meaning and usefulness of equation 2.10 can be illustrated with the following two examples.

Consider the field along the axis of a **charged ring** of constant lineal charge density $\lambda C/m$ and radius a, as shown in Figure 2.4(A). For the sake of convenience, the ring is placed on the plane $z = 0$ of the coordinate system. Then, the differential element of charge in the primed (source) coordinate system is a differential arc of the ring with charge $dq = \lambda dl' = \lambda a d\varphi'$ located at the primed (cylindrical-r'_c, ϕ', z') coordinates (a, ϕ', 0). For an observation point on the axis a distance h from the center of the ring, the unprimed

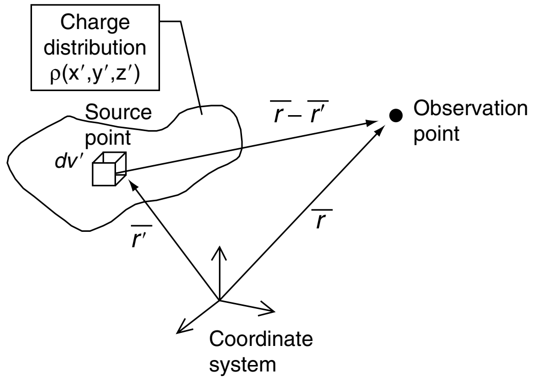

FIGURE 2.3 Definition of the Prime and Unprimed Coordinates for Source–Field Relationships

coordinates are (0,0,h). At this observation point, each particular differential element exerts a vector D field with components in the z and r_c directions. By the symmetry of the problem, the r_c components all cancel out when integrating around the ring, leaving only the z-directed components. Because the charge density is constant around the ring and every differential charge is at the same distance $|\vec{r} - \vec{r}'| = \sqrt{a^2 + h^2}$, the integration over the ring merely contributes a factor $\int dl' = 2\pi a$, giving the result shown in the Figure 2.4(A).

For the second example, consider the field along the axis of a uniformly charged disk of charge density σ and radius b, as shown in Figure 2.4(B). In this special case, the results of Figure 2.4(A) are used to provide us with a new kind of differential elementary charge, namely the ring of radius r'_c and thickness dr'_c, for which the z-directed vector D field along the axis is known. Every such ring is located at the primed coordinate (0,0,0), whereas the observation point is at (0,0,h). Then, the differential charge is $dq = \sigma 2\pi r'_c dr'_c$, and every element is again at the same distance h from the observation point. Because each elementary ring charge has a different radius, the following integral must be performed:

$$\vec{D}(r = 0,\, z = h) = \hat{z}\int_0^b \frac{\sigma 2\pi r'_c dr'_c h}{4\pi\left(r'^{\,2}_c + h^2\right)^{3/2}} \qquad (2.11)$$

The final result is given in Figure 2.4(B). The reader can verify that for observation distances $h \ll b$, the equation in this figure reduces to the case of the infinite plane of charge seen in Table 2.1.

When equation 2.10 is applied to a delta function distribution of charge, equation 2.6 results. This is the field of a **monopole**, or point charge. The fields of ensembles of point charges are obtained by linear superposition of this result. Equation 2.6 states that the D field of a monopole drops as $1/r^2$ with distance. When two or more oppositely charged sources, however, are located in a finite region of space, the external field may drop faster than this. In particular, when the total sum of all charges inside a given volume of space is equal to zero, the far field must drop as $1/r^n$, with $n \geq 3$. Consider the configuration of Figure 2.5, where a negative charge of strength $-q$ is located on the z axis at the point $z = -h/2$, and an equal and opposite charge $+q$ is located a distance h above it on the z axis.

FIGURE 2.4 Examples of the Use of the Source–Field Relationship for Calculating the D-Field of a General Charge Distribution

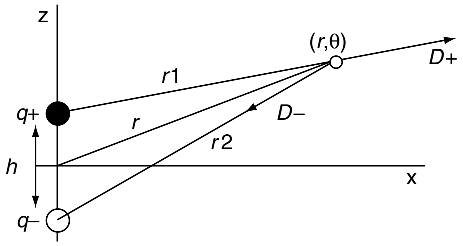

FIGURE 2.5 The Near Cancellation of the Fields of Equal and Opposite Charges Leading to a Far Field that Drops as $1/r^3$

When the observation point is far away, r_1, $r_2 \gg h$. Then $r_1 \approx r_2 - h\ \cos\theta$. In the **far field**, the resultant field is known as a **dipole field**, given by:

$$\vec{D}_{\text{dipole}} = \hat{r}\frac{2p\cos\theta}{4\pi r^3} + \hat{\theta}\frac{p\sin\theta}{4\pi r^3}, \quad (D \text{ field of a point dipole}) \tag{2.12}$$

where the quantity $p = |q|h$ is known as the dipole moment. The dipole moment **vector** points from the negative charge to the positive charge. This equation holds for a dipole of *any orientation*, with θ being the angle subtended to the observation point from the direction of p.

Similarly, the far field of a two-dimensional dipole, consisting of two line charges of equal and opposite strength λ and separated by a distance h, is given by:

$$\vec{D}_{\text{line-dipole}} = \hat{r}\frac{\lambda h\cos\theta}{2\pi r^2} + \hat{\theta}\frac{\lambda h\sin\theta}{2\pi r^2}. \tag{2.13}$$

(D field of a two-dimensional "line" dipole)

Just as a dipole results from the combination of equal and opposite monopoles, a **quadrupole** results from the combination of equal and opposite dipoles. The far field of quadrupoles drops as $1/r^4$. Higher order 2^n poles result from linear combinations of $2^{(n-1)}$ poles.

2.2.3 Second Alternative to Gauss's Law: The Potential Function

The calculation of vector fields from arbitrary charge distributions using equation 2.10 is made straightforward by modern computational machines and vector field visualization software. When simple expressions, however, are desired to aid intuition, or when memory storage is at a premium during numerical computations, a scalar field is much more convenient.

At this point, the second electrostatic vector field, the **electric field E**, measured in Volts per meter must be introduced. It is related to the electric flux density D through the **constitutive relation**:

$$\vec{D} = \varepsilon\vec{E}, \tag{2.14}$$

where the quantity ε is known as the **permittivity** of the medium. Its value for free space is $\varepsilon_0 = 8.854 \times 10^{-12}$ F/m. When the permittivity of a material medium is normalized to this value, it is known as the **relative permittivity** ε_r, or the **dielectric constant**. For most materials, the value is a scalar quantity. However, for anisotropic materials, the value depends on the orientation of the electric field. In such cases, the quantity ε in equation 2.14 is understood to be a tensor.

While the D field is a measure of the amount of flux produced by an electric charge, the E field is a measure of the force that the flux can exert on another charge through the equation:

$$\vec{F} = q\vec{E}. \quad \text{(The electrostatic force equation)} \tag{2.15}$$

Thus, the permittivity can be understood as a proportionality constant that determines the force a charge can exert on neighboring charges in a given material environment. Further discussion on the permittivity function is given in Subsection 2.3.4. All results derived up to this point for the D fields of sources in an infinite homogeneous space translate directly to the E fields of the same sources by simply dividing by ε. When boundaries exist across material properties that change, the field must be obtained as the solution of a boundary value problem (see Subsection 2.3.3). Equation 2.2a reveals that the E field is irrotational, so it must be derivable from the gradient of a scalar potential function because the curl of a gradient is zero. Therefore, the following is true:

$$\vec{E} = -\nabla\Phi,$$

where it follows that:

$$\Phi = \frac{1}{4\pi}\int_{\text{all-space}} \frac{\nabla \cdot \vec{E}}{r}\,dv' + \Phi_0, \tag{2.16}$$

and where Φ_0, as a constant of integration, is an arbitrary fixed potential.

The electrostatic potential Φ constitutes a **conservative field**. To prove this, take the line integral of both sides of the first equation in 2.16, traversing the field E along an arbitrary path from position a to position b:

$$\int_a^b \vec{E}\cdot d\vec{l} = -\int_a^b \nabla\Phi\cdot d\vec{l} = -\int_a^b d\Phi = \Phi(a) - \Phi(b). \tag{2.17}$$

The result is independent of the path of integration followed in going from a to b. The potential function is thus a single-valued point-wise continuous function everywhere in space, even in the presence of material boundaries. Therefore:

</table>

$$\lim_{\vec{\delta}\to 0}\Phi(\vec{r}+\vec{\delta}) = \Phi(\vec{r}) \text{ for all } \vec{r}, \vec{\delta}. \quad \text{(The boundary condition for } \Phi) \tag{2.18}$$

The quantity measured by equation 2.17 is called the **electromotive force** (emf) in the path *a–b*, or the **potential difference** or **voltage difference** between the points *a* and *b* measured in volts.

The second equation of equations 2.16 can be used to derive the relationship between the electrostatic potential and the electric charges inside an infinite homogeneous space by recognizing that:

$$\nabla \cdot \vec{E} = \frac{1}{\varepsilon}\nabla \cdot \vec{D}.$$

Thus:

$$\Phi = \frac{1}{4\pi\varepsilon}\int \frac{\rho}{|\vec{r}-\vec{r}'|}\,dv' + \Phi_0 = \frac{1}{4\pi\varepsilon}\int \frac{dq}{r}, \tag{2.19}$$

(The source – potential relationship)

where, as is customary, the potential at infinity = 0 has been defined; thus, $\Phi_0 = 0$, and $\Phi(r)$ is the *absolute* potential.

Thus, the potential of a point charge, or monopole, is simply:

$$\Phi_{\text{point}}(r) = \frac{q}{4\pi\varepsilon r}. \quad \text{(The potential of a point source)} \tag{2.20}$$

To calculate the electrostatic field of any charge distribution, equation 2.19 can be used first to calculate the electrostatic potential by integration over the source, and then the vector electric field can be derived from its gradient. By this process, the potential on the axis of the **charged ring** of Figure 2.4(A) is easily obtained. Then, the on-axis potential of the disk follows by integration over a continuum of rings, as before. The results are given in Table 2.2. Constructing a spherical shell by integrating over a series of rings spanning the surface of a sphere ($\theta = 0$ to π) yields the potential of a spherical shell of surface charge density σ and radius a. A similar derivation yields the potential of a **uniformly charged sphere**. These are also included in Table 2.2.

The potential function for ensembles of point charges is particularly simple, even in the near field. Thus, for an observation point anywhere near the dipole of Figure 2.5, the total potential is given as the scalar sum of the two point source potentials, shown at the bottom of Table 2.2. The latter discussion naturally applies to the case of two-dimensional charge distributions. In two dimensions, however, the electrostatic potential suffers an ambiguity from the infinite length of the structures in that the potential at infinity becomes undefined. The solution is to always calculate the potential of **pairs** of equal and oppositely charged line charges so that the net charge is zero and so that the potential at infinity is exactly zero. Thus, at an observation point a distance r_1 from a positive line charge and a distance r_2 from an equal and opposite line charge, the potential is as given at the end of Table 2.2.

2.2.4 Energy and Force in the Electrostatic Field

The potential function is positive near positive charges, negative near negative charges, and in general tends to zero at infinity. The function is directly related to the energy stored in the electrostatic system. The **self-energy** of a system of charges in their own potential is contained in all of space surrounding the system and is given by:

$$U_e = \frac{1}{2}\int \rho\Phi dv = \frac{1}{2}\int \vec{E}\cdot\vec{D}dv. \qquad (2.21)$$

Thus, for a spherical shell of radius a:

$$U_{shell} = \frac{q^2}{8\pi\varepsilon a}. \qquad (2.22)$$

The *interaction energy* between two systems of charges (a and b) is defined as the potential of charge b integrated over charge a or as the potential of charge a integrated over charge b. The equality of these two expressions is an instance of the **principle of reciprocity**:

$$U_{\text{int}} = \int_{Va}\rho_a\Phi_b dv = \int_{Vb}\rho_b\Phi_a dv = \frac{\varepsilon}{2}\int \vec{E}_a\cdot\vec{E}_b dv. \qquad (2.22)$$

For a monopole in an external field, the interaction energy is then:

$$U = q_a\Phi_b. \qquad (2.23)$$

For an infinitesimal dipole, the interaction energy in the presence of an external field is given by:

$$U = -\vec{p}_a\cdot\vec{E}_b. \qquad (2.24)$$

The total energy of a system is the sum of all these individual energies. These expressions are useful to determine the forces in electrostatic systems in the same way that the potential is useful for obtaining the electric fields of those systems. For any system of charges where the *individual* charges are conserved, that is, *when the flux is constant*, the force is given by the negative gradient of the energy:

$$\vec{F}_{\textbf{const-flux}} = -\nabla U. \qquad (2.25)$$

Similarly, in situations where the forces can lead to rotations of charged structures (e.g., a dipole in an external field), the torque is given by:

$$T_\theta = -\frac{\partial U}{\partial\theta}. \qquad (2.26)$$

When equations 2.23 and 2.25 are applied to a point charge in the presence of the field caused by another point charge, the result is *Coulomb's law*:

$$\vec{F} = q_a\vec{E}_b = \frac{q_a q_b}{4\pi\varepsilon r^2}\hat{r} \quad \text{(Coulomb's law)} \qquad (2.27)$$

By equation 2.26, a dipole in an external field experiences a torque:

$$\vec{T} = \vec{p}\times\vec{E}. \qquad (2.28)$$

2.3 Boundary Conditions and Laplace's Equation

The definition of an electric field as the negative gradient of the electrostatic potential implies that the direction of the electric field at a given point in space is always perpendicular to the local equipotential line (or surface) at that point in space. When the electric field vectors are drawn throughout an electrostatic field, they take on the character of streamlines in a classic fluid flow field. Those lines are called **electric field lines**, and the tube-like volumes formed by bundles of such lines are called Faraday's tubes of electric flux or **lines of force**. The intensity of the electric field is represented by the density of these lines, being greatest where they are closest to each other. The lines of force and the equipotential surfaces form a curvilinear orthogonal coordinate system with important properties. Figure 2.6 illustrates such a system for the case of two line charges.

2.3.1 The Fields of Charged Conductors and the Method of Images

An idealized conductor, also known as a **perfect electric conductor** (PEC), is defined as a material that allows charges to move freely through its body and on its surface so that (a) the charges move to the configuration of least energy and (b) the surface of the conductor is an equipotential. At zero frequency, all conductors behave as perfect conductors because all charges placed or induced upon them have infinite time available to migrate to the surface. Therefore, for the purposes of electrostatics, all conductors are PECs and will be labeled as such in the figures to follow. When the conductor's surface is an equipotential, by the orthogonality of the system of lines described previously, all the electric field lines enter its surface at 90°. Therefore, another definition of a conductor is a statement of a **boundary condition**: a conductor is a surface on which the tangential component of the E field must vanish.

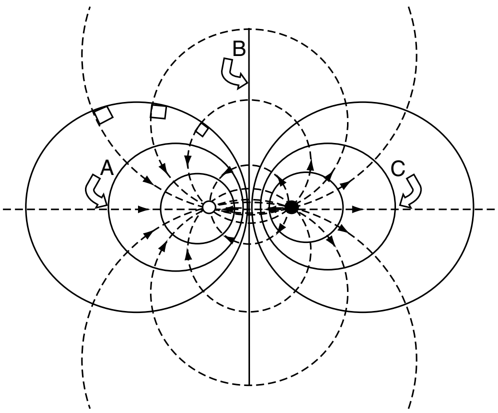

FIGURE 2.6 The Electric Field Lines (dashed) and Equipotentials (solid). These are in a system of two equal and opposite line charges that form a curvilinear orthogonal coordinate system in which the lines intersect each other at 90°.

Because of these properties, a conductor can be slipped into an existing electrostatic field and be left unchanged as long as its surface conforms to an equipotential and it is raised to the same potential level (voltage) as that equipotential relative to infinity (ground). Of course, an arbitrary constant potential can always be added to the entire system without changing the fields. Thus, a system of two line charges, such as the system in Figure 2.6, can also describe a system of one line charge (the black one) in the presence of a grounded PEC cylinder (the circle A in Figure 2.7), of a grounded plane (the symmetry line B in Figure 2.6), inside a grounded cylinder (the circle C in Figure 2.6), or even of the field of two cylindrical conductors raised to different potentials (A and C in Figure 2.6). When a conductor replaces an equipotential surface, all the fields that existed in the space that were replaced, or surrounded, by the conductor vanish. Therefore, the surface of a conductor is a surface across which the normal D field undergoes a jump discontinuity from the value just outside it to zero inside it. Accordingly, by Gauss's law, there must be a surface charge everywhere a D field line terminates on a conductor that is numerically equal to the strength of the D field. Where the lines are crowded closer together, the charge density is greatest. Therefore on the surface of a conductor, the following special boundary conditions hold:

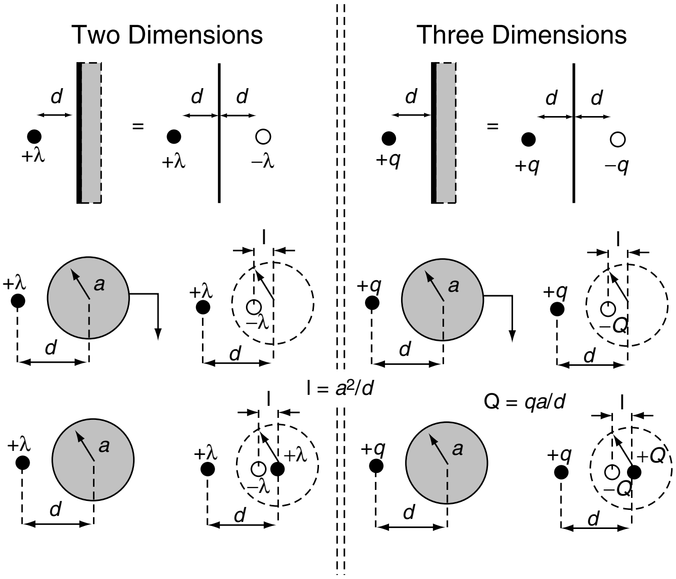

FIGURE 2.7 Image Systems for 2-D and 3-D Charge–Conductor Configurations

$$D_n = \sigma,\ E_{\tan} = 0. \text{ (Boundary conditions on the surface of a conductor)} \qquad (2.29)$$

Problems involving grounded or floating conductors in the presence of sources can be solved by the ***method of images***. In this method, the total field (potential and vector) of a charge in the presence of a PEC object is obtained by finding the position of a fictitious source of appropriate strength that, when combined with the original source, would make the surface of the PEC an equipotential. When the PEC is grounded, there is usually only one oppositely charged image. When the PEC is **floating**, conservation of charge demands that the total charge over its surface remain zero. In that case, the image charges form a dipole. Figure 2.7 summarizes the most common source–conductor–image systems for both two-dimensional and three-dimensional problems.

Note that for the three-dimensional case of a grounded PEC sphere in front of a point charge, the image charge induced on the sphere is smaller than the source charge, whereas in a two-dimensional case the image charge is equal in strength to the source charge. Problems involving combinations of the boundaries shown in Figure 2.7 can be solved by first obtaining the image in one of the boundaries and then reflecting both source and image on the other boundary.

Whenever a two-dimensional configuration of conductor surfaces is not one of the simple planar or cylindrical geometries given in the figures above, they may still be derived from these results through a conformal mapping (Binns *et al.*, 1992).

2.3.2 Laplace's Equation and Boundary Value Problems

Inside any homogeneous region of space, equations 2.2c and 2.16 combine to yield a new equation:

$$\nabla \cdot \vec{E} = \frac{\rho}{\varepsilon} \Rightarrow \nabla \cdot (-\nabla\Phi) = \frac{\rho}{\varepsilon} \Rightarrow \nabla^2\Phi = -\frac{\rho}{\varepsilon}. \qquad (2.30)$$

This last equation is known as **Poisson's equation**. At points in space where there is no charge, it becomes **Laplace's equation**:

$$\nabla^2\Phi = 0 \tag{2.31}$$

The most general method for the solution of electrostatic problems is to solve the partial differential equations (Poisson's or Laplace's) as boundary value problems. Since Poisson's equation is the inhomogeneous version of Laplace's equation, the foundation of all solutions is the solution of Laplace's equation.

Exact solutions only exist for a few coordinate systems; however, these solutions are important both as useful approximations to real problems and as **canonical** problems to use as standards for testing numerical methods of solution. Works by Boyce and DiPrima (1969) and Sommerfeld (1949) are good introductions to the subject, whereas the work by Abramowitz and Stegun (1972) is one of the standard reference handbooks for the functions commonly appearing in boundary value problems. The most common of these problems are those in which the boundaries across which the material properties change either fit Cartesian, cylindrical, or spherical coordinates. Since Laplace's equation is a second-order partial differential equation, two boundary conditions are needed at each boundary to solve the problem in addition to conditions at infinity if the problem space includes the point at infinity.

The first of the two boundary conditions is equation 2.18: the potential must be continuous across every boundary. This condition is equivalent to stating that the tangential E field must be continuous across every boundary. **The second condition is the conservation of flux**, equation 2.8: the jump discontinuity of normal D field across a boundary must equal the free surface charge density on that boundary. In the absence of free boundary charges, this means D_{n} must be continuous across the boundary. **The third boundary condition** is the total field must be regular at infinity.

Solutions by separation of variables in the standard coordinate systems are expressed in the form of a sum of **eigenfunctions** or **Harmonics**. The most common are the following:

- In two-dimensional Cartesian (x,y) coordinates:

$$\Phi = \sum_{n=1}^{\infty}(A_n \sin(\alpha_n x) + B_n \cos(\alpha_n x))(C_n e^{\alpha_n y} + D_n e^{-\alpha_n y}) + K. \tag{2.32}$$

- In two-dimensional cylindrical (r, ϕ) coordinates for z-independent solutions:

$$\Phi = \sum_{n=1}^{\infty}(A_n r^n + B_n r^{-n})(C_n \cos(n\phi) + D_n \sin(n\phi)) + (F \ln r + G)(H\phi + K). \tag{2.33}$$

- In spherical coordinates for azimuthally (ϕ) independent solutions:

$$\Phi = \sum_{n=0}^{\infty}(A_n r^n + B_n r^{-n-1})(C_n P_n(\cos\theta) + D_n Q_n(\sin\theta)) + K. \tag{2.34}$$

In equations 2.32, 2.33, and 2.34, K is a constant, and $P_n(\cos\theta)$ and $Q_n(\cos\theta)$ are the Legendre polynomials of the first and second kind respectively. (Note that the Q_n functions go to infinity on the z-axis, that is $\theta = 0, \pi$).

All solutions in these coordinate systems must be expressible as sums of these harmonics. The method of constructing the solution is (1) assume the solution has the form of the infinite sum, independently, in every region in which the material properties are constant; (2) eliminate the terms in the sums of harmonics that would cause infinities to appear in the given regions; (3) enforce satisfaction of the boundary conditions across every boundary connecting the regions by setting the potentials on either side and the normal D fields equal to each other; and (4) solve for the arbitrary constants. Once the constants are found, according to the **uniqueness theorem**, the solution has been found.

As an example, consider the case of **the dielectric sphere in a uniform field**. A uniform applied field exists in all of space directed along the z direction and of strength E. A material sphere of permittivity ε_1 different from the permittivity ε_2 of the surrounding medium is introduced into the field.

TABLE 2.3 The Boundary Conditions of Electrostatics

The potential function of the original applied field is as written here:

$$\Phi = -Ez = -Er\cos\theta. \tag{2.35}$$

The third boundary condition requires the final total field in region 2 to approach this value as r goes to infinity. The first and second boundary conditions require that:

$$\Phi_1(a,\,\theta) = \Phi_2(a,\,\theta). \tag{2.36a}$$

$$\varepsilon_1\frac{\partial\Phi_1}{\partial r}(a,\,\theta) = \varepsilon_2\frac{\partial\Phi_2}{\partial r}(a,\,\theta). \tag{2.36b}$$

Assuming solutions of the form of equation 2.34 in each region, the results are the following:

$$\Phi_1 = -\frac{3\varepsilon_2}{\varepsilon_1 + 2\varepsilon_2}Er\cos\theta.\ \text{(Inside the sphere)} \tag{2.37a}$$

$$\Phi_2 = -Er\cos\theta + Ea^3\frac{\varepsilon_1 - \varepsilon_2}{\varepsilon_1 + 2\varepsilon_2}\frac{\cos\theta}{r^2}.\ \text{(Outside the sphere)} \tag{2.37b}$$

Two important features of this result are:

(1) The field inside the sphere is a scaled version of the original applied field. It is identical in form but weaker for the case $\varepsilon_1 > \varepsilon_2$ and stronger for the case $\varepsilon_1 < \varepsilon_2$. This is true in general for any ellipsoidal body inserted into a uniform field.

(2) A comparison of equation 1.37b with the far field form of the potential of a dipole in Table 2.2 shows that the external field is a linear superposition of the original applied field and a dipole field. The dielectric sphere has an **induced dipole moment** given by:

$$p = \varepsilon_2 E 4\pi a^3\frac{\varepsilon_1 - \varepsilon_2}{\varepsilon_1 + 2\varepsilon_2}. \tag{2.38}$$

We say that the sphere has been **polarized.** The dipole moment is positive when $\varepsilon_1 > \varepsilon_2$ (e.g., a liquid droplet in air), meaning that the dipole is collinear with the applied field, and is negative for $\varepsilon_1 < \varepsilon_2$ (e.g., a bubble in a liquid), meaning that the dipole moment is antilinear.

The case of a metal sphere can be simulated by setting the permittivity of the sphere equal to infinity. Then the dipole moment is:

$$p = 4\pi a^3\varepsilon_2 E. \tag{2.39}$$

2.3.3 The Connection Between *D, P, E,* and ϵ

In addition to serving as the prototypical example of the boundary value problem for Laplace's equation, this solution of the sphere immersed in the uniform field can be used to show the relationship between the D field and the phenomenon of polarization. The polarization, P, is defined as the dipole moment per unit volume in a dielectric. In the example, the sphere has an induced dipole moment per unit volume given by:

$$\frac{\vec{p}}{(4\pi a^3/3)} = \varepsilon_2\vec{E}\left(3\frac{\varepsilon_1 - \varepsilon_2}{\varepsilon_1 + 2\varepsilon_2}\right) = \vec{P}, \tag{2.40}$$

which has the units of a flux density, like the D field. Now, taking the gradient of equation 2.37a, the D field inside the sphere can be obtained:

$$\vec{D}_1 = -\varepsilon_1\vec{E}_1 = -\varepsilon_1\nabla\Phi_1 = \varepsilon_1\left(\frac{3\varepsilon_2}{\varepsilon_1 + 2\varepsilon_2}\right)\vec{E}. \tag{2.41}$$

It can be shown that:

$$\varepsilon_2\vec{E}_1 + \vec{P} = \vec{D}_1. \tag{2.42}$$

In words: The D field can always be interpreted as the sum of the D field that would be assigned to the region if its material were the same as the external medium (ε_2 in this case) plus a polarization term due to the induced dipole moments arising from the contrast in properties across the boundary of the region.

This statement is true in general even when the dipoles are not induced but intrinsic. **Electrets** are permanently polarized dielectrics in complete analogy to magnets. They are characterized by an internal P. Since P is a flux density, its discontinuity at the faces of an electret has the appearance of surface charges on those faces to external observers. In fact, given any region containing a distribution of P, its electric field E over all of space can be calculated by finding the equivalent charges and replacing the electret by those charges. The charges are found by:

$$\sigma_{\text{equiv}} = \vec{P}\cdot\hat{n} \quad \text{and}\ \rho_{\text{equiv}} = -\nabla\cdot\vec{P}. \tag{2.43}$$

Thus, for a uniformly polarized cylindrical electret found in free space, the total E field can be obtained by replacing the electret with two equivalent surface charge disks at its ends with $\varepsilon = \varepsilon_0$ everywhere. Then, the D field everywhere is obtained by applying equation 2.42.

When in equation 2.42, the permittivity of the surrounding medium is set to that of free space, and the D field only differs from the E field by the polarization P. In particular, if $\vec{D} = \varepsilon_0\vec{E} + \vec{P} = \varepsilon\vec{E}$, a proportionality constant χ can be defined, such that $\vec{P} = \varepsilon_0\chi\vec{E}$. The relative permittivity is given by:

$$\varepsilon_r = \frac{\varepsilon}{\varepsilon_0} = 1 + \chi. \tag{2.44}$$

From the example of the dielectric sphere and equation 2.44, it can be seen that the permittivity function is an expression of the fact that an applied E field induces dipole moments inside material objects. There are two common physical mechanisms for the creation of these induced dipole moments inside matter. The first is the rotation of existing permanently polarized subregions ("dipoles") inside the material into partial alignment with the applied field through the torque of equation 2.28. These subregions can be individual molecules, as in the **polar** molecules of water, or **domains** consisting of thousands of atoms, as in **ferroelectric** ceramics. The second mechanism is the creation of dipoles by charge separation in initially **nonpolar** atoms or molecules. In this case, the electron clouds are pulled in one direction by the E-field, while the positive nuclei are pushed in the opposite direction. Lorrain and Corson (1970), Clemmow (1973), and Bunget and Popescu (1984) provide excellent introductions to the subject of the physics of dielectrics. Work by von Hippel (1995) is the standard engineering reference on dielectric materials.

Table 2.4 gives typical values of the dielectric constant for various materials. It must be emphasized that these values are for electrostatics and will vary dramatically at nonzero frequencies.

2.4 Capacitance

Capacitance is a purely geometric quantity of the form ε times the area through which the flux flows, divided by the distance over which it flows. For instance, a parallel plate capacitor is a structure where two equal metal plates of area A are oppositely charged and brought into close proximity at a distance d from each other. Ignoring the fringing fields the geometric definition just given yields as the capacitance of this structure:

TABLE 2.4 Typical Dielectric Properties of Materials

Gases and liquids		Organic solids		Inorganic solids	
Hydrogen	1.0003	Vaseline	2.2	Quartz	4–5
Air	1.0006	Paraffin	2–2.5	Glass	4–10
Gasoline	1.9	Rubber	3	Mica	5–7
Oils	2.2–4.3	Plexiglass	3.4	Silicon	12
Glycerine	10	Paper	3.7	Rutile TiO_2	89
Ethyl alcohol	28	Wood	2.5–8	Barium titanate $BaTiO_3$	1,200
Distilled water	81	Nylon	8	Barium strontium titanate $2BaTiO_3$: $1SrTiO_3$	10,000

$$C_{par-plate} = \varepsilon\frac{A}{d} \text{ in Farads.} \tag{2.45}$$

Capacitance is a measure of the capacity of a material configuration for storing electrostatic energy.

2.4.1 Capacitance of Various Configurations and Energy

Capacitance is defined as the ratio of the charge stored (or separated) to the potential difference between the conductors. (In the case of only one conductor, the point at infinity serves as the second conductor.) Ignoring fringing in a parallel plate capacitor means the charge distribution is uniform throughout the plates. Since $\sigma = Q/A$, and the D field near a charged plane is $\sigma/2$, the total D field between the two plates is σ. Therefore, E is σ/ε and is practically uniform. The potential difference is then the integral of this nearly uniform E from one plate to the other, or $V = Ed$. Dividing Q by V, the equation 2.45 is obtained.

A pair of concentric spherical shells that are oppositely charged constitutes a spherical capacitor. The inner shell has radius a, and the outer shell has radius b. The capacitance is the following:

$$C_{\text{sph-cap}} = \varepsilon\frac{4\pi ab}{(b-a)}. \tag{2.46}$$

Letting the outer sphere go to infinity, the capacitance of the isolated spherical conductor relative to infinity is obtained:

$$C_{\text{sphere}} = \varepsilon 4\pi a. \tag{2.47}$$

For two-dimensional structures (i.e., structures that are infinitely long along the z-axis), the same method is employed except the charge used in the expression is the charge per unit length, and the resulting capacitance is a capacitance per unit length in Farads per meter (which coincidentally is the same as the units of the permittivity.) Thus, for coaxial cylindrical shells of inner radius a and outer radius b, the result is:

$$C_{cyl-cap} = \varepsilon\frac{2\pi}{\ln\frac{a}{b}}[\text{F/m}]. \tag{2.48}$$

The capacitance of the system is connected to its electrostatic energy by:

$$U_e = \frac{1}{2}CV^2 = \frac{1}{2}\frac{Q^2}{C}. \tag{2.49}$$

The first of these expressions is used in problems where the voltage between the conductors is constant, whereas the second is used when the charge is constant. When the charge is constant, flux is conserved. The force experienced by the system is then:

$$\vec{F}_{\text{const-flux}} = -\nabla U_e. \tag{2.50a}$$

But when voltage is constant, the force equation is:

$$\vec{F}_{\text{const-volt}} = +\nabla U_e. \tag{2.50b}$$

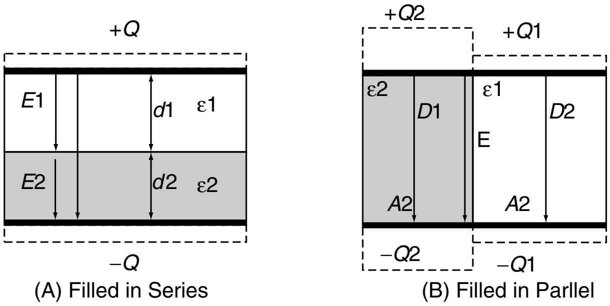
2.4.2 Partially Filled Capacitors

The boundary conditions of continuity of normal D and tangential E allow the determination of the capacitance of capacitors filled with an inhomogeneous dielectric. Consider the parallel plate capacitor filled with two materials. The two basic ways to fill it are shown in Figure 2.9.

Assuming fringing is negligible, the charges on the plates of Figure 2.9(A) are uniformly distributed. In this **series** arrangement, continuity of normal D guarantees that the same uniform D field crosses from the top charges to the bottom charges. Therefore, the E fields in the two regions must be different, with $E_1 = D/\varepsilon_1$ and $E_2 = D/\varepsilon_2$. The total voltage drop from the top plate to the bottom plate is then the sum of the integrals of these or $\text{V} = E_1\text{d}_1 + E_2\text{d}_2 = (D/\varepsilon_1)\text{d}_1 + (D/\varepsilon_2)\text{d}_2$. Because the charge on the plates must be $Q = \sigma A = DA$, the capacitance Q/V is the following:

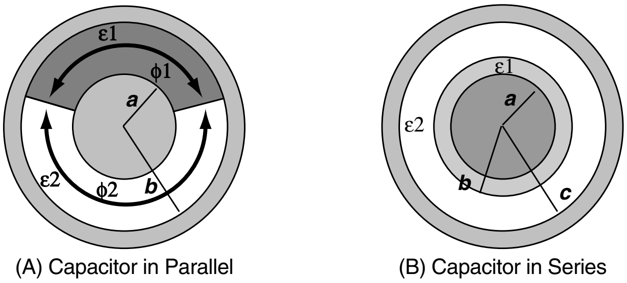
$$C_{\text{series}} = \left(\frac{d_1}{A\varepsilon_1} + \frac{d_2}{A\varepsilon_2}\right)^{-1} = \left(\frac{1}{C_1} + \frac{1}{C_2}\right)^{-1}. \tag{2.51}$$

Note that in this case, the charge (that is the flux) was treated as the constant parameter. For the case of Figure 2.9(B), the voltage difference between the plates is the constant parameter because continuity of tangential E guarantees that the E field is the same everywhere between the plates. As the figure indicates, the charges on the plates are not uniformly distributed. They are denser where the flux density is greater. Now, $E = V/d$, and so the D fields ($D_1 = \varepsilon_1 E$ and $D_2 = \varepsilon_2 E$) are different. The charges Q_1 and Q_2 are given by $Q_1 = D_1 A_1 = \varepsilon_1 V A_1/d$ and $Q_2 = D_2 A_2 = \varepsilon_2 V A_2/d$, so the total capacitance $(Q_1 + Q_2)/V$ is given by:



(A) Filled in Series (B) Filled in Parllel

FIGURE 2.9 A Parallel Capacitor Filled with Two Different Dielectrics. The capacitor can be filled in series or in parallel.



(A) Capacitor in Parallel (B) Capacitor in Series

FIGURE 2.10 Partially Filled Cylindrical Capacitors

$$C_{\text{parallel}} = \frac{\varepsilon_1 A_1}{d} + \frac{\varepsilon_2 A_2}{d} = C_1 + C_2. \tag{2.52}$$

These two fundamental ways of adding dielectric regions inside a capacitor can be used to determine the capacitance of arbitrarily filled capacitors, as long as the path taken by the lines of flux can be recognized. Thus, the partially filled coaxial cylindrical capacitors of Figure 2.10 have the following capacitances **per unit length**

$$C_a = \frac{\phi_1 \varepsilon_1}{\ln(b/a)} + \frac{\phi_2 \varepsilon_2}{\ln(b/a)}. \tag{2.53a}$$

$$C_b = \left(\frac{\ln(b/a)}{2\pi\varepsilon_1} + \frac{\ln(c/b)}{2\pi\varepsilon_2}\right)^{-1}. \tag{2.53b}$$

In a problem involving both series and parallel combinations of regions, a reasonable estimate can be obtained by partitioning the capacitor into individual regions and combining them appropriately.

In general, a partially filled capacitor exerts a force on its dielectric sections. A dielectric plunger partly inserted into a parallel plate capacitor will experience a force that tends to pull it inside the capacitor.

2.4.3 Static Current Fields

There is one more field that obeys all the laws of electrostatics: the static conduction current field. The last divergence equation of equations 2.1c also known as the equation of continuity is a conservation law, just like the equation for the D field. Invoking Ohm's law:

$$\vec{J} = \sigma\vec{E}, \tag{2.54}$$

as the fundamental relationship between the electric field in conducting media and the current density J and specializing to the case of statics, reduces that equation to:

$$\nabla \cdot \vec{J} = \nabla \cdot \sigma\vec{E} = 0. \tag{2.55}$$

In these equations, σ is the conductivity of the material measured in siemens/meter. By the same argument employed in the derivation of equations 2.30 and 2.31, it is seen that the problem of current flow in conducting bodies also satisfies Laplace's equation. This means that replacing D by J and ε by σ translates every solution of Laplace's equation for the electric field in the presence of perfect conductors and dielectric objects into a solution of an equivalent electric current problem involving perfect conductors and conducting objects. The total flux of current density crossing a cross-sectional area is called the current *1* measured in amperes. The **conductance** $G = I/V$, of a system of perfectly conducting electrodes immersed in a system of interconnected conducting regions is the direct analog of the capacitance. Its inverse is the **resistance**, $R = 1/G$, from which the more familiar form of Ohm's law is obtained:

$$V = IR. \tag{2.56}$$

The resistivity in ohm–meters is defined as the inverse of the conductivity: $\rho = 1/\sigma$. Therefore, from equations 2.51 and 2.52 follow the rules for adding resistors in parallel or in series.

Finally, it is pointed out that the power dissipated in a conductor is given by:

$$\int \vec{J} \cdot \vec{E} dv = IV[\mathrm{J/sec}] \text{ or } [\mathrm{w}]. \tag{2.62}$$

Plane Wave Propagation and Reflection

David R. Jackson
Department of Electrical and Computer Engineering, University of Houston, Houston, Texas, USA

3.1 Introduction

Plane waves are the simplest solution of Maxwell's equations in a homogeneous region of space, such as free space (vacuum). In spite of their simplicity, plane waves have played an important role throughout the development of electromagnetics, starting from the time of the earliest radio transmissions through the development of modern communications systems. Plane waves are important for several reasons. First, the far-field radiation from any transmitting antenna has the characteristics of a plane wave sufficiently far from the antenna. The incoming wave field impinging on a receiving antenna can therefore usually be approximated as a plane wave. Second, the exact field radiated by any source in a region of space can be constructed in terms of a continuous spectrum of plane waves via the Fourier transform. Understanding the nature of plane waves is thus important for understanding both the far-field and the exact radiation from sources.

The theory of plane wave reflection from layered media is also a well-developed area, and relatively simple expressions suffice for understanding reflection and transmission effects when layers are present. Problems involving reflections from the earth or sea, for example, are easily treated using plane wave theory. Even when the incident wave front is actually spherical in shape, as from a transmitting antenna, plane wave theory may often be approximately used with accurate results.

This chapter's discussion assumes article that the regions of interest are homogeneous (the material properties are constant) and isotropic, which covers most cases of practical interest.

3.2 Basic Properties of a Plane Wave

3.2.1 Definition of a Plane Wave

The most general definition of a **plane wave** is an electromagnetic field having the form:

$$\boldsymbol{E} = \boldsymbol{E}_0\psi(x, y, z) \tag{3.1}$$

and

$$\boldsymbol{H} = \boldsymbol{H}_0\psi(x, y, z). \tag{3.2}$$

In equations 3.1 and 3.2, $\boldsymbol{E}_0$ and $\boldsymbol{H}_0$ are constant vectors, and the wave function ψ is defined as:

$$\begin{aligned}\psi(x, y, z) &= e^{-j(k_x x + k_y y + k_z z)} \\ &= e^{-j\mathbf{k}\cdot\mathbf{r}},\end{aligned} \tag{3.3}$$

where

$$\boldsymbol{k} = \hat{\boldsymbol{x}}k_x + \hat{\boldsymbol{y}}k_y + \hat{\boldsymbol{z}}k_z = \beta - j\alpha \tag{3.4}$$

$$\boldsymbol{r} = \hat{\boldsymbol{x}}x + \hat{\boldsymbol{y}}y + \hat{\boldsymbol{z}}z. \tag{3.5}$$

The k_x, k_y, and k_z are complex constants that define a wave number vector k. (A time-harmonic dependence of $e^{j\omega t}$ is assumed and suppressed.) The vector $\boldsymbol{E}_0$ defines the polarization of the plane wave. The real and imaginary parts of the wave number vector $\boldsymbol{k}$ define the phase vector $\boldsymbol{\beta}$ and an attenuation vector $\boldsymbol{\alpha}$. The phase vector has units of radians per meter and gives the direction of most rapid phase change, whereas the attenuation vector has units of nepers per meter and gives the direction of most rapid attenuation. The magnitude of the phase vector gives the phase change per unit length along the direction of the phase vector, and the magnitude of the attenuation vector determines the attenuation rate along the direction of the attenuation vector.

Basic Properties

Wave Number Vector

In a homogeneous lossless space, a plane wave must satisfy Maxwell's equations, which in the time-harmonic form are the following (Harrington, 1961):

$$\nabla \times \boldsymbol{H} = j\omega\varepsilon\boldsymbol{E}. \tag{3.6}$$

$$\nabla \times \boldsymbol{E} = -j\omega\mu\boldsymbol{H}. \tag{3.7}$$

$$\nabla \cdot \boldsymbol{E} = \mathbf{0}. \tag{3.8}$$

$$\nabla \cdot \boldsymbol{H} = \mathbf{0}. \tag{3.9}$$

In these equations, ε_c and μ are the permittivity and permeability of the space. For free space, $\varepsilon = \varepsilon_0$ and $\mu = \mu_0$, where μ_0 is defined as $4\pi \times 10^{-7}$ H/m, and ε_0 is determined from the **defined** velocity of light (or any plane wave) in a vacuum (Hayt, 1989): $c = 2.99792458 \times 10^8$ m/sec because $c = 1/\sqrt{\varepsilon_0\mu_0}$. This gives the approximate value $\varepsilon_0 = 8.85418781762039 \times 10^{-12}$ F/m. A lossy medium can be modeled using a complex effective permittivity, accounting for conduction loss and/or polarization loss (Harrington, 1961). The complex effective permittivity is expressed as:

$$\varepsilon = \varepsilon - j\left(\frac{\sigma}{\omega}\right). \tag{3.10}$$

In this equation, ε is the complex permittivity of the material, accounting for polarization loss (if any), and σ is the conductivity of the medium. Henceforth, $\varepsilon_e = \varepsilon' - j\varepsilon''$ will be denoted as ε for simplicity. Therefore, equations (3.6)–(3.9) will remain valid in the general lossy case.

Taking the curl of equation 3.7 and then substituting in equation 3.6 gives the vector wave equation:

$$\nabla \times (\nabla \times \boldsymbol{E}) - k^2\boldsymbol{E} = \mathbf{0}, \tag{3.11}$$

where k is the (possibly complex) **wave number** defined by:

$$k = k' - jk'' = \omega\sqrt{\mu\varepsilon}, \tag{3.12}$$

with the square root chosen so that k lies in the fourth quadrant on the complex plane. The definition of the vector Laplacian is:

$$\nabla^2\boldsymbol{E} \equiv \nabla(\nabla \cdot \boldsymbol{E}) - \nabla \times (\nabla \times \boldsymbol{E}). \tag{3.13}$$

The fact that the divergence of the electric field is zero for a time-harmonic field in a homogeneous region (Harrington, 1961) results in the vector Helmholtz equation:

$$\nabla^2\boldsymbol{E} + k^2\boldsymbol{E} = \mathbf{0}. \tag{3.14}$$

In rectangular coordinates, the vector Laplacian is expressed as:

$$\nabla^2\boldsymbol{E} = \hat{\boldsymbol{x}}\nabla^2E_x + \hat{\boldsymbol{y}}\nabla^2E_y + \hat{\boldsymbol{z}}\nabla^2E_z. \tag{3.15}$$

Hence, all three rectangular components of the electric field satisfy the scalar Helmholtz equation in a homogeneous region:

$$\nabla^2\Psi + k^2\Psi = 0. \tag{3.16}$$

Substituting equation 3.3 into equation 3.16 gives the result:

$$k_x^2 + k_y^2 + k_z^2 = k^2$$

or

$$\boldsymbol{k} \cdot \boldsymbol{k} = k^2. \tag{3.17}$$

This is the **separation equation** that relates the components of the wave number vector $\boldsymbol{k}$ defined in equation 3.4. Note that the term on the left side of equation 3.17 is not in general equal to $|\boldsymbol{k}|^2$, because $\boldsymbol{k}$ may be complex.

Orthogonality of Vectors and Impedance Relations

Other fundamental relations for a plane wave may be found by substituting equations 3.1 and 3.2 into Maxwell's equations 3.6 through 3.9. Noting that $\nabla \to -j\boldsymbol{k}$ for a plane wave, Maxwell's equations reduce to:

$$\boldsymbol{k} \times \boldsymbol{H} = -\omega\varepsilon\boldsymbol{E}. \tag{3.18}$$

$$\boldsymbol{k} \times \boldsymbol{E} = \omega\mu\boldsymbol{H}. \tag{3.19}$$

$$\boldsymbol{k} \cdot \boldsymbol{E} = 0. \tag{3.20}$$

$$\boldsymbol{k} \cdot \boldsymbol{H} = 0. \tag{3.21}$$

Equations 3.18 and 3.19 each imply that $\boldsymbol{E} \cdot \boldsymbol{H} = 0$, and together, they also imply that $\boldsymbol{k} \cdot \boldsymbol{E} = 0$ and $\boldsymbol{k} \cdot \boldsymbol{H} = 0$; that is, all three vectors $\boldsymbol{k}$, $\boldsymbol{E}$, and $\boldsymbol{H}$ are **mutually orthogonal**. Another interesting property that is true for any plane wave, which may be derived directly from equations 3.18, or 3.19, is that:

$$\boldsymbol{E} \cdot \boldsymbol{E} = \eta^2 \boldsymbol{H} \cdot \boldsymbol{H}, \tag{3.22}$$

where η is the **intrinsic impedance** of the space (possibly complex) defined from:

$$\eta = \sqrt{\frac{\mu}{\varepsilon}}. \tag{3.23}$$

The principle branch of the square root is chosen so that the real part of η is non-negative. For a vacuum, the intrinsic impedance is often denoted as η_0 and has a value of approximately 376.7303 Ω.

Power Flow

The complex Poynting vector for a plane wave, giving the **complex power flow**, is (assuming peak notation for phasors):

$$\boldsymbol{S} = \frac{1}{2} \boldsymbol{E} \times \boldsymbol{H}^*. \tag{3.24}$$

Using equation 3.19, the Poynting vector for a plane wave can be written as:

$$\boldsymbol{S} = \frac{1}{2\omega\mu^*} |\Psi|^2 \boldsymbol{E}_0 \times \left(\boldsymbol{k}^* \times \boldsymbol{E}_0^*\right). \tag{3.25}$$

Using the triple product rule $\boldsymbol{A} \times (\boldsymbol{B} \times \boldsymbol{C}) = (\boldsymbol{A} \cdot \boldsymbol{C})\boldsymbol{B} - (\boldsymbol{A} \cdot \boldsymbol{B})\boldsymbol{C}$, this can be rewritten as:

$$\boldsymbol{S} = \frac{1}{2\omega\mu^*} |\Psi|^2 |\boldsymbol{E}_0|^2 \boldsymbol{k}^* - \frac{1}{2\omega\mu^*} |\Psi|^2 (\boldsymbol{E}_0 \cdot \boldsymbol{k}^*) \boldsymbol{E}_0^*. \tag{3.26}$$

The second term in equation 3.26 is not always zero for an arbitrary plane wave, even though $\boldsymbol{E}_0 \cdot \boldsymbol{k} = 0$, since $\boldsymbol{k}$ may be complex in the most general case. If either $\boldsymbol{k}$ or $\boldsymbol{E}_0$ is proportional to a real vector (i.e., all of the components of the vector have the same phase angle), then it is easily demonstrated that the second term vanishes. In this case, the Poynting vector becomes:

$$\boldsymbol{S} = \frac{1}{2\omega\mu^*} |\Psi|^2 |\boldsymbol{E}_0|^2 \boldsymbol{k}^*. \tag{3.27}$$

If the medium is also lossless (μ is real), the time-average power flow (coming from the real part of the complex Poynting vector) is in the direction of the phase vector $\boldsymbol{\beta}$. A similar derivation, casting the Poynting vector in terms of the $\boldsymbol{H}_0$ vector, yields:

$$\boldsymbol{S} = \frac{1}{2\omega\varepsilon} |\Psi|^2 |\boldsymbol{H}_0|^2 \boldsymbol{k}, \tag{3.28}$$

provided either $\boldsymbol{k}$ or $\boldsymbol{H}_0$ is proportional to a real vector. If the region is lossless (ε is real), the time-average power flow is then in the direction of the phase vector. Hence, for a lossless region, the time-average power flow is in the direction of the phase vector $\boldsymbol{\beta}$ if one of the three vectors $\boldsymbol{k}$, $\boldsymbol{E}_0$, or $\boldsymbol{H}_0$ is proportional to a real vector. In many practical cases of interest, one of the three vectors will be proportional to a real vector, and hence, the conclusion will be valid. However, it is always possible to find exceptions, even for free space. One such example is the plane wave defined by the vectors $\boldsymbol{k} = (1, j, 1)$, $\boldsymbol{E}_0 = (2, 1 - 2 - j)$, and $\boldsymbol{H}_0 = (1/(\omega\mu))\,(-2j, 4 + j, 1 - 2j)$ at a frequency $\omega = c$ ($k_0 = 1$). This plane wave satisfies Maxwell's equations 3.18 through 3.21. For this plane wave, however, the vectors $\boldsymbol{\beta}$, $\boldsymbol{\alpha}$, and the power-flow vector $\boldsymbol{p} = \mathrm{Re}(\boldsymbol{S})$ are all in different directions because the power flow is in the direction of the vector (5,0,4). One must then be careful to define what is meant by the "direction of propagation" for such a plane wave.

Direction Angles

One way to characterize a plane wave is through **direction angles** (θ, ϕ) in spherical coordinates. The direction angles (which are in general complex) are defined from the relations:

$$k_x = k \sin\theta \cos\phi. \tag{3.29}$$

$$k_y = k \sin\theta \sin\phi. \tag{3.30}$$

$$k_z = k \cos\theta. \tag{3.31}$$

Homogeneous (Uniform) Plane Wave

One important class of plane waves is the class of **homogeneous** or **uniform** plane waves. A homogeneous plane wave is one for which the direction angles are, by definition, **real**. A homogeneous plane wave enjoys certain special properties that are not true in general for all plane waves. For such a plane wave, the wave number vector can be written as:

$$\boldsymbol{k} = k\hat{\boldsymbol{R}} = \hat{\boldsymbol{R}}(k' - jk''), \tag{3.32}$$

where $\hat{\boldsymbol{R}}$ is a real unit vector defined from:

$$\hat{\boldsymbol{R}} = \hat{\boldsymbol{x}} \sin\theta \cos\phi + \hat{\boldsymbol{y}} \sin\theta \sin\phi + \hat{\boldsymbol{z}} \cos\theta. \tag{3.33}$$

In this case, the $\boldsymbol{k}$ vector is proportional to the real vector $\hat{\boldsymbol{R}}$, so the result of equation 3.27 applies. The unit vector $\hat{\boldsymbol{R}}$ then gives the direction of time-average power flow and also points in the direction of the phase and attenuation vectors. That is, all three vectors point in the same direction for a homogeneous plane wave. This direction is, unambiguously, the direction of propagation of the plane wave. The planes of constant phase are also then the planes of constant amplitude, being the planes perpendicular to the $\hat{\boldsymbol{R}}$ vector. That is, the plane wave has a uniform amplitude across the plane perpendicular to the direction of propagation. If the plane wave is not homogeneous, corresponding to complex direction angles, then the physical interpretation of the direction angles is not clear.

From equations 3.18 or 3.19, it may be easily proven that the fields of a homogeneous plane wave obey the relation:

$$|\boldsymbol{E}| = |\eta||\boldsymbol{H}|. \tag{3.34}$$

(Recall that all plane waves obey equation 3.22 but not in general equation 3.34).

Any homogeneous plane wave can be broken up into a sum of two plane waves, with real electric field vectors to within multiplicative constants polarized perpendicular to each other. This follows from a simple rotation of coordinates (the direction of propagation is then z', with electric field vectors in the x' and y' directions). The two plane waves have the fields (E_x, H_y) and (E_y, H_x), with $E_x/H_y = -E_y/H_x = \eta$. This decomposition is used later in the discussion of polarization.

Lossless Media: Relation Between Phase and Attenuation Vectors

Another important special case for a plane wave concerns a lossless medium, so that $k'' = 0$. If equation 3.4 is substituted into the separation equation 3.17, the imaginary part of this equation immediately yields the relation:

$$\boldsymbol{\beta} \cdot \boldsymbol{\alpha} = 0. \tag{3.35}$$

Hence, for a lossless region, **the phase and attenuation vectors** are always perpendicular. In some applications (e.g., a Fourier transform solution of radiation from an aperture in a ground plane at $z = 0$ or from a planar current source at $z = 0$ [Clemmow, 1996]), a plane wave propagating in a lossless region has the characteristic of that two wave numbers (e.g., k_x and k_y) are real (corresponding to the transform variables). In this case, the third wave number k_z will be real if $k_x^2 + k_y^2 < k^2$ and will be imaginary if $k_x^2 + k_y^2 > k^2$; that is, all transverse wave numbers (k_x, k_y) that lie in a circle of radius k in the wave number plane will be propagating, while all wave numbers outside the circle will be evanescent. In the first case, the power flow is in the direction of the (real) $\boldsymbol{k}$ vector (k_x, k_y, k_z), so power leaves the aperture from this plane wave. In the second case, the power flow is in the direction of the transverse wave number vector $(k_x, k_y, 0)$, so no power leaves the aperture for this plane wave component. If the medium is lossy, there is no sharp distinction between propagating and evanescent plane waves. In this case, all plane waves carry power in the direction of the vector $(k_x, k_y, \mathrm{Re}k_z)$.

Finally, it can be noted that if a homogeneous plane wave is propagating in a lossless region, then the attenuation vector α must be zero, and all wave number components k_x, k_y, and k_z are real.

Summary of Basic Properties

A summary of the basic properties of a plane wave, discussed in the previous subsections, is given in Table 3.1.

3.3 Propagation of a Homogeneous Plane Wave

The case of a homogeneous plane wave is important enough to warrant further attention. Far away from a transmitting antenna, the radiation field always behaves as a homogeneous plane wave (if the spherical wave front is approximated as

TABLE 3.1 Summary of the Basic Properties of a Plane Wave

	Inhomogeneous		Homogeneous	
Property	Lossy	Lossless	Lossy	Lossless
Direction angles	Complex	Complex	Real	Real
Relation between phase and attenuation vectors	$\boldsymbol{\beta} \cdot \boldsymbol{\alpha} = k',\ k''$	$\boldsymbol{\beta} \cdot \boldsymbol{\alpha} = 0$	$\boldsymbol{\beta} \parallel \boldsymbol{\alpha}$	$\boldsymbol{\alpha} = \boldsymbol{0}$
Impedance relations	$\boldsymbol{E} \cdot \boldsymbol{E} = \eta^2 \boldsymbol{H} \cdot \boldsymbol{H}$	$\boldsymbol{E} \cdot \boldsymbol{E} = \eta^2 \boldsymbol{H} \cdot \boldsymbol{H}$	$\boldsymbol{E} \cdot \boldsymbol{E} = \eta^2 \boldsymbol{H} \cdot \boldsymbol{H}$ $\lvert\boldsymbol{E}\rvert = \lvert\eta\rvert\lvert\boldsymbol{H}\rvert$	$\boldsymbol{E} \cdot \boldsymbol{E} = \eta^2 \boldsymbol{H} \cdot \boldsymbol{H}$ $\lvert\boldsymbol{E}\rvert = \eta\lvert\boldsymbol{H}\rvert$
Direction of power flow vector	Not necessarily in $\boldsymbol{\beta}$ direction	$\boldsymbol{\beta}$ If $\boldsymbol{k}$, $\boldsymbol{E}_0$, or $\boldsymbol{H}_0$ is proportional to a real vector	$\boldsymbol{\beta}$	$\boldsymbol{\beta}$
Wave number vector	$\boldsymbol{k} \cdot \boldsymbol{k} = k^2$	$\boldsymbol{k} \cdot \boldsymbol{k} = k^2$	$\boldsymbol{k} \cdot \boldsymbol{k} = k^2$ $\boldsymbol{k} \cdot \boldsymbol{k}^* = \lvert k^2\rvert$	$\boldsymbol{k} \cdot \boldsymbol{k} = k^2$ $\boldsymbol{k} \cdot \boldsymbol{k}^* = k^2$
Orthogonality of vectors	$\boldsymbol{E} \cdot \boldsymbol{H} = 0$ $\boldsymbol{E} \cdot \boldsymbol{k} = 0$ $\boldsymbol{H} \cdot \boldsymbol{k} = 0$	$\boldsymbol{E} \cdot \boldsymbol{H} = 0$ $\boldsymbol{E} \cdot \boldsymbol{k} = 0$ $\boldsymbol{H} \cdot \boldsymbol{k} = 0$	$\boldsymbol{E} \cdot \boldsymbol{H} = 0$ $\boldsymbol{E} \cdot \boldsymbol{k} = 0$ $\boldsymbol{H} \cdot \boldsymbol{k} = 0$	$\boldsymbol{E} \cdot \boldsymbol{H} = 0$ $\boldsymbol{E} \cdot \boldsymbol{k} = 0$ $\boldsymbol{H} \cdot \boldsymbol{k} = 0$

planar). As mentioned, a homogeneous plane wave propagates with real direction angles in space, with a direction of propagation described by a real unit vector. By a suitable rotation of coordinate axis, the direction of propagation may be assumed to be along the z-axis. Furthermore, the plane wave can always be represented as a sum of two separate plane waves, one with the electric field polarized in the x direction and the other polarized in the y direction. Considering the wave polarized in the x direction, the fields are as follows:

$$E_x = E_0 e^{-jkz}. \tag{3.36}$$

$$H_y = \frac{E_0}{\eta} e^{-jkz}. \tag{3.37}$$

The wave number k and the intrinsic impedance η of the space are given by equations 3.12 and 3.23, respectively.

3.3.1 Wavelength, Phase Velocity, and Group Velocity

The **wavelength** λ is defined at the distance required for the plane wave to change phase by 2π radians and is given by:

$$\lambda = \frac{2\pi}{k}. \tag{3.38}$$

The **phase velocity** of the plane wave is defined as the velocity at which a point of constant phase travels (such as the crest of the wave where the electric field is the maximum). The phase velocity is given by:

$$v_p = \frac{\omega}{k'} = \frac{\omega}{\mathrm{Re}\left(\omega\sqrt{\mu\varepsilon}\right)}. \tag{3.39}$$

If the permittivity ε is not a function of frequency (true for a vacuum and often approximately true for nonconducting media over a certain frequency range), then the phase velocity is constant with frequency (the plane wave propagates without dispersion). For a vacuum, the phase velocity is $c = 2.99792458 \times 10^8$ m/sec. The group velocity (velocity of energy flow and often a good approximation to the velocity of signal propagation [Collin, 1991], is given by:

$$v_g = \frac{d\omega}{dk'} = \frac{1}{\frac{d}{d\omega}\mathrm{Re}\left(\omega\sqrt{\mu\varepsilon}\right)}. \tag{3.40}$$

For a nondispersive lossless media (constant real-valued permittivity), the group velocity is equal to the phase velocity, and both are equal to:

$$v_p = v_g = \frac{1}{\sqrt{\mu\varepsilon}}. \tag{3.41}$$

3.3.2 Depth of Penetration (Skin Depth)

For a lossy medium, the plane wave decays as it propagates because $k'' > 0$. The **depth of penetration**, d_p, is defined as the distance required to reduce the field level by a factor of $e \approx 2.71828$, so the field is 36.788% of the starting value (the power is reduced by a factor of e^2 or is at a level of 13.534% of the starting value). The depth of penetration is given as:

$$d_p = \frac{1}{k''} = \frac{-1}{\mathrm{Im}(\omega\sqrt{\mu\varepsilon})}. \tag{3.42}$$

The permittivity is complex for lossy media and is represented by equation 3.10. Special cases are of particular interest. For low-loss media, $\varepsilon'' \ll \varepsilon'$, a simple binomial approximation of the square root in equation 3.42 gives:

$$d_p = \frac{1}{k''} \approx \frac{1}{0.5\, k' \tan\delta}, \tag{3.43}$$

where the following is true:

$$k' \approx \omega\sqrt{\mu\varepsilon'}, \tag{3.44}$$

and the loss tangent is defined as:

$$\tan\delta = \frac{\varepsilon''}{\varepsilon'}. \tag{3.45}$$

If the loss is purely due to medium conductivity (no polarization loss so that $\varepsilon_c = \varepsilon'$ is a real number), the penetration depth formula 3.43 for the low-loss case becomes:

$$d_p \approx \frac{2}{\sigma}\sqrt{\frac{\varepsilon'}{\mu}}. \tag{3.46}$$

For a highly lossy medium, $\varepsilon' \ll \varepsilon''$, in which case:

$$k' \approx k'' \approx \omega\sqrt{\frac{\mu\varepsilon''}{2}}. \tag{3.47}$$

For a good conductor, the conductivity is very large, and $\varepsilon'' \approx \sigma/\omega$ from equation 3.10. In this case, the penetration depth is more commonly referred to as the **skin depth** δ because the value may be very small. (There is no relation to the δ symbol appearing in the loss tangent symbol.) For a good conductor:

$$\delta = d_p \approx \sqrt{\frac{2}{\omega\mu\sigma}}. \tag{3.48}$$

For pure copper ($\sigma = 5.8 \times 10^7$ S/m, $\mu \approx \mu_0$) at 2.45 GHz, $\delta = 1.335\ \mu$m.

Whether a particular material falls into the low-loss or highly lossy categories may depend on frequency. For example, consider typical seawater, which has roughly $\varepsilon_r = 78$ (ignoring polarization losses) and $\sigma = 4.0\,\text{S/m}$. (In actuality, polarization loss also becomes important at microwave and higher frequencies.) Table 3.2 shows the loss tangent versus frequency. The loss tangent is on the order of unity at microwave frequencies. For much lower frequencies the seawater is highly lossy; for much higher frequencies, it is a low-loss media. Note that the depth of penetration continues to decrease as the frequency is raised, even though the medium becomes more of a low-loss material at higher frequencies according to the definition used (a low-loss tangent). At low frequencies, the penetration depth is increasing inversely as the square root of frequency according to equation 3.48. At high frequencies, the penetration depth approaches a constant according to equation 3.46.

3.3.3 Summary of Homogeneous Plane Wave Properties

A summary of the properties relating to wavelength, velocity, and depth of penetration for a homogeneous plane wave is given in Table 3.3.

3.3.4 Polarization

The previous discussion assumed a homogeneous plane wave propagating in the z direction, polarized with the electric field in the x direction. The most general polarization of a wave propagating in the z direction is one having both x and y components of the field:

TABLE 3.2 Loss Tangent and Penetration Depth for Typical Seawater Versus Frequency

$$\boldsymbol{E} = \left(\hat{\boldsymbol{x}}E_{x0} + \hat{\boldsymbol{y}}E_{y0}\right)e^{-j(kz)}. \tag{3.49}$$

The field components are represented in polar form as:

$$E_{x0} = |E_{x0}|e^{j\phi_x}. \tag{3.50}$$

$$E_{y0} = |E_{y0}|e^{j\phi_y}. \tag{3.51}$$

The phase difference between the two components is defined as:

$$\phi = \phi_y - \phi_x. \tag{3.52}$$

Without any real loss of generality, ϕ_x may be chosen as zero, so that $\phi = \phi_y$. In the time domain, the field components are then:

$$\varepsilon_x = |E_{x0}|\cos(\omega t) \tag{3.53}$$

$$\varepsilon_y = |E_{y0}|\cos(\omega t + \phi). \tag{3.54}$$

Using trigonometric identities, equation 3.54 may be expanded into a sum of $\sin(\omega t)$ and $\cos(\omega t)$ functions, and then equation 3.53 may be used to put both $\cos(\omega t)$ and $\sin(\omega t)$ in terms of ε_x (using $\sin^2 = 1 - \cos^2$). After simplification, the result is as follows:

$$A\varepsilon_x^2 + B\varepsilon_x\varepsilon_y + C\varepsilon_y^2 = D, \tag{3.55}$$

where the following holds:

$$A = \left|\frac{E_{y0}}{E_{x0}}\right|^2. \tag{3.56}$$

$$B = -2\left|\frac{E_{y0}}{E_{x0}}\right|\cos\phi. \tag{3.57}$$

$$C = 1. \tag{3.58}$$

$$D = |E_{y0}|^2\sin^2\phi. \tag{3.59}$$

After simplification, the discriminant of this quadratic curve is:

$$\Delta = B^2 - 4AC = -4\left|\frac{E_{y0}}{E_{x0}}\right|^2\sin^2\phi, \tag{3.60}$$

which is always negative. This curve thus always represents an ellipse. The general form of the ellipse is shown in Figure 3.1. The tilt angle of the ellipse is τ, and the **axial ratio** (AR) is defined as the ratio of the major axis of the ellipse to the

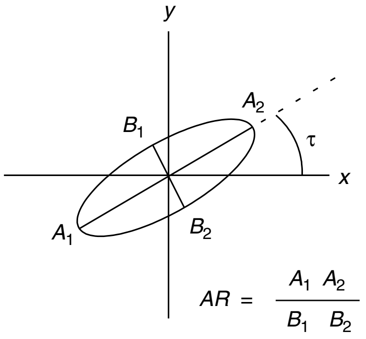

FIGURE 3.1 Geometry of the Polarization Ellipse

minor axis (AR ≥ 1). In the time domain, the electric field vector rotates with the tip of the vector lying on the ellipse. **Right-handed elliptical polarization** (RHEP) corresponds to counterclockwise rotation (the thumb of the right hand aligns with the direction of propagation, and the fingers of the right hand align with the direction of rotation in time; this is the IEEE definition, which is opposite to the usual optics convention.) LHEP corresponds to rotation in the opposite direction.

A convenient way to represent the polarization state is with the Poincaré sphere (Kraus, 1988). Using spherical trigonometric relations, the following results may be derived for the tilt angle of the ellipse and the axial ratio:

$$\tan 2\tau = \tan 2\gamma \cos\phi, \tag{3.61}$$

$$\sin 2\xi = \sin 2\gamma \sin\phi. \tag{3.62}$$

The parameter ξ is related to the axial ratio as:

$$\xi = \cot^{-1}(\pm AR), \quad -45^\circ \leq \xi \leq +45^\circ.$$
$$+\text{for LHEP} \tag{3.63}$$
$$-\text{for RHEP}$$

The phase angle ϕ is defined in equation 3.52. The parameter γ characterizes the ratio of the fields along the x- and y-axes, and is defined from:

$$\gamma = \tan^{-1}\left|\frac{E_{y0}}{E_{x0}}\right|. \tag{3.64}$$

There is no ambiguity in equation 3.62 for ξ because $-90^\circ \leq 2\xi \leq +90^\circ$. Equation 3.61, however, gives an ambiguity for τ because adding multiples of 180° does not change the tangent. To resolve this ambiguity, Table 3.4 may be used to determine the appropriate quadrant (1, 2, 3, or 4) the angle 2τ is in based on the Poincaré sphere (Kraus, 1988).

The following special cases are important.

(1) **Linear polarization**: $\phi = 0$ or 180°, or either E_{x0} or E_{y0} is zero.

TABLE 3.4 Quadrant Containing the Angle 2τ

	$\cos\phi > 0$	$\cos\phi < 0$
$\cos 2\gamma > 0$	1	4
$\cos 2\gamma < 0$	2	3

In this case, AR = ∞ (the ellipse degenerates to a straight line).

(2) **Circular polarization:** $E_{y0} = E_{x0}$ and $\phi = \pm 90^\circ$ (to within any multiple of 180°).

In this case, the ellipse becomes a circle (either RHCP or LHCP), and AR = 1.

It can also be noted that a wave of arbitrary polarization can be represented as a sum of RHCP and LHCP waves, by noting that the arbitrarily polarized wave in equation 3.49 can be written as:

$$\boldsymbol{E} = \hat{\boldsymbol{r}}\left[\frac{1}{\sqrt{2}}(E_{x0} + jE_{y0})\right] + \hat{\boldsymbol{l}}\left[\frac{1}{\sqrt{2}}(E_{x0} - jE_{y0})\right], \tag{3.65}$$

where the unit-amplitude RHCP and LHCP waves are the following:

$$\hat{\boldsymbol{r}} = \frac{1}{\sqrt{2}}(\hat{\boldsymbol{x}} - j\hat{\boldsymbol{y}})e^{-jkz}. \tag{3.66}$$

$$\hat{\boldsymbol{l}} = \frac{1}{\sqrt{2}}(\hat{\boldsymbol{x}} + j\hat{\boldsymbol{y}})e^{-jkz}. \tag{3.67}$$

3.4 Plane Wave Reflection and Transmission

A general plane wave **reflection and transmission problem** consists of an incident plane wave impinging on a multilayer structure, as shown in Figure 3.2. An important special case is the two-region problem shown in Figure 3.3. The incident plane wave may be either homogeneous or inhomogeneous, and any of the regions may have an arbitrary amount of loss. The vector representing the direction of propagation for the incident wave in Figures 3.2 and 3.3 is a real vector (as shown) if the incident wave is homogeneous, but the analysis is valid for the general case.

The key to obtaining a simple solution to such reflection and transmission problems is the use of a transmission line model of the layered structured, which is based on TE–TM decomposition of the plane waves, discussed next.

3.4.1 Transverse Electric and Transverse Magnetic Decomposition

According to a basic electromagnetic theorem (Harrington, 1961) the fields in a source-free homogeneous region can be

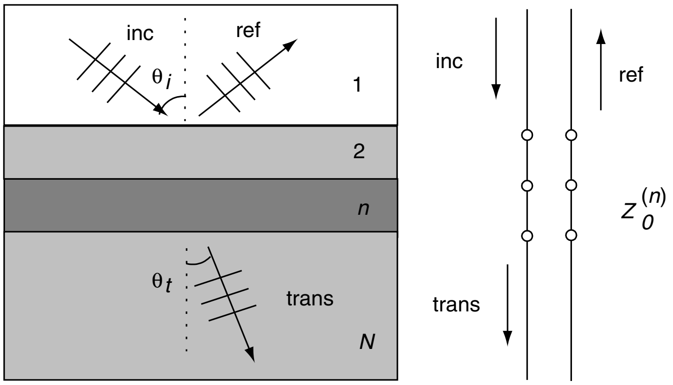

FIGURE 3.2 A Plane Wave Reflecting from a Multilayer Stack of Different Materials. Each layer has a uniform (constant) set of material parameters. On the right side, the equivalent transmission-line model (transverse equivalent network) is shown.

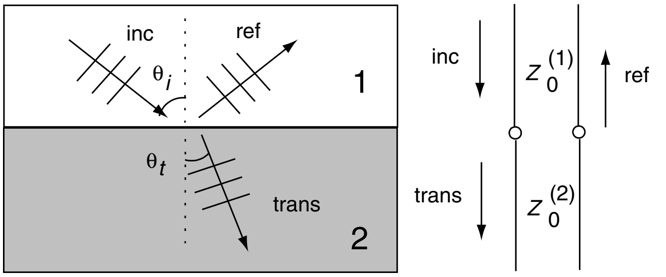

FIGURE 3.3 Reflection and Transmission from a Single Interface Between Two Different Media. The transmission-line model (transverse equivalent network) for the two-region reflection problem is shown on the right.

represented as the sum of two types of fields: a field that is **transverse magnetic** to z (TM$_z$) and a field that is **transverse electric** to z (TE$_z$). The TM$_z$ field has $\mathrm{H}_z = 0$, and the TE$_z$ field by definition has $\mathrm{E}_z = 0$. A general plane wave field may therefore be written as the sum of a TM$_z$ plane wave and a TE$_z$ plane wave. In free space, the direction z is rather arbitrary. When a layered media is present, the preferred direction z is perpendicular to the layers because this allows for the TM$_z$ and TE$_z$ plane waves in each region to be modeled independently as waves on a transmission line. Standard transmission-line theory may then be conveniently used to solve plane wave reflection and transmission problems in a relatively simple manner, without having to solve the electromagnetic boundary-value problem of matching fields at the interfaces. The TM$_z$ plane wave is commonly referred to as one that is polarized with the electric field "in the place of incidence," whereas the TE$_z$ place wave is polarized with the electric field "perpendicular to the plane of incidence." (The plane of incidence is the $y-z$ plane.) For a homogeneous plane wave with an incident wave vector in the $y-z$ plane, the polarizations are shown in Figure 3.4.

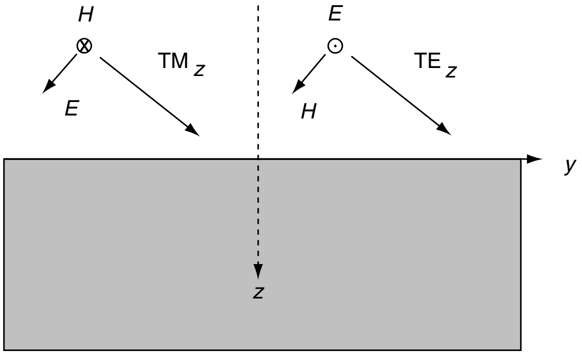

FIGURE 3.4 Polarizations of Incident TM$_z$ and TE$_z$ Plane Waves

The field components may be found by using Maxwell's equations to write the transverse (x and y) field components in terms of the longitudinal components E_z and H_z. The nonzero longitudinal component is assumed to be proportional to the wave function:

$$\psi = \exp\big(-j(k_x x + k_y y \pm k_z z)\big). \tag{3.68}$$

The plus sign in this equation is chosen for plane waves propagating or decaying in the positive z direction, while the negative sign is for propagation or decay in the minus z direction. This representation is convenient for plane wave reflection problems, since the characteristic impedance of a transmission line that models a particular region will then have a positive characteristic impedance for both upward and downward propagating plane waves, in agreement with the usual transmission line convention.

For the TM$_z$ plane wave, the normalized field components may then be written as:

$$\begin{aligned} &E_x = \mu\ k_x k_z \Psi(x, y, z). && H_x = \omega\varepsilon\ k_y \Psi(x, y, z). \\ &E_y = \mu\ k_y k_z \Psi(x, y, z). && H_y = -\omega\varepsilon\ k_x \Psi(x, y, z). \\ &E_z = (k^2 - k_z^2)\Psi(x, y, z). && H_z = 0. \end{aligned} \tag{3.69}$$

For a TE$_z$, plane wave the corresponding results are the following:

$$\begin{aligned} &E_x = -\omega\mu\ k_y \Psi(x, y, z). && H_x = \mu\ k_x k_z \Psi(x, y, z). \\ &E_y = \omega\mu\ k_x \Psi(x, y, z). && H_y = \mu\ k_y k_z \Psi(x, y, z). \\ &E_z = 0. && H_z = (k^2 - k_z^2)\Psi(x, y, z). \end{aligned} \tag{3.70}$$

Note that a plane wave propagating in the z direction ($k_z = k$) has both longitudinal field components that are zero. Such a plane wave is transverse electric and magnetic (TEM) to the z direction.

It may be seen from the above equations that the transverse fields obey the relations:

$$\boldsymbol{E}_t^{TM} = \mu Z_0^{TM}(\hat{\boldsymbol{z}} \times \boldsymbol{H}_t^{TM}), \tag{3.71}$$

and

$$\boldsymbol{E}_t^{TE} = \mu Z_0^{TE}(\hat{\boldsymbol{z}} \times \boldsymbol{H}_t^{TE}), \tag{3.72}$$

where the following equations apply:

$$Z_0^{TM} = \frac{k_z}{\omega\varepsilon}. \tag{3.73}$$

$$Z_0^{TE} = \frac{\omega\mu}{k_z}. \tag{3.74}$$

3.4.2 Transverse Equivalent Network

From the equations 3.71 and 3.76, the transverse (perpendicular to z) field components behave as voltages and currents on a transmission line model called the **transverse equivalent network**. In particular, the correspondence is given through the relations ($i =$ TM or TE):

$$\boldsymbol{E}_t^i = \hat{\boldsymbol{e}}\psi_t(x, y)V^i(z). \tag{3.75}$$

$$\boldsymbol{H}_t^i = \hat{\boldsymbol{h}}\psi_t(x, y)I^i(z). \tag{3.76}$$

In these equations, the unit vectors are chosen so that:

$$\hat{\boldsymbol{e}} \times \hat{\boldsymbol{h}} = \pm\hat{\boldsymbol{z}}, \tag{3.77}$$

for a plane wave propagating in the $\pm\hat{\boldsymbol{z}}$ direction. The transverse wave function is written as:

$$\psi_t(x, y) = e^{-j(k_x x + k_y y)}, \tag{3.78}$$

which is a common transverse phase term that must be the same for all regions (if the transverse wave numbers k_x or k_y were different between two regions, a matching of transverse fields at the boundary would not be possible). The fact that the transverse wave numbers are the same in all regions leads to the **law of reflection** that states the direction angle θ for a reflected plane wave must equal the direction angle for the incident plane wave. This fact also leads to Snell's law that states the direction angles θ inside each of the regions are related to each other, through the following:

$$n_i \sin\theta_i = n_1 \sin\theta_1 \text{ and } i = 1, 2, \ldots\ N, \tag{3.79}$$

where n_i is the index of refraction (possibly complex) of region i, defined as $n_i = k_i/k_0 = \sqrt{\varepsilon_{ri}\mu_{ri}}$. It is often convenient to express the characteristic impedance for region i from equations 3.73 and 3.74 in terms of the medium intrinsic impedance η_i as:

$$Z_0^{TM} = \eta_i \cos\theta_i, \tag{3.80}$$

$$Z_0^{TE} = \eta_i \sec\theta_i. \tag{3.81}$$

Using Snell's law, the impedances then become:

$$Z_0^{TM} = \eta_i\sqrt{1 - \left(\frac{n_1}{n_i}\right)^2 \sin^2\theta_1}. \tag{3.82}$$

$$Z_0^{TE} = \frac{\eta_i}{\sqrt{1 - \left(\frac{n_1}{n_i}\right)^2 \sin^2\theta_1}} \tag{3.83}$$

The above expressions remain valid for lossy media. The square roots are chosen so that the real part of the characteristic impedances are positive.

The functions $V(z)$ and $I(z)$ behave as voltage and current on a transmission line, with characteristic impedance Z_0^{TM} or Z_0^{TE}, depending on the case. Hence, any plane wave reflection and transmission problem reduces to a transmission line problem, giving the exact solution that satisfies all boundary conditions. One consequence of this is that TM$_z$ and TE$_z$ plane waves do not couple at a boundary. If the incident plane wave is TM$_z$, for example, the waves in all regions will remain TM$_z$ plane waves. Hence, this situation creates the motivation for the TM$_z$−TE$_z$ decomposition. The transverse equivalent network for the multilayer and two-region problems are shown on the right sides of Figures 3.2 and 3.3, respectively. The network model is the same for either TM$_z$ or TE$_z$ polarization, except that the characteristic impedances are different. If an incident plane wave is a combination of both TM$_z$ and TE$_z$ waves, the two parts are solved separately and then summed to get the total reflected or transmitted field.

3.4.3 Special Case: Two-Region Problem

For the simple **two-region problem** of Figure 3.3, the reflected and transmitted voltages (modeling the transverse electric fields) are represented as:

$$V^{\text{ref}}(z) = \Gamma V^{\text{inc}}(0)e^{+jk_z^{(1)}z} \tag{3.84}$$

and

$$V^{\text{trans}}(z) = TV^{\text{inc}}(0)e^{-jk_z^{(2)}z}, \tag{3.85}$$

where the reflection and transmission coefficients are given by the standard transmission line equations:

$$\Gamma = \frac{Z_0^{(2)} - Z_0^{(1)}}{Z_0^{(2)} + Z_0^{(1)}}. \tag{3.86}$$

$$T = 1 + \Gamma. \tag{3.87}$$

Note that a plus sign is used in the exponent of equation 3.84 to account for upward propagation of the reflected wave.

Critical Angle

If regions 1 and 2 are lossless, and region 1 is more dense than region $2 (n_1 > n_2)$, an incident angle $\theta_1 = \theta_c$ will exist for which $k_z^{(2)} = 0$. From Snell's law, this **critical angle** is the following:

$$\theta_c = \sin^{-1}\left(\frac{n_2}{n_1}\right). \tag{3.88}$$

When $\theta_1 > \theta_c$, the wave number $k_z^{(2)}$ will be purely imaginary, of the form $k_z^{(2)} = -j\alpha_z^{(2)}$. In this case, there is no power flow into the second region because the phase vector in region 2 has no z component. In this case, 100% of the incident power is reflected back from the interface. There are, however, fields still present in region 2, decaying exponentially with distance z. In region 2, the power flow is in the horizontal direction only.

Brewster Angle

For lossless layers, it is possible to have 100% of the incident power transmitted into region 2 with no reflection. This corresponds to a matched transmission line circuit, with:

$$Z_0^{(1)} = Z_0^{(2)}. \tag{3.89}$$

For nonmagnetic layers, it may be easily shown that this matching equation can only be satisfied in the TM$_z$ case (there is always a nonzero reflection coefficient in the TE$_z$ case, unless the trivial case of identical medium is considered). The angle θ_b, at which no reflection occurs, is called the **Brewster angle**. For the TM$_z$ case, a simple algebraic manipulation of equation 3.89 yields the result:

$$\tan\theta_b = \sqrt{\frac{\varepsilon_2}{\varepsilon_1}}. \tag{3.90}$$

3.4.4 Orthogonality

When treating reflection problems, there is more than one plane wave in at least one of the regions: a wave traveling in the positive z direction (focusing on the z variation) and a wave traveling in the negative z direction. Often, calculating power flow in such a region is desired. For a single plane wave, the complex power density in the z direction (the z component of the complex Poynting vector) is equal to the complex power flowing on the corresponding transmission line of the transverse equivalent network. When both an incident and a reflected wave are present, or both TM$_z$ and TE$_z$ waves are present, the following orthogonality results are useful. These theorems related to power flow in the z direction may be proven by direct calculation using the field components in rectangular coordinates.

1. An **orthogonality** exists between a homogeneous TM$_z$ plane wave and a homogeneous TE$_z$ plane wave propagating in the same direction in the sense that the complex power density in the z direction, S_z, is the sum of the two complex power densities S_{1z} and S_{2z}. This is true for a lossy or lossless media.

2. An **orthogonality** exists between an incident wave and a reflected wave in a lossless medium (both are either TE$_z$ or TM$_z$), provided the wave number component k_z of the two waves is real. The two waves are orthogonal in the sense that the time-average power density in the z direction, ReS_z, is the sum of the two time-average power densities ReS_{1z} and ReS_{2z}.

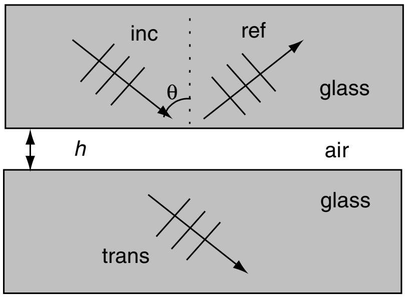

FIGURE 3.5 An Incident Wave Traveling in a Semi-Infinite Region of Lossless Glass. The wave impinges on an air gap separating the glass region from an identical region below. Incident, reflected, and transmitted plane waves are shown.

To illustrate the second orthogonality property, consider an incident plane wave traveling in a glass region, impinging on an air gap that separates the glass region from another identical glass region, as shown in Figure 3.5.

If the incident plane wave is beyond the critical angle, the plane waves in the air region will be evanescent with an imaginary vertical wave number k_z. Each of the two plane waves in the air region (upward and downward) that constitute a standing wave field do not, individually, have a time-average power flow in the z direction because k_z is imaginary. There is an overall power flow in the z direction inside the air region, however, because there is a transmitted field in the lower region. The total power flow in the z direction is thus not the sum of the two individual power flows. The two waves in the air region are not orthogonal, and the second orthogonal property does not apply since the wave number k_z is not real.

3.5 Example: Reflection of an RHCP Wave

An RHCP plane wave at a frequency of 1.0 GHz is incident on the surface of the ocean at an angle of $\theta = 30^\circ$. Determine the percentage of power that is reflected from the ocean, and characterize the polarization of the reflected wave (axial ratio, tilt angle, and handedness). In addition, determine the field of the inhomogeneous transmitted plane wave. The parameters of the ocean water are assumed to be $\varepsilon' = 78$ (ignoring polarization loss) and $\sigma = 4$ S/m.

3.5.1 Solution

The geometry of the incident and reflected waves is shown in Figure 3.6. The incident plane wave is represented as:

$$\boldsymbol{E}^{\text{inc}} = E_0[\hat{\boldsymbol{x}} + \hat{\boldsymbol{u}}(-j)]e^{-j(k_y y + k_{z|} z)}, \tag{3.91}$$

where the following equations apply:

$$k_y = k_0 \sin\theta = \frac{1}{2} k_0. \tag{3.92}$$

$$k_{z1} = k_0 \cos\theta = \frac{\sqrt{3}}{2} k_0. \tag{3.93}$$

$$\hat{\boldsymbol{u}} = \hat{\boldsymbol{y}} \cos\theta - \hat{\boldsymbol{z}} \sin\theta. \tag{3.94}$$

The reflected wave is represented as:

$$\boldsymbol{E}^{\text{ref}} = E_0[A\hat{\boldsymbol{x}} + B\hat{\boldsymbol{v}}]e^{-j(k_y y - k_{z1} z)}, \tag{3.95}$$

where:

$$\hat{\boldsymbol{v}} = -\hat{\boldsymbol{y}} \cos\theta - \hat{\boldsymbol{z}} \sin\theta. \tag{3.96}$$

The x component of the incident and reflected waves corresponds to TE$_z$ waves, whereas the u and v components correspond to TM$_z$ waves. (The u and v directions substitute for the y direction in the previous discussion on polarization.) The transverse equivalent network is shown in Figure 3.3. From equations 3.82 and 3.83, the impedances are $Z_1^{TM} = 326.258\Omega$, $Z_1^{TE} = 435.011\Omega$, $Z_2^{TM} = 34.051 + j(13.269)\Omega$, and $Z_2^{TE} = 34.089 + j(13.346)\Omega$. The reflection coefficients are then $\Gamma^{TM} = -0.808535 + j(0.066600)$ and $\Gamma^{TE} = -0.853161 + j(0.052724)$.

The coefficient A in equation 3.95 is determined directly from:

$$A = \Gamma^{TE} = -0.853161 + j(0.052724). \tag{3.97}$$

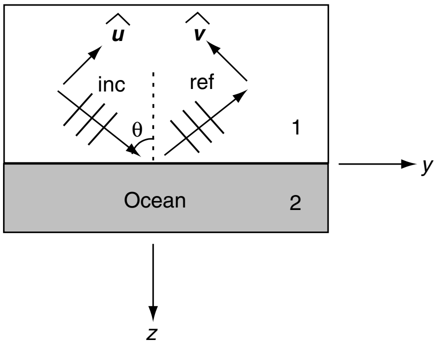

FIGURE 3.6 Geometry that Defines the Coordinate System for the Example of a Plane Wave Reflecting from the Surface of the Ocean

To determine the coefficient B, recall that the voltages in the transverse equivalent network model only the transverse (horizontal) component of the electric field (the y component in the TM case). Hence, the following equation results:

$$-BE_0 \cos\theta^{\text{ref}} = \Gamma^{TM} E_0(-j)\cos\theta^{\text{inc}}. \tag{3.98}$$

Since $\theta^{\text{inc}} = \theta^{\text{ref}} = \theta$, B is determined directly as:

$$B = \Gamma^{TM}(j) = -0.066600 - j(0.808535). \tag{3.99}$$

The percent power reflected is calculated from:

$$P_{\%}^{\text{ref}} = 100\left(\frac{\frac{1}{2}\left[\frac{|A|^2}{Z_1^{TE}} + \frac{|B\cos\theta|^2}{Z_1^{TM}}\right]}{\frac{1}{2}\left[\frac{1}{Z_1^{TE}} + \frac{|-j\cos\theta|^2}{Z_1^{TM}}\right]}\right), \tag{3.100}$$

which yields:

$$P_{\%}^{\text{ref}} = 69.441. \tag{3.101}$$

Hence, 30.559% of the incident power is transmitted into the ocean.

The phase angle between the v and x components of the reflected field is as written here:

$$\phi = \angle B - \angle A = 88.827^\circ. \tag{3.102}$$

Hence, the reflected wave is a left-handed elliptically polarized wave.

The parameter γ is determined from the ratio of the magnitudes of the v and x components of the reflected field as:

$$\gamma = \tan^{-1}\left(\frac{|B|}{|A|}\right) = 43.504^\circ. \tag{3.103}$$

From the formulas in the polarization section, Subsection 3.34, the tilt angle τ of the polarization ellipse from the x-axis (toward the positive v-axis) is then:

$$\tau = 10.690^\circ, \tag{3.104}$$

and the polarization parameter ξ is the following:

$$\xi = 43.393^\circ. \tag{3.105}$$

The axial ratio of the reflected wave is then:

$$AR = +\cot\xi = 1.058. \tag{3.106}$$

The reflected wave is nearly CP because the ocean is highly reflecting (if the ocean were replaced by a perfect conductor, the reflected wave would be LHCP).

The transmitted field in the ocean is represented as:

$$\boldsymbol{E}^{\text{trans}} = E_0[\hat{\boldsymbol{x}}C + \hat{\boldsymbol{y}}D + \hat{\boldsymbol{z}}E]\,e^{-j(k_y y - k_{z23})}, \tag{3.107}$$

where k_{z2} is the vertical wave number in the ocean found from equation 3.31 as:

$$\begin{aligned} k_{z2} = k_2 \cos\theta_2 = k_0 n_2 \sqrt{1 - \left(\frac{1}{n_2}\right)^2 \sin^2\theta} \\ = k_0(9.582527 - j3.751642). \end{aligned} \tag{3.108}$$

From the transverse equivalent network:

$$C = T^{TE} = 1 + \Gamma^{TE} = 0.146839 + j(0.052724), \tag{3.109}$$

and

$$\begin{aligned} D = T^{TM}(-j\cos\theta) = (1 + \Gamma^{TM})(-j\cos\theta) \\ = 0.057678 - j(0.165813). \end{aligned} \tag{3.110}$$

The z component of the transmitted field can be determined from the electric Gauss's law equation 3.20, which yields:

$$E = -\frac{1}{k_{z2}}(k_y D). \tag{3.111}$$

Hence, the following result is obtained:

$$E = -0.0055466 + j(0.00648030). \tag{3.112}$$

From the wave numbers k_y and k_{z2}, the direction angles of the transmitted wave may be determined from equations 3.29 through 3.31. The results are as follows:

$$\phi = 90^{\circ}, \tag{3.113}$$

$$\theta_2 = 0.045227 + j(0.017679)\text{radians}. \tag{3.114}$$

The transmitted plane wave is inhomogeneous because the angle θ_2 is complex.

Transmission Lines

Krishna Naishadham
Massachusetts Institute of Technology,
Lincoln Laboratory,
Lexington, Massachusetts, USA

4.1 Introduction

A transmission line is used to transfer a signal from the generator to the load, as in Figure 4.1, by guiding an electromagnetic (EM) wave between two conductors. In microwave communications, the signal is usually some form of modulation on a high-frequency carrier. The generator circuit represents the Thevenin equivalent (a voltage V_g in series with an impedance Z_g) of the EM wave's source, such as a radar transmitter, a continuous tone source, or a high-speed data terminal. The load Z_L represents the equivalent impedance at the terminals of the receiver (e.g., the transmitting antenna's input impedance).

Figure 4.2 illustrates a cross section of some common transmission lines. The transmission lines are assumed to be uniform along the direction of propagation, so discontinuity effects are not considered in the field distribution. All these lines, except the microstrip, support electric and magnetic field distributions, which are entirely **transverse** to the direction of propagation. Thus, they can be described mathematically in terms of **transverse electromagnetic** (TEM) waves. The microstrip line has a small longitudinal field component relative to the transverse component because of flux leakage across the air–dielectric interface. Such a transmission line can be considered as **quasi-TEM**. The coaxial line and the stripline are completely shielded and do not have any leakage under ideal conditions.

A TEM wave has the same phase constant and intrinsic impedance as a plane wave propagating in an unbounded medium and can be uniquely represented by voltages and currents of the form:

$$v(z, t) = -\int_{C_V} \boldsymbol{E}(r, z) \cdot \boldsymbol{dl}. \tag{4.1}$$

$$i(z, t) = \int_{C_I} \boldsymbol{H}(r, z) \cdot \boldsymbol{dl}. \tag{4.2}$$

In equations 4.1 and 4.2, $\boldsymbol{E}$ and $\boldsymbol{H}$ are the electric and magnetic field intensities. C_V and C_I are arbitrary integration contours, parallel to electric and magnetic flux lines, respectively, as displayed in Figure 4.3 for a coaxial line. The TEM field distribution can be entirely calculated by considering static electric and magnetic fields, namely, an irrotational (or curl-free) electric field and the absence of displacement currents. Hence, the voltages and currents defined in equations 4.1 and 4.2 are independent of the integration contour's orientation.

With reference to Figure 4.3, assuming that the current (I) flows out of the center conductor and returns into the outer conductor, the contour C_V terminates radially on the conductors, while C_I follows a closed circular path along a magnetic flux line.

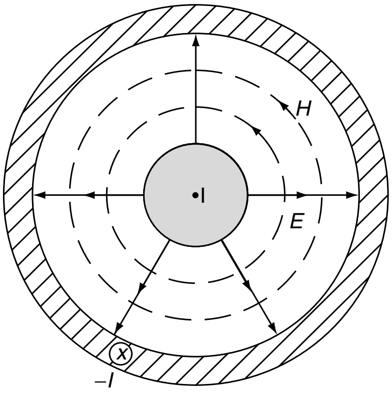

FIGURE 4.3 Transverse Electric and Magnetic Field Distribution in a Coaxial Line

4.1.1 What Is a Transmission Line?

A **transmission line** is a distributed circuit element. Unlike a conventional low-frequency circuit, the voltages and currents on a transmission line vary with longitudinal position because they experience a phase (or time) delay as the wave propagates from one end of the line to the other. This effect becomes important when the line length becomes an appreciable fraction of the wavelength at the operating frequency. Consider the circuit shown in Figure 4.4, where a lossless transmission line of length ℓ is connected between an ideal generator and a load resistance, R_L. For simplicity, the load is assumed to be matched to Z_0, the characteristic impedance of the line, so that there is no reflected wave.

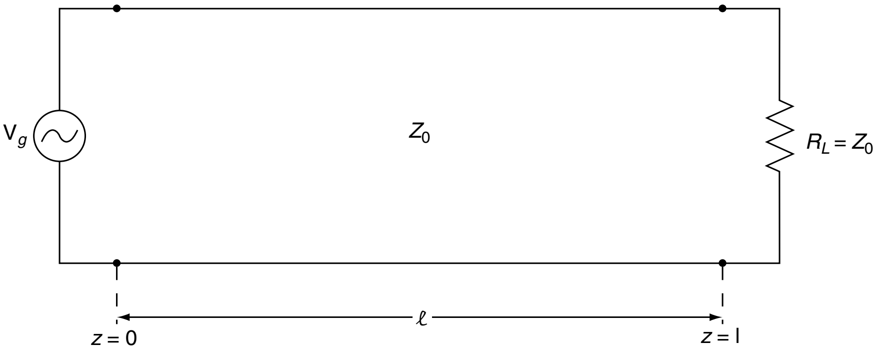

FIGURE 4.4 A Matched Transmission Line of Characteristic Impedance, Z_0

At time $t = 0$, let a sinusoidal signal be given by:

$$v_g(t) = V_0 \cos(\omega t), \tag{4.3}$$

where $\omega = 2\pi f$ is the radian frequency. Let this signal be applied to the generator located at $z = 0$. If the line is an air line, the signal travels at a velocity $v_p = 3 \times 10^8$ m/sec and reaches the load at time $\tau = \ell / v_p$. Thus, the signal experiences a time delay proportional to the distance that the wave has traveled along the line. At the load, the signal waveform is given by:

$$v_L(t) = V_0 \cos[\omega(t - \tau)] = V_0 \cos\left[\omega t - \frac{2\pi\ell}{\lambda}\right], \tag{4.4}$$

where $v_p = \lambda f$ is used to obtain the second equality. It is evident from equation 4.4 that the delay tracks with the distance traveled, normalized to the wavelength λ. The larger the fraction ℓ/λ gets, the longer is the delay. For conventional circuits operated at a low frequency, the fraction ℓ/λ is small; hence, the phase delay along the wire can be neglected. At higher frequencies, the wavelength gets shorter; hence, ℓ/λ becomes larger for a fixed ℓ. An important effect of the phase delay is that the line voltage varies with position along the line because the wave requires a finite time to travel from the source location to the measurement location. At low frequencies, these local potential differences are negligible because of very short transit times. This is not valid, however, when the line length becomes an appreciable fraction of the operating wavelength. Equation 4.4 can be generalized to any position z along the line by writing:

$$v(z, t) = V_0 \cos[\omega(t - \tau_z)] = V_0 \cos\left[\omega t - 2\pi\frac{z}{\lambda}\right], \tag{4.5}$$

where $\omega\tau_z$ is the phase delay incurred over a transit distance z, measured relative to the origin $z = 0$ at the generator-end of the line. The electrical distance may be written in terms of the phase constant:

$$\beta = \frac{2\pi}{\lambda} (\text{rad/m}), \tag{4.6}$$

so that the voltage wave becomes:

$$v(z, t) = V_0 \cos[\omega t - \beta z)]. \tag{4.7}$$

Equation 4.7 represents an incident wave traveling from the generator toward the load, and it remains valid on an infinitely long line, in which case there is no reflected wave. We can obtain some insight into wave propagation along the line by plotting the voltage as a function of phase delay βz for a fixed time variable ωt. Figure 4.5 shows three progression stages of the voltage waveform.

As time progresses from $t = 0$ to $t = t_1$ and then to $t = t_2$, the reference voltage sample at the waveform's peak moves along the positive z direction from location $z = 0$ to z_1 to z_2, for example. This is true for every point on the waveform. In fact, there is a constant phase delay, $\beta\Delta z = \omega\Delta t$, between successive snapshots. Since ω and β are constant, it means that as time increases by Δt, the position of the reference sample is proportionately displaced along positive z direction

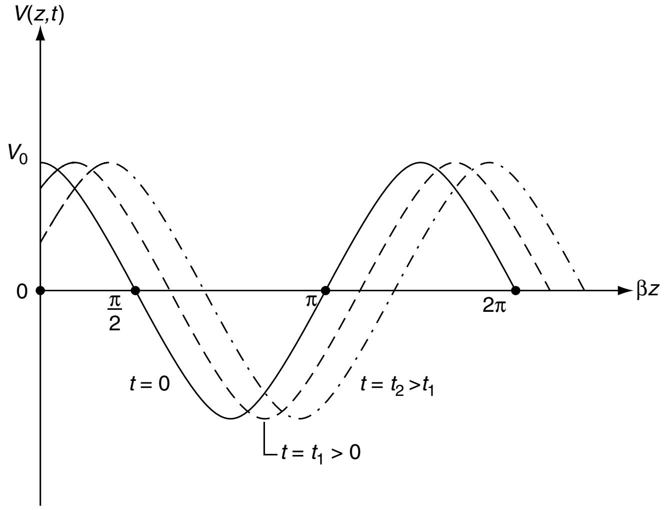

FIGURE 4.5 Progression of the Voltage Waveform on a Lossless Transmission Line

by a distance $(\omega/\beta)\Delta t$. The displacement per unit time is defined as the velocity of propagation or the **phase velocity**:

$$v_p = \frac{\omega}{\beta} = f\lambda. \tag{4.8}$$

The current on the incident wave is given by:

$$i(z,\ t) = \frac{v(z,\ t)}{Z_0} = \frac{V_0}{Z_0}\cos[\omega t - \beta z]. \tag{4.9}$$

Equation 4.9 depicts only a change in amplitude relative to the voltage in equation 4.7. Since the phase is unchanged, the conclusions on the distributed nature, discussed earlier for the voltage, are also valid for the current.

4.1.2 Lossy Transmission Line

On a **lossy transmission line** the voltage and current waveforms for a wave traveling along the z direction are given by:

$$v(z,\ t) = V_0 e^{-\alpha z}\cos[\omega t - \beta z], \tag{4.10}$$

$$i(z,\ t) = \frac{v(z,\ t)}{Z_0} = \frac{V_0}{Z_0}e^{-\alpha z}\cos[\omega t - \beta z]. \tag{4.11}$$

In addition to the phase delay linearly proportional to the distance traveled, the envelope of the wave pattern attenuates in amplitude exponentially according to $e^{-\alpha z}$, as shown in Figure 4.6. In this case, the propagation constant is $\gamma = \alpha + j\beta$, where α is the attenuation constant (measured in nepers per meter) and β is the phase constant. In general, the characteristic impedance Z_0 is also complex. For practical low-loss lines, however, Z_0 can be considered approximately real. The next section shows that these two parameters, Z_0 and γ, are complex because of series resistive loss in the conductors and shunt conductive loss in the dielectric medium.

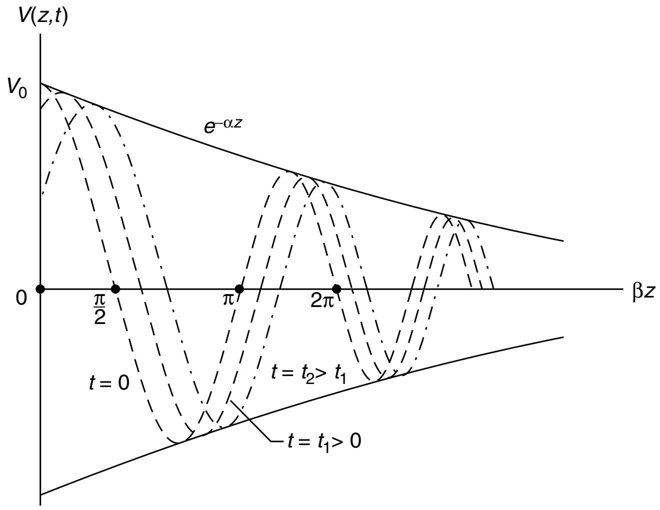

FIGURE 4.6 Progression of the Voltage Waveform on a Lossy Transmission Line

4.2 Equivalent Circuit

The TEM mode on a transmission line can be represented by the **equivalent circuit**, shown in Figure 4.7, for a length Δz. Physically, this is a **distributed circuit** because the circuit elements are not lumped at discrete locations as in a conventional low-frequency circuit but distributed uniformly along the length of the line. Thus, the elements are defined on **per-unit-length** basis. The series resistance per unit length, R, is the combined resistance of all the conductors in the line, and it accounts for power dissipation in the conductors. As exemplified in Figure 4.3 for a coaxial line, current flow along the conductor's surface is accompanied by a circumferential magnetic field. The linkage of this magnetic flux with the current produces a combined inductance per unit length, L, which accounts for flux linkages both internal and external to the conductors. Positive and negative charges of equal magnitude are deposited on the two conductors (Figure 4.3). This charge separation creates a potential difference between the conductors, which accounts for the capacitance per unit length, C. The shunt conductance per unit length, G, accounts for the power dissipation in the non-ideal dielectric medium between the conductors.

Application of Kirchhoff's voltage and current laws to the circuit in Figure 4.7 leads to the system of coupled differential equations for the phasor voltage and current in the limit $\Delta z \to o$:

$$\begin{aligned}\frac{dV(z)}{dz} &= -(R + j\omega L)I(z),\\ \frac{dI(z)}{dz} &= -(G + j\omega C)V(z).\end{aligned} \tag{4.12}$$

Eliminating the current variable in the former and the voltage variable in the latter of equation 4.12 leads to the uncoupled system of second-order differential equations:

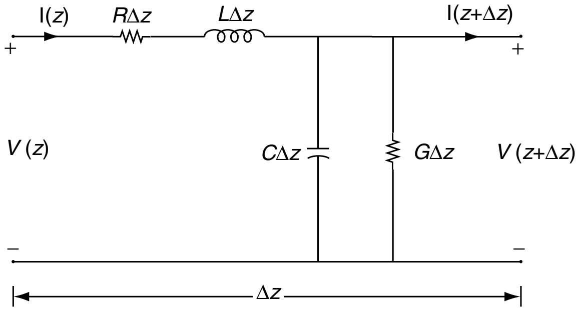

FIGURE 4.7 Lumped Parameter Equivalent Circuit of a General Transmission Line

$$\frac{d^2V(z)}{dz^2} - \gamma^2 V(z) = 0, \qquad \frac{d^2I(z)}{dz^2} - \gamma^2 I(z) = 0. \tag{4.13}$$

The propagation constant is defined by:

$$\gamma = \sqrt{(R + j\omega L)(G + j\omega C)}. \tag{4.14}$$

Solution of the differential equations 4.13 results in the time-instantaneous traveling wave representation:

$$v(z, t) = V_0^+ e^{-\alpha z} \cos[\omega t - \beta z] + V_0^- e^{\alpha z} \cos[\omega t + \beta z], \tag{4.15}$$

$$i(z, t) = \frac{V_0^+}{Z_0} e^{-\alpha z} \cos[\omega t - \beta z] - \frac{V_0^-}{Z_0} e^{\alpha z} \cos[\omega t + \beta z]. \tag{4.16}$$

Equations 4.15 and 4.16 use the following equation:

$$f(z, t) = \mathcal{R}e[F(z)e^{j\omega t}], \tag{4.17}$$

to convert the voltage and current phasors, $V(z)$ and $I(z)$, into the time-domain. The first term in each equation corresponds to a wave traveling along the $+z$ direction, while the second corresponds to a wave traveling along the opposite direction. Section 4.3 analyzes the transmission line circuit shown in Figure 4.1 using equations 4.15 and 4.16 and also determines the wave amplitudes V_0^+ and V_0^-. The characteristic impedance Z_0 can be calculated using:

$$Z_0 = \sqrt{\frac{R + j\omega L}{G + j\omega C}}. \tag{4.18}$$

The per-unit-length elements R, L, G, and C depend on the resistivity of the conductors, cross-sectional dimensions and shape of the transmission line, and the permittivity of the dielectric medium. Expressions of these elements for some practical transmission lines can be found in any standard electromagnetics text, such as in Ulaby (1999), listed in Appendix A. In summary, the propagation constant γ and the characteristic impedance Z_0 for the TEM mode depend only on the transmission line's geometrical and physical parameters.

4.2.1 Lossless Line

For the **lossless line** $R = 0 = G$; hence, the attenuation constant $\alpha = 0$, and the characteristic impedance Z_0 is real. In this case, these equations apply:

$$\gamma = j\beta = j\omega\sqrt{LC}. \tag{4.19}$$

$$Z_0 = \sqrt{\frac{L}{C}}. \tag{4.20}$$

A lossless line has these properties: (a) it does not dissipate any power, (b) it is non-dispersive (i.e., the phase constant varies linearly with frequency ω, or the velocity $v_p = \omega/\beta$ is independent of frequency), and (c) its characteristic impedance Z_0 is real.

4.2.2 Low-Loss Line

A **low-loss line** is one for which $R \ll \omega L$ and $G \ll \omega C$. In this case, γ and Z_0 can be approximated from equations 4.14 and 4.18, respectively, as:

$$\alpha \cong \frac{R}{2}\sqrt{\frac{C}{L}} + \frac{G}{2}\sqrt{\frac{L}{C}}. \tag{4.21}$$

$$\beta \cong \omega\sqrt{LC}. \tag{4.22}$$

$$Z_0 \cong \sqrt{\frac{L}{C}}, \; 2\omega \gg \frac{R}{L} - \frac{G}{C}. \tag{4.23}$$

It is emphasized that a low-loss line is non-dispersive subject to the approximations used to derive equation 4.22.

4.2.3 Distortionless Line

A **distortionless line** is truly non-dispersive, exhibits a real characteristic impedance Z_0, and satisfies the condition $RC = LG$. Thus, despite being dissipative, it possesses two of the three desirable characteristics of the lossless line. In this case, the propagation parameters are *exactly* given by:

$$\alpha = R\sqrt{\frac{C}{L}}. \tag{4.24}$$

$$\beta = \omega\sqrt{LC}. \tag{4.25}$$

$$Z_0 = \sqrt{\frac{L}{C}}. \tag{4.26}$$

4.3 Alternating Current Analysis

This section focuses on the steady-state alternating current (ac) analysis of transmission lines using the basic configuration in Figure 4.8, which shows a line connected between a generator of impedance Z_g and a load of impedance Z_L. This discussion begins with the general solution in equations 4.15 and 4.16, which contain two unknown voltage amplitudes, V_0^+ and V_0^-. The boundary condition is applied at the load to introduce the reflection coefficient, which relates V_0^+ to V_0^-. The condition at the generator-end of the line gives an expression for V_0^-. The standing wave properties of terminated lossless lines as well as lossy transmission lines are presented with examples.

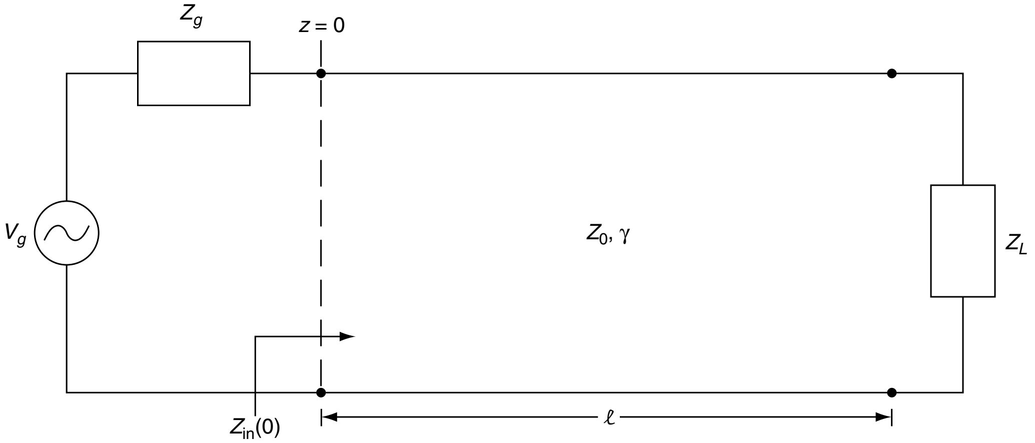

FIGURE 4.8 A Terminated Transmission Line of Characteristic Impedance, Z_0, and Propagation Constant, γ

4.3.1 Terminated Lossless Line

Reflection Coefficient

For a lossless transmission line, the voltage and current phasors can be calculated from equations 4.15 and 4.16 subject to $\alpha = 0$ and are given by:

$$V(z) = V_0^+ e^{-j\beta z} + V_0^- e^{j\beta z} = V_0^+ e^{-j\beta z}[1 + \Gamma(z)], \qquad (4.27)$$

$$I(z) = \frac{1}{Z_0}\left[V_0^+ e^{-j\beta z} - V_0^- e^{j\beta z}\right] = \frac{V_0^+ e^{-j\beta z}}{Z_0}[1 - \Gamma(z)]. \quad (4.28)$$

In these equations, the voltage reflection coefficient has been introduced as:

$$\Gamma(z) = \frac{V_0^-}{V_0^+} e^{j2\beta z}. \qquad (4.29)$$

Specializing equations 4.27 and 4.28 to the load position $z = \ell$ and taking the ratio of voltage to current yields:

$$\frac{V(\ell)}{I(\ell)} = Z_L = Z_0 \frac{1 + \Gamma(\ell)}{1 - \Gamma(\ell)}. \qquad (4.30)$$

Equation 4.30 defines the **load reflection coefficient**:

$$\Gamma_L \equiv \Gamma(\ell) = \frac{Z_L - Z_0}{Z_L + Z_0}. \qquad (4.31)$$

We can eliminate V_0^-/V_0^+ from equation 4.29 by specializing it to $z = \ell$ and the **translation formula**, which relates the reflection coefficient for any z to that at the load:

$$\Gamma(z) = \Gamma_L e^{j2\beta(z-\ell)}. \qquad (4.32)$$

Input Impedance

The voltage to current ratio for any z, called the **input impedance** of the line, can be calculated using equations 4.27 and 4.28 as:

$$Z_{in}(z) = Z_0 \frac{1 + \Gamma(z)}{1 - \Gamma(z)}. \qquad (4.33)$$

After substituting the translation formula 4.32 for $\Gamma(z)$ into equation 4.33, using equation 4.31 and the identity $e^{j\theta} = \cos\theta + j\sin\theta$, equation 4.33 can be rewritten as:

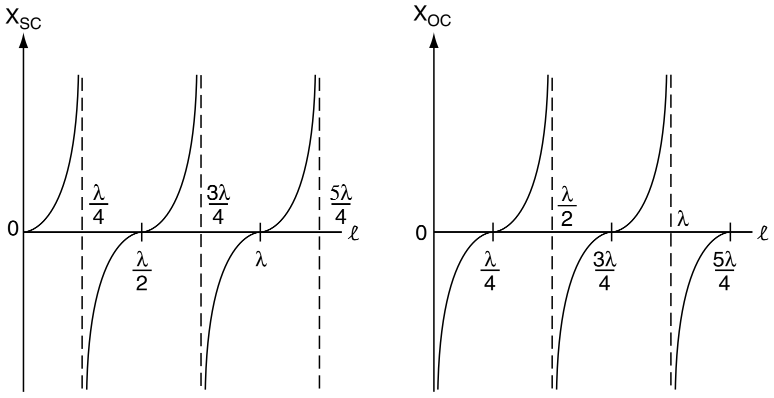
$$Z_{in}(z) = Z_0 \frac{Z_L + jZ_0 \tan[\beta(\ell - z)]}{Z_0 + jZ_L \tan[\beta(\ell - z)]}. \qquad (4.34)$$

At the input terminal $z = 0$, the following equation is obtained:

$$Z_{in}(0) = Z_0 \frac{Z_L + jZ_0 \tan\beta\ell}{Z_0 + jZ_L \tan\beta\ell}. \qquad (4.35)$$

In particular, for a short circuit ($Z_L = 0$), $Z_{in}(0) = jZ_0 \tan\beta\ell$; for an open circuit ($Z_L \to \infty$), $Z_{in}(0) = -jZ_0 \cot\beta\ell$. Clearly, the input impedance is periodic in position with a period of a **half wavelength**. It can be seen from equation 4.32 that the reflection coefficient also has the same periodicity. Thus, both the input impedance and the reflection coefficient attain identical values at points separated by a distance of $\lambda/2$. This property, known as the **replication property**, has been used in designing a graphical tool called the **Smith chart** and considerably simplifies the analysis of lossless transmission lines (see Appendix A, Smith [1969], for more information and further reading).

We conclude this discussion now with some examples. Figure 4.9 shows the input impedance of a reactively termin-



(A) Short-Circuited Line (B) Open-Circuited Line

FIGURE 4.9 The Input Reactance of Lossless Lines

ated line (open or short) plotted as a function of its length. The half wavelength periodicity is evident. Depending on the line's electrical length, the input reactance is either capacitive ($X < 0$) or inductive ($X > 0$). This suggests that a discrete capacitor or inductor can be constructed from an appropriate length of shorted or open-circuited transmission line. In practice, at microwave frequencies, it is necessary to have a small footprint and reduced parasitic effects for the element. This precludes the use of conventional transmission lines. Instead, for example, an RF inductor is made of a planar spiral etched on a printed circuit board, and a miniature capacitor is constructed in parallel plate configuration using a material with high ε_r and metallized pads for the contacts (see Wadell [1991] in Appendix A for further reading).

Quarter Wavelength Transformer

The input impedance of a $\lambda/4$ long line can be calculated from equation 4.35 as:

$$Z_{\text{in}}(0) = \frac{Z_0^2}{Z_L}, \tag{4.36}$$

which indicates that a $\lambda/4$ line can be used as an impedance inverter, (i.e., a high impedance at the load can be converted to a low impedance at the input and vice versa). Using equation 4.36, it follows that a $\lambda/4$ line with characteristic impedance given by $Z_0 = \sqrt{Z_{01}Z_{02}}$ provides matched impedance when connected between two transmission lines of characteristic impedances Z_{01} and Z_{02}. Such a line, known as a **quarter-wave impedance transformer**, is frequency-selective (i.e., the mismatch becomes significant as the operating frequency deviates from the narrow band around the center frequency at which the line length $\ell = \lambda/4$).

Standing Waves

From equations 4.27, 4.28, and 4.32 the voltage and current on a lossless line are given by:

$$V(z) = V_0^+ e^{-j\beta z}[1 + \Gamma_L e^{j2\beta(z-\ell)}] \tag{4.37}$$

$$I(z) = \frac{V_0^+}{Z_0} e^{-j\beta z}[1 - \Gamma_L e^{j2\beta(z-\ell)}]. \tag{4.38}$$

At the generator end $z = 0$, this equation results:

$$V(0) = V_0^+\left[1 + \Gamma_L e^{-j2\beta\ell}\right]. \tag{4.39}$$

Applying voltage division at the generator-end of the line (see Figure 4.8), the following is calculated:

$$V(0) = V_g \frac{Z_{\text{in}}(0)}{Z_g + Z_{\text{in}}(0)}, \tag{4.40}$$

where, using equations 4.32 and 4.33:

$$Z_{\text{in}}(0) = Z_0 \frac{1 + \Gamma_L e^{-j2\beta\ell}}{1 - \Gamma_L e^{-j2\beta\ell}}. \tag{4.41}$$

From equations 4.39 through 4.41, the unknown amplitude V_0^+ is calculated as:

$$V_0^+ = V_g \frac{Z_0}{Z_g + Z_0} \frac{1}{1 - \Gamma_g \Gamma_L e^{-j2\beta\ell}}. \tag{4.42}$$

Therefore, the voltage and current on a lossless transmission line are given by:

$$V(z) = V_g \frac{Z_0}{Z_g + Z_0} \frac{e^{-j\beta z}[1 + \Gamma_L e^{j2\beta(z-\ell)}]}{1 - \Gamma_g \Gamma_L e^{-j2\beta\ell}}, \tag{4.43}$$

$$I(z) = V_g \frac{1}{Z_g + Z_0} \frac{e^{-j\beta z}[1 - \Gamma_L e^{j2\beta(z-\ell)}]}{1 - \Gamma_g \Gamma_L e^{-j2\beta\ell}}. \tag{4.44}$$

The voltage or current magnitude describes the standing wave nature of the field on a terminated transmission line. Standing waves result from reflections along the line, and they describe mismatch between load or source termination and the line. From equations 4.37 and 4.42, these equations are calculated:

$$\begin{aligned} |V(z)| &= \left|V_0^+\right| \left|1 + |\Gamma_L| e^{j[\theta_L + 2\beta(z-\ell)]}\right| \\ &= \left|V_0^+\right| \left[1 + |\Gamma_L|^2 + 2|\Gamma_L| \cos\theta\right]^{1/2}, \end{aligned} \tag{4.45}$$

and

$$\left|V_0^+\right| = \left|V_g\right| \left|\frac{Z_0}{Z_g + Z_0}\right| \left[1 + |\Gamma_g \Gamma_L|^2 - 2|\Gamma_g \Gamma_L| \cos\phi\right]^{-1/2}, \tag{4.46}$$

where $\theta = \theta_L\ 2\beta(z - \ell)$, $\phi = \theta_g + \theta_L - 2\beta\ell$, $\Gamma_L = |\Gamma_L| \angle \theta_L$, and $\Gamma_g = |\Gamma_g| \angle \theta_g$. The voltage magnitude in equation 4.45 depends on the position as $2\beta z$ and, thus, replicates every half wavelength. The phase can be calculated from equation 4.37 and shown to replicate at full wavelength spacing. The magnitude of the current is derived from equation 4.37 as:

$$\begin{aligned} |I(z)| &= \frac{|V_0^+|}{Z_0} \left|1 - |\Gamma_L| e^{[\theta_L + 2\beta(z-\ell)]}\right| \\ &= \frac{|V_0^+|}{Z_0} \left[1 + |\Gamma_L|^2 - 2|\Gamma_L| \cos\theta\right]^{1/2}. \end{aligned} \tag{4.47}$$

It can be observed from equations 4.45 and 4.47 that the voltage is maximum when the current is minimum and vice versa. The maximum voltage is given by:

$$|V|_{\max} = \left|V_0^+\right| (1 + |\Gamma_L|), \tag{4.48}$$

and occurs for $\cos\theta = 1$ in equation 4.45 or at:

$$z_{\max} = \ell + \frac{n\lambda}{2} - \frac{\theta_L \lambda}{4\pi}, n = 0, 1, \ldots N. \tag{4.49}$$

Likewise, the voltage minimum of:

$$|V|_{\min} = \left|V_0^+\right| (1 - |\Gamma_L|), \tag{4.50}$$

occurs for $\cos\theta = -1$ in (4.45) or at:

$$z_{\min} = z_{\max} \pm \frac{\lambda}{4}. \tag{4.51}$$

The ratio of maximum to minimum voltage (or current) is called the **standing wave ratio** (SWR) and is given by:

$$S = \frac{|V|_{\mathbf{max}}}{|V|_{\mathbf{min}}} = \frac{1 + |\Gamma_L|}{1 - |\Gamma_L|}. \tag{4.52}$$

This factor defines the mismatch along the line and can range from unity for a matched load to infinity for an ideal short or open termination. When the load termination is resistive, equation 4.52 yields:

$$S = \begin{cases} R_L/Z_0, & R_L > Z_0. \\ Z_0/R_L, & R_L < Z_0. \end{cases} \tag{4.53}$$

When $R_L > Z_0$ ($R_L < Z_0$), a voltage maximum (minimum) occurs at the load position.

Figure 4.10 displays the magnitude of the voltage and current for a terminated transmission line with $V_g = 10\angle 45^\circ V$, $Z_0 = 50\Omega$, $Z_g = 75\Omega$, $Z_L = 100\Omega$, and $\ell = \lambda$. The voltage and current magnitudes replicate every half wavelength. The

(C) Matched Termination

FIGURE 4.11 The Voltage Standing Wave Patterns on a Lossless Line

standing wave ratio is observed to be $5.7/2.85 = 2$, which agrees with equation 4.53. Likewise, Figure 4.11 shows the voltage standing wave patterns for a short circuit, an open circuit, and a matched termination, with $\ell = \lambda$. For the short circuit, equation 4.45 yields:

$$|V(z)| = 2\left|V_0^+\right|\left|\sin\left[\frac{2\pi}{\lambda}(z-\ell)\right]\right|, \tag{4.54}$$

and for the open circuit, the pattern is as follows:

$$|V(z)| = 2\left|V_0^+\right|\left|\cos\left[\frac{2\pi}{\lambda}(z-\ell)\right]\right|. \tag{4.56}$$

These waves are known as **complete** standing waves. The minimum value is zero, the nulls are sharper than those in Figure 4.10 for the resistive load, and the SWR becomes infinite. For a matched load $Z_L = Z_0$, equation 4.52 shows that there are no standing waves ($S = 1$) because $\Gamma_L = 0$. In this case, the standing wave pattern looks flat as shown in Figure 4.11.

Power Flow

A transmission line is intended for power transfer between the generator and the load. The average power flow along a lossless line can be calculated using:

$$P_{av} = \frac{1}{2}\text{Re}[V(z)I(z)^*], \tag{4.57}$$

where the voltage and current are given by equations 4.37 and 4.38, respectively, and the asterisk denotes a complex conjugate. On a lossless line, since there is no dissipation, the average power is independent of position z. Therefore, the voltage and current in equation 4.57 can be calculated at any point along the line. Using the conditions at the load in equations 4.37 and 4.38, it follows that:

$$P_{av} = \frac{1}{2Z_0}|V_0^+|^2\left(1 - |\Gamma_L|^2\right). \tag{4.58}$$

The first term in equation 4.58 corresponds to the incident wave, and the second corresponds to the reflected wave. The magnitude $|V_0^+|$ can be computed using equation 4.46.

For a matched load, $\Gamma_L = 0$ ($Z_L = Z_0$); therefore, the power transferred to the load is just the first term in equation 4.58. This is not the maximum power transfer, however, for there is still a mismatch at the generator-end of the line because $Z_g \neq Z_{\text{in}} = Z_0$ ($\Gamma_g \neq 0$). The maximum power transfer on a lossless line occurs for a conjugate match at the generator-end, $Z_{\text{in}} = Z_g^*$, irrespective of the load impedance, and is given by:

$$P_{av} = \frac{\left|V_g\right|^2}{4R_g}. \tag{4.59}$$

4.3.2 Terminated Lossy Transmission Line

The voltage and current on a lossy transmission line are given by:

$$\begin{aligned} V(z) &= V_0^+ e^{-\alpha z}e^{-j\beta z} + V_0^- e^{\alpha z}e^{j\beta z} \\ &= V_0^+ e^{-\alpha z}e^{-j\beta z}[1 + \Gamma(z)]. \end{aligned} \tag{4.60}$$

$$\begin{aligned} I(z) &= \frac{1}{Z_0}\left[V_0^+ e^{-\alpha z}e^{-j\beta z} - V_0^- e^{\alpha z}e^{j\beta z}\right] \\ &= \frac{V_0^+ e^{-\alpha z}e^{-j\beta z}}{Z_0}[1 - \Gamma(z)]. \end{aligned} \tag{4.61}$$

The translation formula for the reflection coefficient follows from:

$$\Gamma(z) = \Gamma_L e^{2\alpha(z-\ell)}e^{j2\beta(z-\ell)} \tag{4.62}$$

The magnitude of the reflection coefficient is given by:

$$|\Gamma(z)| = |\Gamma_L|e^{2\alpha(z-\ell)}, \tag{4.63}$$

which is a function of both frequency and position, unlike the constant reflection coefficient magnitude:

$$|\Gamma(z)| = |\Gamma_L|. \tag{4.64}$$

Equation 4.64 is for a lossless line. The input impedance at $z = 0$ is as follows:

$$Z_{\text{in}}(0) = Z_0 \frac{Z_L + Z_0 \tanh\ \gamma\ell}{Z_0 + Z_L \tanh\ \gamma\ell}. \tag{4.65}$$

The impedance at any position z is obtained by replacing $\ell \to (\ell - z)$. It should be noted that the characteristic impedance Z_0 for a lossy line is complex. For practical low-loss lines, however Z_0 may be considered as real. Because of attenuation, it is observed from equations 4.63 and 4.65 that neither the reflection coefficient nor the input impedance exhibit the replication property. Also varying with position along the line is the standing wave ratio:

$$S = \frac{1 + |\Gamma_L|e^{2\alpha(z-\ell)}}{1 - |\Gamma_L|e^{2\alpha(z-\ell)}}. \tag{4.66}$$

The power flow is calculated from equation 4.57 using the voltage and current from equations 4.60 and 4.61, respectively. Denoting $\Gamma_L = |\Gamma_L|\angle\theta_L$ and $Z_0 = |Z_0|\angle\theta_0$, the following is obtained:

$$\begin{aligned} P_{av}(z) = \frac{|V_0^+|^2}{2|Z_0|} e^{-2\alpha z} \cos\theta_0 \left[1 - |\Gamma_L|^2 e^{4\alpha(z-\ell)}\right] \\ - \frac{|V_0^+|^2}{|Z_0|} |\Gamma_L| e^{-2\alpha\ell} \sin\theta_0 \sin[\theta_L + 2\beta(z-\ell)]. \end{aligned} \tag{4.67}$$

The first term in 4.67 computes the incident power, the second term corresponds to the reflected power, and the third term represents the interference between these two waves. Note that for a lossless line, since $\theta_0 = 0$, the interaction term will vanish, and the power transferred to the load reduces to the difference between incident and reflected contributions.

The power dissipated along the line can be computed by subtracting the power at the load, $P_{av}(\ell)$, from the power at the input, $P_{av}(0)$, and is given by:

$$\begin{aligned} P_{diss} = P_{av}(0) - P_{av}(\ell) = \frac{|V_0^+|^2}{2|Z_0|} \cos\theta_0 \left[\left(1 - e^{-2\alpha\ell}\right)\right. \\ \left. + |\Gamma_L|^2 e^{-2\alpha\ell}\left(1 - e^{-2\alpha\ell}\right)\right] \\ + \frac{2|V_0^+|^2}{|Z_0|} |\Gamma_L| e^{-2\alpha\ell} \sin\theta_0 \sin(\beta\ell) \cos(\theta_L - \beta\ell). \end{aligned} \tag{4.68}$$

Again, the first term denotes the power loss in the incident wave, the second term denotes the power loss in the reflected wave, and the third term represents power loss due to interaction between the two. As α increases, the power loss in the incident and reflected waves as well as in the interaction term increases. In the limiting case of a lossless line, there should not be any dissipation. Clearly, the interaction term vanishes because $\theta_0 = 0$, and the power dissipation in the first two terms reduces to zero.

4.4 Smith Chart

The Smith chart is a graphical tool for determination of the reflection coefficient and impedance along a transmission line. It is an integral part of microwave circuit performance visualization, modern computer-aided design (CAD) tools, and RF/microwave test instrumentation. Basically, a Smith chart is a polar graph of normalized line impedance in the complex reflection coefficient plane. Let $Z = R + jX$ be the impedance at some location along a lossless line. The reflection coefficient is given by:

$$\Gamma = \frac{Z - Z_0}{Z + Z_0} = \Gamma_r + j\Gamma_i. \tag{4.69}$$

If the impedance Z is normalized with respect to Z_0 and $z \equiv Z/Z_0 = r + jx$ is written in terms of the reflection coefficient (z in this section should not be confused with the position variable z used elsewhere), the following equation is obtained:

$$r + jx = \frac{(1 + \Gamma_r) + j\Gamma_i}{(1 - \Gamma_r) - j\Gamma_i}. \tag{4.70}$$

The key to understanding the Smith chart is the realization that equation 4.70 corresponds to two families of circles given by:

$$r = \frac{1 - \Gamma_r^2 - \Gamma_i^2}{(1 - \Gamma_r)^2 + \Gamma_i^2}, \tag{4.71}$$

$$x = \frac{2\Gamma_i}{(1 - \Gamma_r)^2 + \Gamma_i^2}. \tag{4.72}$$

For a given r, 4.71 represents a circle in the complex Γ-plane that is centered at the point $[r/(1 + r), 0]$ and has a radius of $1/(1 + r)$. For a given x, equation 4.72 yields a circle centered at $[1, 1/x]$ with a radius $1/|x|$. A few of the former circles are shown as solid lines and the latter circles as dashed lines in Figure 4.12. The reactance is inductive in the upper half of the plane and capacitive in the lower half. Viewed in terms of impedance coordinates, the Smith chart displays the normalized impedance $z = r + jx$ at the intersection of an $r - x$ circle

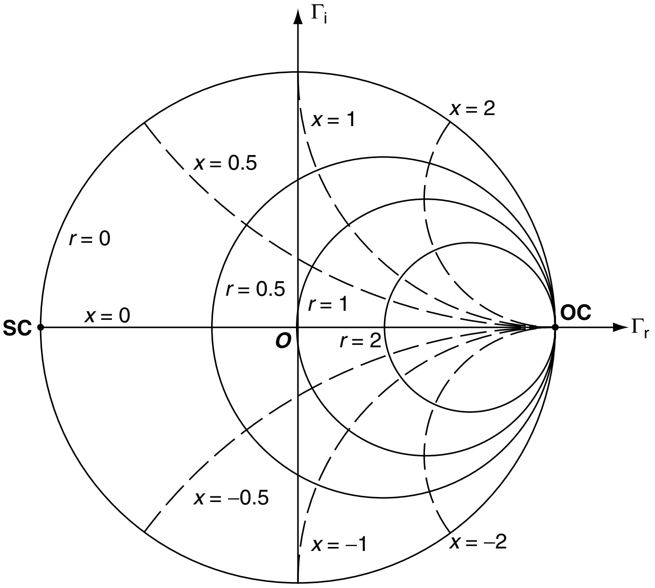

FIGURE 4.12 Basic Construction of the Smith Chart

pair. Because the underlying polar grid is a reflection coefficient plane, at any point on the chart the reflection coefficient can be read by measuring the radius and angle of the point (polar coordinates) on an appropriate scale. The outermost circle (OC) corresponds to the unity reflection coefficient. The open circuit lies at (1,0) in the reflection coefficient plane, and the short circuit (SC) is at (− 1, 0).

Figure 4.13 displays a typical commercially available Smith chart. The basic operations of the chart can be understood by an example to be discussed next. For better clarity and practice, it is highly recommended to follow this example by repeating the graphical solution taps on a new Smith chart. Suppose that a (1/3)λ-long, 50Ω line is connected to a load impedance of $(25 + j25)$ Ω. The input impedance and reflection coefficient can be determined by using the Smith chart. The load impedance is normalized, and the point $(0.5 + j0.5)$ is plotted and shown as point A in Figure 4.13. This point can be translated to the input by moving (1/3)λ *toward the generator*. Two scales on the Smith chart's outer periphery indicate movement in wavelengths either **toward the generator** (clockwise) or **toward the load** (counterclockwise). One complete rotation around the

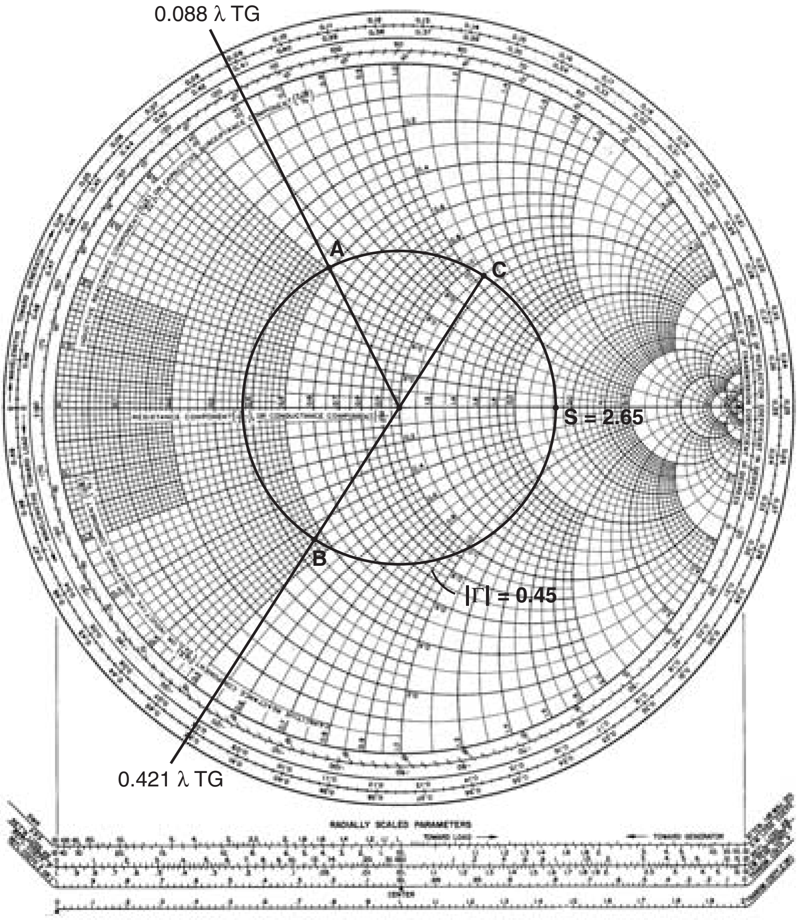

FIGURE 4.13 Smith Chart with Solution to an Example Problem

chart amounts to a half wavelength traversal. The relative position of a point on the transmission line can be determined by extending the radius of the point to intersect one of these two scales and reading its value in λ. Thus, point A reads 0.088λ toward generator (TG). If the radius of point A is projected onto the **reflection coefficient, E or I**, scale at the bottom of the chart, the measurement is $|\Gamma_L| = 0.45$. The angle of Γ_L is measured using the corresponding **angle of reflection coefficient** scale on the periphery of the unit circle as 116.5°. Therefore, $\Gamma_L = 0.45\angle 116.5°$. The input terminal is at a distance of 0.333λ TG from the load, located at 0.088λ. Thus, the position of the input terminal is at $0.088 + 0.333 = 0.421\lambda$ TG. Since $|\Gamma|$ is constant for a lossless transmission line, the reflection coefficient at the input, denoted by point B on the 0.421λ TG radial line, has the same radius as point A (= 0.45). Thus, we obtain the input reflection coefficient $\Gamma_{\text{in}} = 0.45\angle -123°$. For convenience, $|\Gamma| = 0.45$ circle is drawn in Figure 4.13 and allows the determination of the reflection coefficient at any point along the line. The normalized impedance at point B is read as $0.47 - j0.44$, which, after denormalization (multiplication by 50), yields $(23.5 - j22)\ \Omega$.

The standing wave ratio can be directly read from the scale at the bottom of the chart by projecting the radius of the reflection coefficient circle. It is instructive, however, to determine the point at which the normalized impedance equals SWR. From equation 4.48 there is a voltage maximum of:

$$|V|_{\max} = \left|V_0^+\right|(1 + |\Gamma_L|), \tag{4.73}$$

which occurs at points along the line where the incident and reflected waves add *in* phase (**constructive interference**). Likewise, from equation 4.50 there is a voltage minimum of:

$$|V|_{\min} = \left|V_0^+\right|(1 - |\Gamma_L|), \tag{4.74}$$

which occurs when the incident and reflected waves add *out of* phase (**destructive interference**). Because the current reflection coefficient is negative of the voltage reflection coefficient, at a voltage maximum location the current is a minimum and is given by:

$$|I|_{\min} = \frac{|V_0^+|}{Z_0}(1 - |\Gamma_L|). \tag{4.75}$$

Dividing equation 4.75 into 4.73 and normalizing with respect to Z_0 results in the impedance:

$$z_{\max} = \left|\frac{V_{\max}}{I_{\min}}\right| = \frac{1 + |\Gamma_L|}{1 - |\Gamma_L|} \overset{\Delta}{=} S. \tag{4.76}$$

Thus, at the position of a voltage maximum (or a current minimum), the normalized impedance is a maximum and equals S. Similarly, it can be shown that at the position of a voltage minimum (or a current maximum), the normalized impedance is a minimum and equals:

$$z_{\min} = \left|\frac{V_{\min}}{I_{\max}}\right| = \frac{1 - |\Gamma_L|}{1 + |\Gamma_L|} \overset{\Delta}{=} \frac{1}{S}. \tag{4.77}$$

These two points can be easily obtained on the Smith chart as the two points where the real axis intersects the constant $|\Gamma|$ circle. From Figure 4.13, $S = 2.65$ at the intersection of the $|\Gamma|$ circle and the positive real axis. This agrees with the value read from the SWR scale at the bottom of the chart. In addition, the voltage maximum nearest to the load is at a distance of $0.25 - 0.088 = 0.162\lambda$ from the load.

The Smith chart can be used to calculate admittances, a feature very useful in designing impedance matching circuits. The normalized admittance occurs on the reflection coefficient circle, diametrically opposite to the normalized impedance. Corresponding to the r and x circles, respectively, the admittance coordinates are the constant conductance and constant susceptance circles. The upper half of the plane yields positive susceptances, and the lower half of the plane yields negative susceptances. The normalized input admittance for the example in Figure 4.13 is observed (at point C) as $(1.1 + j1.08)$. The net admittance follows from:

$$\mathbb{Y}_n = \frac{y}{Z_0} = \frac{1.1 + j1.08}{50}\ \text{(mhos)}. \tag{4.78}$$

The Smith chart is used in several applications, including microwave measurements, instrument displays, and computer-aided design of microwave circuits. For example, impedance matching networks such as single-stub and double-stub tuners or quarter-wave transformers can be conveniently designed using the Smith chart (see Cheng [1989] in Appendix A for further reading). For space limitations, these applications are not presented in this chapter. The reader is referred to Appendix A at the end of the chapter for several useful references illustrating microwave circuit design utilizing the Smith chart.

4.5 Summary

This chapter was devoted to the fundamentals of frequency-domain analysis of transmission lines with an emphasis on physical concepts rather than detailed mathematical derivations. A distributed circuit model was employed to derive the transmission line equations, whose solution describes the wave behavior of voltages and currents along the line. Initially, we considered an infinite line to emphasize the concepts of phase delay and spatial dependence, which account for the distributed nature of voltages and currents along a transmission line. The propagation characteristics of lossless and lossy lines were discussed, with the latter specialized to low-loss and distortionless cases. Properties of the standing waves along a terminated transmission line, such as impedance, reflection coefficient, voltage and current distribution, were discussed in detail. Mathematical expressions were derived for power flow, including power loss due to interference between incident and reflected waves on a lossy line and the condition of conjugate matching for maximum power transfer. Finally, the basic operations of the Smith chart to characterize standing waves on a terminated line were explained with an example.

Appendix A: References

The technical literature on transmission lines is pervasive with several articles scattered in books and journals, ranging from introductory material to advanced topics and covering both theoretical and practical aspects. The basic background material introduced in this chapter can be supplemented with further reading from the references listed below that are arranged by topics. A few books are devoted exclusively to transmission lines. Transmission line theory, however, is covered exhaustively in several electromagnetics textbooks. The list is not intended to be exhaustive.

Guided Waves

Franco De Flaviis
Department of Electrical and Computer Engineering, University of California, Irvine, California, USA

5.1 Definition of Guiding Structure or Waveguide

A **waveguide** can be defined as a geometrical structure capable of propagating electromagnetic energy in a preferred direction in space within a certain frequency range. Usually, this direction is referred to as the **direction of propagation**, and the frequency range is referred as the **waveguide operating bandwidth**. The lower operating frequency is determined by the electrical property of the guiding structure and does not necessarily start from zero (dc field) unless the guide is capable of supporting transverse electromagnetic modes (TEM) as in the case of a transmission line. It has been proven (Balanis, 1989) that to support a TEM, a structure must be also capable of supporting static field distribution (multiconductor topology), so structures made of a single conductor are not capable of supporting TEMs. The higher operating frequency is usually determined by the **single-mode guide operation**, which is the highest frequency at which the waveguide operates while supporting a single field distribution usually referred as the **fundamental mode**. The propagation of an electromagnetic wave inside a waveguide is quite different from the propagation of a TEM wave, which usually occurs in a traditional transmission line. This is because when a wave is introduced at one end of the waveguide, it is reflected from the sides of the waveguide whenever it hits them. These various reflected waves interact with each other to produce an infinite number of discrete characteristic patterns called **modes**. The existence of a discrete mode depends on the shape of and size of the waveguide, the medium in the waveguide, and the operating frequency. Unlike the TEM, which can be excited at any frequency, the transverse magnetic (TM) and transverse electric (TE) modes can only propagate when the wave frequency is higher than a certain frequency, called the **cutoff frequency**. The cutoff frequency is different for each mode. When the operating frequency of the wave is lower than the cutoff frequency of the lowest mode, the wave experiences exponential attenuation and disappears after traveling a very short distance. On the other hand, those modes with cutoff frequencies lower than the operating frequency can exist simultaneously inside the waveguide. To avoid existence of multiple modes, the waveguide is operated at a frequency that lies between the cutoff frequencies of the lowest and the next lowest modes. Guided waves can have different shapes and be made for different materials, such as metal or dielectrics or a combination of them. The shape and the type of waveguide used in a specific application depends on the desired performance, geometrical constraint, and cost.

5.2 Classification and Definitions

There are two major types of waveguides, namely of the metallic or dielectric type. **Metallic waveguides** are closed structures surrounded by metal and confine the electric field inside the guide. **Dielectric waveguides** are open structures where the field confinement is obtained from the dielectric constant discontinuities between the dielectric waveguiding structure and free space. In addition, a third category of waveguide can be identified under the name of **planar waveguide**, whose structure is a combination of metal and dielectric assembled in a planar geometry. Figure 5.1 gives a schematic diagram of the most common type of waveguide.

Several parameters are used to describe waveguide structures. The following list provides a description of some of them and their corresponding meanings.

- The **operating frequency** is the frequency range at which the guide operates for each field distribution, called **modes**. Some modes have overlapping frequency ranges for some geometrical dimensions of the waveguide. Such modes are called **degenerate modes**.

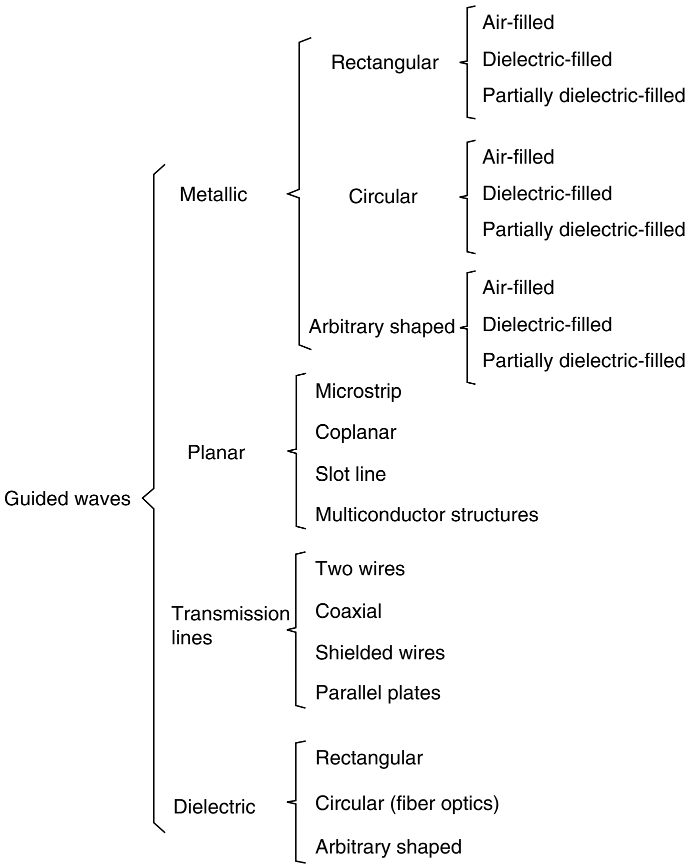

FIGURE 5.1 Schematic Classification of Waveguides

- The **operation mode** represents the field distribution of the guide and, more specifically, the type of field distribution. If both the electric and magnetic field components are zero in the direction of propagation, the mode is called **transverse electromagnetic** (TEM waves). If only the electric field is zero in the direction of propagation of the guide, then the mode is called **transverse electric** (TE wave); it is called **transverse magnetic** (TM) if the magnetic field is zero in the direction of propagation. In some cases, the field is a combination of the two (TE and TM). For such a case, the mode is referred to as a **hybrid mode**.
- The **propagation constant** (β) of a waveguide is defined as the rate of change (radians per second) of the phase angle of the signal and is directly related to the wavelength (λ) and its frequency (f):

$$\beta = \frac{2\pi}{\lambda} = \frac{2\pi f}{v_p}, \tag{5.1}$$

where v_p is the phase velocity.

- The **phase velocity** is the speed v_p, of the constant phase points on the wave as the wave travels and is usually represented by the symbol v_p and expressed in meters per second (MKS) units.
- The **group velocity** is the speed at which the energy propagates in the waveguide, usually referred to as v_g, and is expressed in meters per second.
- The **wavelength** is the distance in space (usually called λ_0 of free space or λ_g if inside the waveguide and expressed in meters) between two points having the same value in terms of field amplitude, phase, and correspondent derivatives.
- The **characteristic impedance** quantity is borrowed from transmission line theory and is also used for a waveguide to define the ratio between the transverse electric field and the corresponding transverse magnetic field. It is usually represented by the letter Z and is expressed in ohms. In case a structure supports more than one mode (for example TE and TM), two types of impedances corresponding to each mode (Z^{TE} and Z^{TM}) need to be identified.

5.3 Rectangular Waveguide

A rectangular waveguide is among the most commonly used waveguides. This is due to its manifacturing simplicity, low cost, and low-loss operation up to 100 GHz. Rectangular waveguides are also capable of handling very high-power microwave signals, and they are suitable for operations in outdoor environments. Because these waveguides are made of metals such as brass, copper, silver, or iron, they are heavy. Their

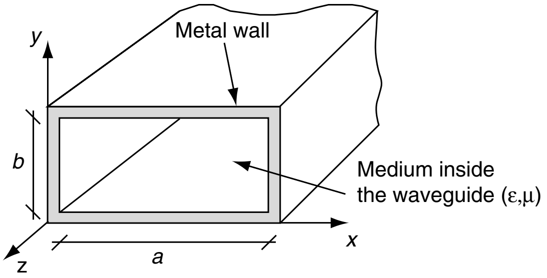

FIGURE 5.2 Schematic View of a Metallic Rectangular Waveguide

dimensions become large at low frequency (below X-band). A schematic view of a rectangular wave guide is shown in Figure 5.2.

5.3.1 Field Configuration

Because of its electrical topology (single conductor), a structure cannot support a static electric field, so it will not support TEM modes. The modes supported are TM. As mentioned earlier for these modes, either the electric or the magnetic field is zero along the direction of propagation (*z* direction in the figure). Starting from Maxwell's equations and imposing the proper boundary conditions for the field components on the four sides of the rectangular waveguide (Balanis, 1989), it is possible to derive the exact field expressions for all the field components in the guide. The reason there are more possible modes in a rectangular section waveguide (TE$_{mn}$TM$_{mn}$) is because imposing boundary conditions on the waveguide walls produce multiple solutions due to the periodicity of the trigonometric functions in which the fields are expressed:

TE$_{mn}$

$$E_x = A_{mn}\frac{\beta_v}{\varepsilon}\cos(\beta_x x)\sin(\beta_y y)e^{-j\beta_z z} \tag{5.2}$$

$$E_y = -A_{mn}\frac{\beta_x}{\varepsilon}\sin(\beta_x x)\cos(\beta_y y)e^{-j\beta_z z} \tag{5.3}$$

$$E_z = 0 \tag{5.4}$$

$$H_x = -A_{mn}\frac{\beta_x\beta_z}{\omega\mu\varepsilon}\sin(\beta_x x)\cos(\beta_y y)e^{-j\beta_z z} \tag{5.5}$$

$$H_y = -A_{mn}\frac{\beta_y\beta_z}{\omega\mu\varepsilon}\cos(\beta_x x)\sin(\beta_y y)e^{-j\beta_z z} \tag{5.6}$$

$$H_z = -A_{mn}\frac{\beta_c^2}{\omega\mu\varepsilon}\cos(\beta_x x)\cos(\beta_y y)e^{-j\beta_z z} \tag{5.7}$$

$$E_x = -B_{mn}\frac{\beta_x\beta_z}{\omega\varepsilon\mu}\cos(\beta_x x)\sin(\beta_y y)e^{-j\beta_z z} \tag{5.8}$$

$$E_y = -B_{mn}\frac{\beta_y\beta_z}{\omega\varepsilon\mu}\sin(\beta_x x)\cos(\beta_y y)e^{-j\beta_z z} \tag{5.9}$$

$$E_z = -jB_{mn}\frac{\beta_c^2}{\omega\varepsilon\mu}\sin(\beta_x x)\sin(\beta_y y)e^{-j\beta_z z} \tag{5.10}$$

$$H_x = B_{mn}\frac{\beta_y}{\mu}\sin(\beta_x x)\cos(\beta_y y)e^{-j\beta_z z} \tag{5.11}$$

$$H_y = -B_{mn}\frac{\beta_x}{\mu}\cos(\beta_x x)\sin(\beta_y y)e^{-j\beta_z z} \tag{5.12}$$

$$H_z = 0 \tag{5.13}$$

In all the equations listed under TE$_{mn}$ and TM$_{mn}$, A_{mn} and B_{mn} are the constant coefficients proportional to the amplitude of the TE$_{mn}$ and TM$_{mn}$ wave, respectively. $\beta_i^s(i \equiv x, y, or\ z)$ are the propagation constants along the three Cartesian directions, and they satisfy the following relationship:

$$\beta_x^2 + \beta_y^2 + \beta_z^2 = \beta^2 = \omega^2\varepsilon\mu, \tag{5.14}$$

where β is the propagation constant of the signal in the particular mudium and is linked to the operating frequency ($\omega = 2\pi f$) and material property (ε and μ). The propagation constants along each direction ($\beta_{x/y/z}$) are linked to the guide dimension and operating frequency using the following equations:

$$\beta_x = \frac{m\pi}{a}. \quad m = 0, 1, 2, \ldots \tag{5.15}$$

$$\beta_y = \frac{n\pi}{b}. \quad n = 0, 1, 2, \ldots \tag{5.16}$$

$$\beta_z = \sqrt{\beta^2 - \beta_c^2} = \sqrt{\beta^2 - \beta_x^2 - \beta_y^2};\ \beta_c = \sqrt{\beta_x^2 - \beta_y^2}. \tag{5.17}$$

The constant β_c represents the value of the propagation, for which there is no propagation along the *z* direction ($\beta_z = 0$). It is also referred to as the **cutoff wave number**. The cutoff frequency from a given mode *mn* (either TE or TM) is given by:

$$f_{mn} = \frac{1}{2\pi\sqrt{\varepsilon\mu}}\sqrt{\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2} = \frac{\beta_c}{2\pi\sqrt{\varepsilon\mu}}. \tag{5.18}$$

The phase velocity v_p of the wave along the direction of propagation is derived from equations 5.14 and 5.18 and is expressed as:

$$v_{p_{mn}} = \frac{\omega}{\beta_z} = \frac{1}{\sqrt{\varepsilon\mu}\sqrt{1 - (f_{mn}/f)^2}}. \tag{5.19}$$

Equation 5.19 provides the $\omega - \beta$ diagram for a waveguide operating with the TE$_{mn}$ or TM$_{mn}$ mode. The $\omega - \beta$ diagram is also known as a **dispersion diagram**. From equation 5.19, observe that when $f = f_c$, $v_p = \infty$ and $\beta_z = 0$. This is defined as the **cutoff frequency** of the waveguide (no propagation along the *z* direction). Also note that for a particular mode, the phase velocity of propagation along the guide varies with frequency. As a consequence of this characteristic of the guided wave propagation, the field patterns of different frequency components of a signal composing a band of frequencies do not maintain the same relationship as they propagate down the guide. This phenomenon is known as **dispersion**, so termed after the phenomenon of dispersion of colors by prism. The phase velocity is actually the speed of the constant phase points on the wave as it travels. So it does not represent the velocity of the propagating energy in the waveguide. The energy propagates at a speed equal to the group velocity (v_g) of the wave. The group velocity is related to the cutoff frequency as the following:

$$v_g = \frac{d\beta_z}{d\omega} = v_p\sqrt{1-[(f_c)_{mn}/f]^2}. \qquad (5.14)$$

Figure 5.3 shows the variations of the phase and group velocities versus the operating frequency.

From what has been illustrated so far, a signal of a given frequency can propagate in a rectangular waveguide in several modes for which the cutoff frequencies are less than the signal frequencies. Waveguides, are however, designed so that only one mode, the one with the lowest cutoff frequency, propagates. This is known as the **dominant mode**. The reason for using a single-mode waveguide is because in a multimode waveguide, the total energy is distributed among the propagating modes. For such a case, the instrumentation (e.g., detectors, exitation probes, etc.) required to detect the total power of multimode is more complex compared to instrumentation needed for single-mode operation.

From equation 5.18, the dominant mode is the $\text{TE}_{1,0}$ mode or the $\text{TE}_{0,1}$ mode depending on whether the dimension a or the dimension b is the larger of the two. By convention, the larger dimension is designed to be a, hence, the $\text{TE}_{1,0}$ mode is the dominant mode. For example, consider a rectangular waveguide with dimensions $a/b = 3.0$, $a/b = 2.0$, and $a/b = 1.0$, and find the propagation modes that occur in the guide. From equation 5.18, the cutoff frequency of the $\text{TE}_{1,0}$ case is the following:

$$[f_c]_{TE_{1,0}} = \frac{1}{2a\sqrt{\varepsilon\mu}}. \qquad (5.15)$$

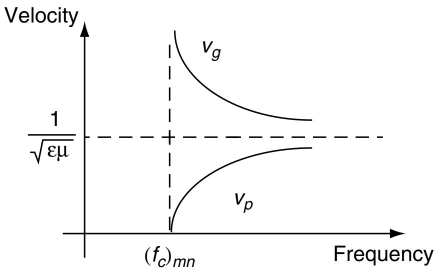

FIGURE 5.3 Variation of v_p and v_g with Frequency

$f_c/[f_c]_{TE_{1,0}}$

FIGURE 5.4 Cutoff Frequency of Different Modes in a Rectangular Waveguide for Different Ratios *a/b*.

Hence:

$$\frac{f_c}{[f_c]_{TE_{1,0}}} = \sqrt{m^2 + \left(n\frac{a}{b}\right)^2}. \qquad (5.16)$$

By assigning different pairs of values for m and n, the lowest four values of $f_c/[f_c]_{TE_{1,0}}$ can be computed for different ratios of *a/b* as reported in Figure 5.4.

From Figure 5.4 the second lowest cutoff frequency, for $b/a \leq 1/2$, which corresponds to that of the $\text{TE}_{2,0}$ mode, is twice the cutoff frequency of the dominant mode $\text{TE}_{1,0}$. For this reason, the dimension b of a rectangular waveguide is generally chosen to be less than or equal to $a/2$ to achieve a single-mode transmission over a complete octave (factor 2:1) range of frequencies.

5.3.2 Power

The field inside a waveguide has power associated with each mode propagating in the guide. The total **power** propagating can be calculated using the **Poynting vector formulation** to find the power associated with each mode in the waveguide. The result is reported as (Balanis, 1989).

$$P^{TE}_{m,n} = |A_{m,n}|^2 \frac{\beta_c^2}{2\eta\varepsilon}\left(\frac{a}{\varepsilon_{0,m}}\right)\left(\frac{b}{\varepsilon_{0,n}}\right)\sqrt{1-\left(\frac{f_{c,m,n}}{f}\right)^2}. \qquad (5.17)$$

$$P^{TM}_{m,n} = |B_{m,n}|^2 \frac{\beta_c^2\eta}{2\mu^2}\left(\frac{a}{2}\right)\left(\frac{b}{2}\right)\sqrt{1-\left(\frac{f_{c,m,n}}{f}\right)^2}. \qquad (5.18)$$

In equations 5.17 and 5.18, η is the wave medium impedance defined as $\eta = \sqrt{\mu/\varepsilon}$. The total power associated with the wave is the sum of all the power components associated with each mode that exist inside the waveguide.

5.3.3 Attenuation

An important parameter in a rectangular section waveguide is the **attenuation per unit length**. The attenuation for propagating modes in a waveguide results from two types of losses: those due to the dielectric imperfection (dielectric loss α_d) and those due to the finite conductivity of the waveguide metal walls (conductor loss α_c). The calculation of those losses is performed considering the time average power lost in the conducting walls and in the dielectric per unit length. The resulting expressions for this calculation are reported, respectively, for TE and TM modes as (Collin, 1991):

$$(\alpha_c)_{TE_{m,n}} = \frac{2R_s}{b\eta\sqrt{1-(f_c/f)}}\left\{\left(1+\frac{b}{a}\right)\left(\frac{f_c}{f}\right)^2 + \left[1-\left(\frac{f_c}{f}\right)^2\right]\left[\frac{\frac{b}{a}\left(\frac{b}{a}m^2+n^2\right)}{\frac{b^2m^2}{a^2}+n^2}\right]\right\}(np/m). \quad (5.19)$$

$$(\alpha_c)_{TM_{m,n}} = \frac{2R_s}{b\eta\sqrt{1-(f_c/f)}}\frac{m^2(b/a)^3+n^2}{m^2(b/a)^2+n^2}(np/m). \quad (5.20)$$

$$\alpha_D = \frac{k\varepsilon''/\varepsilon'}{2\sqrt{1-(f_c/f)^2}}(np/m). \quad (5.21)$$

In equations 5.19 through 5.21, η is the medium impedance, k is the propagation constant for the lossy medium, and R_s the surface resistivity due to the skin effect of the walls. The R_s value is obtained from the metal conductivity (σ_m) and its permeability (μ_m) by:

$$R_s = \sqrt{\pi f \mu_m/\sigma_m} \quad (5.22)$$

Note that the dielectric loss is independent from the type of mode (TE or TM), but it depends on the frequency of the mode. A complete reference table for a commercially available rigid rectangular waveguide and its fundamental characteristics are reported in Table 5.1.

The first two columns of Table 5.1 represent the waveguide designation name and the corresponding designated band

symbol. The third and fourth columns are the waveguide physical dimensions, and the fifth and sixth columns are the operating frequency and the cutoff frequency, respectively. The last column gives the loss per unit length for different plating materials in the waveguide internal walls, such as aluminum (Al), silver (Ag), and copper (Cu).

5.4 Partially Filled Metallic Rectangular Waveguide

A **dielectric-filled metallic waveguide** has the same property as an air-filled metallic waveguide with the only exception: the cutoff frequency for the modes is lower due to the presence of the dielectric ($\varepsilon > 1$ or $\mu > 1$) as seen from equation 5.18. A schematic view of this type of guide is given in Figure 5.5.

Partially filled waveguides are a classic type of waveguide with a dielectric slab placed on one wall of the guide, either the broad wall or the narrow one, as illustrated in Figure 5.6.

For this type of structure, the field distribution is a combination of TE and TM modes. Those modes are referred to as hybrid modes or longitudinal section electric (LSE) and longitudinal section magnetic (LSM) modes (Balanis, 1989). Using perturbation technique shows that, in general, the cutoff frequency of the partially filled waveguide is between the same air-filled waveguide and the one that is fully loaded:

$$\frac{1}{2b\sqrt{\mu\varepsilon}} \le (f_c)_{01}^{TE} \le \frac{1}{2b\sqrt{\mu_0\varepsilon_0}}. \tag{5.23}$$

$$\frac{1}{2a\sqrt{\mu\varepsilon}} \le (f_c)_{01}^{TM} \le \frac{1}{2a\sqrt{\mu_0\varepsilon_0}}. \tag{5.24}$$

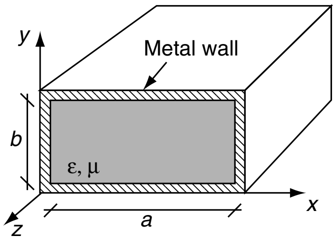

FIGURE 5.5 Cross Section of Dielectric-Filled Metallic Rectangular Waveguide

5.5 Circular Metal Waveguide

The **circular waveguide** is also very popular due to its simplicity in manufacturing and low attenuation of the fundamental mode. The circular waveguide is made of a cylindrical structure that maintains a uniform cross section along the length as illustrated in Figure 5.7. As in the case of a rectangular waveguide, the inside of the waveguide is either filled with air or with dielectric material.

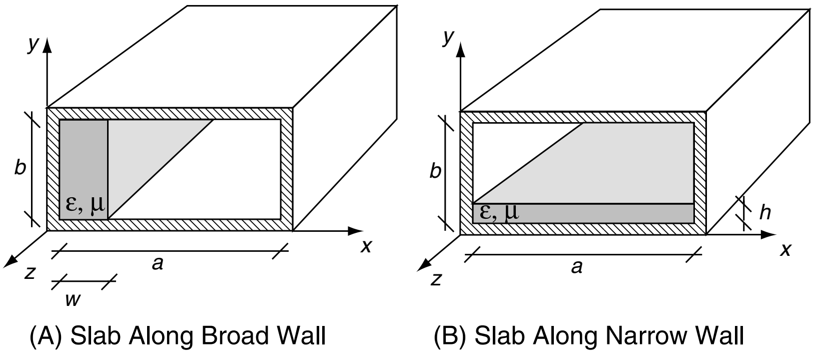
The field configurations (modes) that can be supported by such a structure are TE and TM modes along the longitudinal direction (z-axis in the figure). Starting from Maxwell's equations after proper expansion in cylindrical coordinates and imposing the boundary conditions, it is possible to obtain the propagation constant and the field distribution for each TE mode and TM mode in the waveguide. The propagation constant for the TE modes can be written as a function of the roots (χ'_{mn}) of the derivative of the Bessel function of the first kind (Balanis, 1989). The result is the following equation:

$$\beta_{mn} = \begin{cases} \sqrt{\beta^2 - \beta_\rho^2}, & \beta > \beta_\rho \\ 0, & \beta = \beta_\rho = \beta_c, \\ -j\sqrt{\beta_\rho^2 - \beta^2}, & \beta < \beta_\rho \end{cases} \tag{5.25}$$

where the following is true:

$$\beta_\rho = \frac{\chi'_{mn}}{a}. \tag{5.26}$$

In equation 5.25, χ'_{mn} is the mth root of the derivative of the nth order Bessel function, and β_c is called the **cutoff**



(A) Slab Along Broad Wall (B) Slab Along Narrow Wall

FIGURE 5.6 Schematic View of Dielectric Loaded Waveguide

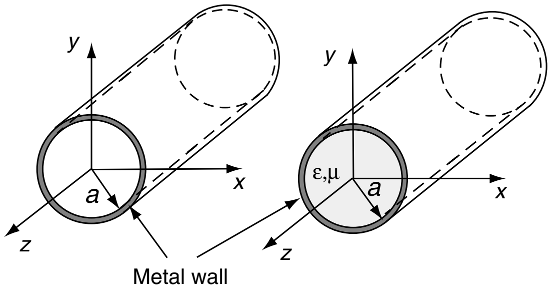


FIGURE 5.7 Circular Waveguide Structure

propagation constant of the *mn* mode. Since $\beta_c = \omega_c\sqrt{\varepsilon\mu}$, the result for the TE_{mn} mode is as written here:

$$(f_c)_{mn} = \frac{\chi'_{mn}}{2\pi a\sqrt{\varepsilon\mu}}. \tag{5.27}$$

The corresponding guide wavelength is defined as $(\lambda_g)_{mn} = \frac{2\pi}{(\beta_z)_{mn}}$ and is given by:

$$(\lambda_g)_{mn} = \begin{cases} \frac{2\pi}{\beta\sqrt{1-\left(\frac{f_c}{f}\right)^2}} & \text{for } f > (f_c)_{mn}. \\ \infty & \text{for } f = (f_c)_{mn}. \end{cases} \tag{5.28}$$

In equation 5.28, λ_g is the wavelength of the wave in an infinite medium having the same electrical property as the one inside the waveguide. Below the cutoff, there is no expression for the wavelength because the wave decays exponentially. The values of χ'_{mn} for the first five values of m and n are reported in Table 5.2.

The electric and magnetic field components for the TE_{mn} can be expressed in cylindrical coordinate as:

$$E_\rho = -A_{mn}\frac{m}{\varepsilon\rho}J_m(\beta_\rho\rho)[-C_2\sin(m\phi) + D_2\cos(m\phi)]e^{-j\beta_z z}. \tag{5.29}$$

$$E_\phi = A_{mn}\frac{\beta_\rho}{\varepsilon}J'_m(\beta_\rho\rho)[C_2\cos(m\phi) + D_2\sin(m\phi)]e^{-j\beta_z z}. \tag{5.30}$$

$$E_Z = 0. \tag{5.31}$$

$$H_\rho = -A_{mn}\frac{\beta_\rho\beta_z}{\omega\varepsilon\mu}J'_m(\beta_\rho\rho)[C_2\cos(m\phi) + D_2\sin(m\phi)]e^{-j\beta_z z}. \tag{5.32}$$

$$H_\phi = -A_{mn}\frac{m\beta_z 1}{\omega\mu\varepsilon}\frac{1}{\rho}J'_m(\beta_\rho\rho)[C_2\sin(m\phi) + D_2\cos(m\phi)]e^{-j\beta_z z}. \tag{5.33}$$

$n=2$	7.0156	5.3315	6.7062	8.0153	9.2824	10.5199
$n=3$	10.1735	8.5363	9.9695	11.3459	12.6819	13.9872
$n=4$	13.3237	11.7060	13.1704	14.5859	15.9641	17.3129
$n=5$	16.4706	14.8636	16.3475	17.7888	19.1960	20.5755

$$H_z = -jA_{mn}\frac{\beta_\rho^2}{\omega\varepsilon\mu}J_m(\beta_\rho\rho)[C_2\cos(m\phi) + D_2\sin(m\phi)]e^{-j\beta_z z}. \tag{5.34}$$

According to the values of χ'_{mn} in Table 5.2, the order in which the TE modes propagate along the z direction is TE_{11}, TE_{21}, TE_{01}, and so forth. The bandwidth of the first single-mode TE_{11} operation is 1.6588:1 (less than 2:1 obtained with rectangular waveguide obtained for $a/b \geq 2$).

The expression of the propagation constant for the TM modes can be written as function of the derivative (χ_{mn}), the Bessel function of the first kind, as:

$$\beta_{mn} = \begin{cases} \sqrt{\beta^2 - \beta_\rho^2} & , \beta > \beta_\rho \\ 0 & , \beta = \beta_\rho = \beta_c, \\ -j\sqrt{\beta_\rho^2 - \beta^2} & , \beta < \beta_\rho \end{cases} \tag{5.35}$$

where the following is true:

$$\beta_\rho = \frac{\chi_{mn}}{a}. \tag{5.36}$$

The β_c is the cutoff propagation constant of the *mn* mode. Since $\beta_c = \omega_c\sqrt{\varepsilon\mu}$, the result for the TE_{mn} mode is as written here:

$$(f_c)_{mn} = \frac{\chi_{mn}}{2\pi a\sqrt{\varepsilon\mu}}. \tag{5.37}$$

The corresponding guide wavelength is defined as $(\lambda_g)_{mn} = 2\pi/(\beta_2)_{mn}$ and is given by:

$$(\lambda_g)_{mn} = \begin{cases} \frac{2\pi}{\beta\sqrt{1-\left(\frac{f_c}{f}\right)^2}} & \text{for } f > (f_c)_{mn.} \\ \infty & \text{for } f = (f_c)_{mn.} \end{cases} \tag{5.40}$$

In equation 5.40, as in the case of TE waves, λ_g is the wavelength of the wave in an infinite medium having the same electrical property as the one inside the waveguide. The values of χ_{mn} for the first five values of m and n are reported in Table 5.3.

The electric and magnetic field components for the TM_{mn} modes can be expressed in cylindrical coordinates as:

TABLE 5.3 χ_{mn} for the First Five Values of m and n

	$m=0$	$m=1$	$m=2$	$m=3$	$m=4$	$m=5$
$n=1$	2.409	3.8318	5.1357	6.3802	7.5884	8.7715
$n=2$	5.5201	7.0156	8.4173	9.7610	11.0647	12.3386
$n=3$	8.6537	10.1735	11.6199	13.0152	14.3726	15.7002
$n=4$	11.7915	13.3237	14.7960	16.2235	17.6160	18.9801
$n=5$	14.9309	16.4706	17.9598	19.4094	20.8269	22.2178

$$E_\rho = -B_{mn}\frac{\beta_\rho\beta_z m}{\omega\varepsilon\mu}J_m(\beta_\rho\rho)[C_2\cos(m\phi) + D_2\sin(m\phi)]e^{-j\beta_z z}. \quad (5.41)$$

$$E_\phi = B_{mn}\frac{m\beta_z}{\omega\mu\varepsilon\rho}J_m(\beta_\rho\rho)[-C_2\sin(m\phi) + D_2\cos(m\phi)]e^{-j\beta_z z}. \quad (5.42)$$

$$E_z = -jB_{mn}\frac{\beta_\rho^2}{\omega\varepsilon\mu}J_m(\beta_\rho\rho)[C_2\cos(m\phi) + D_2\sin(m\phi)]e^{-j\beta_z z}. \quad (5.43)$$

$$H_\rho = -B_{mn}\frac{m}{\mu}\frac{1}{\rho}J_m(\beta_\rho\rho)[-C_2\sin(m\phi) + D_2\cos(m\phi)]e^{-j\beta_z z}. \quad (5.44)$$

$$H_\phi = -B_{mn}\frac{\beta_\rho}{\mu}J_m(\beta_\rho\rho)[C_2\cos(m\phi) + D_2\sin(m\phi)]e^{-j\beta_z z}. \quad (5.45)$$

$$H_z = 0. \quad (5.46)$$

According to the values of χ_{mn} of Table 5.3, the order in which the TM modes propagate along the z direction is TM_{01}, TM_{11}, TM_{21}, and so forth. The bandwidth of the first single-mode TM_{01} operation is 1.5933:1 (less than 2:1 of rectangular waveguide). From the results in the Tables 5.2 and 5.3, the order of the modes for circular waveguide is associated with the values of χ_{mn} and χ'_{mn} and the sequence of modes is as follows: TE_{11}, TM_{01}, TE_{21}, TE_{10}, TM_{11}, TE_{31}, and so forth. Because the zero of the Bessel function of the first kind is the same as the derivative of the Bessel function of order zero, the TE_{0n} and TM_{0n} modes have same cutoff frequency and are *degenerate*.

5.6 Microstrip Line

A **microstrip line** is a guided wave structure consisting of a strip conductor and a ground plane separated by a dielectric substrate as shown in Figure 5.8.

The electromagnetic field in the microstrip is not contained entirely in the substrate. Therefore, the propagating mode in the microstrip is not a pure TEM but a hybrid one. Assuming a quasi-TEM mode (valid for lower frequencies) of propagation in the microstrip line, the phase velocity is given by:

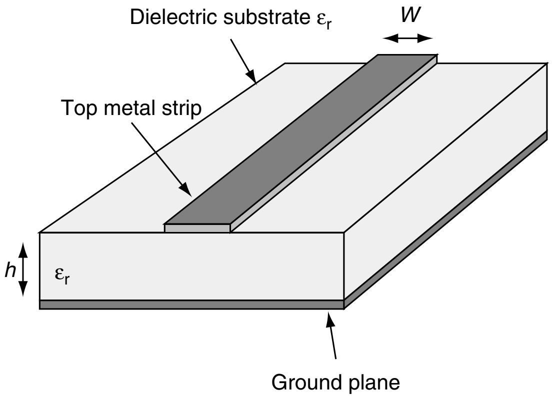

FIGURE 5.8 Microstrip Line Geometry

$$v_p = \frac{c}{\sqrt{\varepsilon_{ff}}}, \quad (5.47)$$

where c is the speed of light (3×10^8 m/sec), and ε_{ff} is the effective relative dielectric constant of the dielectric substrate.

5.6.1 Characteristic Impedance and Wavelength

The effective relative dielectric constant of the microstrip is related to the relative dielectric constant of the dielectric substrate, and the constant takes into account the effect of the external electromagnetic fields. The **characteristic impedance** of the microstrip line is given by:

$$Z_0 = \frac{1}{v_p C}, \quad (5.48)$$

where C is the capacitance per unit length of the microstrip. The **wavelength** in the microstrip is given by:

$$\lambda = \frac{v_p}{f} = \frac{c}{f\sqrt{\varepsilon_{ff}}} = \frac{\lambda_0}{\sqrt{\varepsilon_{ff}}}, \quad (5.49)$$

where λ_0 is the free space wavelength ($\lambda_0 = c/f$). There are different methods for determining ε_{ff} and C. Of course, closed-form expressions are of great importance in microstrip line design. The evaluation of ε_{ff} and C based on a quasi-TEM approximation is accurate for design at lower microwave frequencies. At higher microwave frequencies, however, the longitudinal components of the electromagnetic fields are significant, and the quasi-TEM assumption is no longer valid. A useful set of relations for the characteristic impedance, assuming zero or negligible thickness of the strip conductor (i.e., $t/h < 0.005$), is provided here (Bahl, 1977):

$$\begin{cases} Z_0 = \frac{60}{\sqrt{\varepsilon_{ff}}}\ln\left(8\frac{h}{W} + 0.25\frac{W}{h}\right) & \text{for } W/h \leq 1.0. \\ Z_0 = \frac{120\pi/\sqrt{\varepsilon_{ff}}}{W/h + 1.393 + 0.667\ln(W/h + 1.444)} & \text{for } W/h \geq 1.0. \end{cases} \quad (5.50)$$

For equations 5.50:

$$\begin{cases} \varepsilon_{ff} = \frac{\varepsilon_r+1}{2} + \frac{\varepsilon_r-1}{2}\left[\left(1 + 12\frac{h}{W}\right)^{-1/2} + 0.04\left(1 - \frac{W}{h}\right)^2\right] & \text{for } W/h \leq 1.0. \\ \varepsilon_{ff} = \frac{\varepsilon_r+1}{2} + \frac{\varepsilon_r-1}{2}\left[\left(1 + 12\frac{h}{W}\right)^{-1/2}\right] & \text{for } W/h \geq 1.0. \end{cases} \quad (5.51)$$

Based on the results for equations 5.49 through 5.51 and/or in experimental data, the wavelength in the microstrip line, assuming zero or negligible thickness (i.e., $t/h \leq 0.005$) for the strip conductor, is given by the relations (Sobol, 1967):

$$\begin{cases} \lambda = \frac{\lambda_0}{\sqrt{\varepsilon_r}}\left[\frac{\varepsilon_r}{1 + 0.63(\varepsilon_r - 1)(W/h)^{0.1255}}\right]^{1/2} & \text{for } W/h \geq 0.6. \\ \lambda = \frac{\lambda_0}{\sqrt{\varepsilon_r}}\left[\frac{\varepsilon_r}{1 + 0.63(\varepsilon_r - 1)(W/h)^{0.1255}}\right]^{1/2} & \text{for } W/h \leq 0.6. \end{cases} \quad (5.52)$$

For design purposes, a set of equations relating Z_0 and ε_r to the ratio *W/h* of the microstrip line is desirable. Assuming zero or negligible thickness of the strip conductor (i.e., $t/h < 0.005$), the expressions are as follows (Sobol, 1971):

$$\begin{cases} \frac{W}{h} = \frac{8e^A}{e^{2A}-2} & \text{for} \quad W/h \leq 2.0. \\ \frac{W}{h} = \frac{2}{\pi}\Big\{B - 1 - \ln(2B-1) + \frac{\varepsilon_r - 1}{2\varepsilon_r} & \\ \qquad \Big[\ln(B-1) + 0.39 - \frac{0.61}{\varepsilon_r}\Big]\Big\} & \text{for} \quad W/h \geq 2.0. \end{cases} \tag{5.53}$$

For equations 5.53:

$$A = \frac{Z_0}{60}\sqrt{\frac{\varepsilon_r + 1}{2}} + \frac{\varepsilon_r - 1}{\varepsilon_r + 1}\left(0.23 + \frac{0.11}{\varepsilon_r}\right), \tag{5.54}$$

and

$$B = \frac{377\pi}{2Z_0\sqrt{\varepsilon_r}}. \tag{5.55}$$

The zero or negligible thickness formulas given in equations 5.50 to 5.55 can be modified to include the thickness of the strip conductor. The first-order effect of a strip conductor of finite thickness t is to increase the capacitance. Therefore, an approximate correction is made by replacing the strip width W by the effective width W_{eff}. The following relations for W_{eff}/h are useful when $t < h$ and $t < W/2$:

$$\begin{cases} \frac{W_{eff}}{h} = \frac{W}{h} + \frac{t}{\pi h}\left(1 + \ln\frac{2h}{t}\right) & \text{for } W/h \geq 0.5\pi. \\ \frac{W_{eff}}{h} = \frac{W}{h} + \frac{t}{\pi h}\left(1 + \ln\frac{4\pi W}{t}\right) & \text{for } W/h \leq 0.5\pi. \end{cases} \tag{5.56}$$

The restrictions $t < h$ and $t < W/2$ are usually satisfied because for dielectric substrates, a typical thickness is $t = 0.002$ in. The formulas presented thus far are valid at frequencies where the quasi-TEM assumption can be made. When the quasi-TEM assumption is not valid, ε_{ff} and Z_0 are functions of frequency and, therefore, the microstrip line becomes dispersive. The phase velocity of the microstrip line decreases with increasing frequency. Therefore, $\varepsilon_{ff}(f)$ increases with frequency. Moreover, the characteristic impedance of the microstrip line increases with frequency, and it follows that the effective width $W_{eff}(f)$ decreases. The frequency in equation 5.57, in which dispersion may be neglected, is given by:

$$f_0(GH_z) = 0.3\sqrt{\frac{Z_0}{h\sqrt{\varepsilon_r - 1}}}, \tag{5.57}$$

where h must be expressed in centimeters. An analytical expression that shows the effect of dispersion in $\varepsilon_{ff}(f)$ is the following (Bahl and Trivedi, 1977):

$$\varepsilon_{ff}(f) = \varepsilon_r - \frac{\varepsilon_r - \varepsilon_{ff}}{1 + G\left(f/f_p\right)^2} \text{ [}f\text{ in gigahertz]}, \tag{5.58}$$

where:

$$f_p = \frac{Z_0}{8\pi h} \text{ [}h\text{ in centimeters]}, \tag{5.59}$$

and

$$G = 0.6 + 0.009Z_0. \tag{5.60}$$

Observe that when $f_p \gg f$, then $\varepsilon_{ff}(f) = \varepsilon_{ff}$. In other words, high-impedance lines on thin substrates are less dispersive. The expression for the dispersion in Z_0 is (Bahl and Trivedi, 1977):

$$Z_0(f) = \frac{377h}{W_{eff}(f)\sqrt{\varepsilon_{ff}}}, \tag{5.61}$$

where the following is true:

$$W_{eff}(f) = W + \frac{W_{eff}(0) - W}{1 + \left(f/f_p\right)^2}, \tag{5.62}$$

and

$$W_{eff}(0) = \frac{377h}{Z_0(0)\sqrt{\varepsilon_{ff}(0)}}. \tag{5.63}$$

5.6.2 Attenuation

The **attenuation constant** is a function of the microstrip geometry, the electrical properties of the dielectric substrate and the conductors, and frequency. There are two types of losses in a microstrip line: a dielectric substrate loss and than ohmic skin loss in the conductors. The losses can be expressed as a loss per unit length along the microstrip line in terms of the attenuation factor α. The power carried by a wave traveling in the positive direction in a quasi-TEM mode is given by:

$$P^+(z) = \frac{1}{2}\left(V^+e^{-\alpha z}I^+e^{-\alpha z}\right) = \frac{1}{2}\frac{|V^+|^2}{Z_0}e^{-2\alpha z} = P_0e^{-2\alpha z}, \tag{5.64}$$

where $P_0 = |V^+|^2/2Z_0$ is the power at $z = 0$. Then, from equation 5.64:

$$\alpha = \frac{-dP(z)/dz}{2P(z)} = \alpha_d + \alpha_c, \tag{5.65}$$

where α_d is the dielectric loss factor and where α_c the conduction loss factor. A useful set of expressions for calculating α_d (Bahl and Trivedi, 1977) for a dielectric with low losses is written as:

$$\alpha_d = 27.3\frac{\varepsilon_r}{\sqrt{\varepsilon_{ff}}}\frac{\varepsilon_{ff} - 1}{\varepsilon_r - 1}\frac{\tan\delta}{\lambda_0} \text{ [decibels/centimeter]}, \tag{5.66}$$

where the loss tangent δ is given by:

$$\tan\delta = \frac{\sigma}{\omega\varepsilon}. \tag{5.67}$$

For a dielectric with $\sigma \neq 0$:

$$\alpha_d = 4.34 \frac{\varepsilon_{ff} - 1}{\sqrt{\varepsilon_{ff}}(\varepsilon_r - 1)} \left(\frac{\mu_0}{\varepsilon_0}\right)^{1/2} \sigma[\text{decibels/centimeter}]. \tag{5.68}$$

In (38) and (40) σ is the conductivity of the dielectric and $\mu_0 = 4\pi \times 10^{-7}$ H/m. A set of expressions for calculating α_c is as follows (Bahl and Trivedi, 1977)

$$\alpha_c = \frac{8.68}{Z_0 W} R_s \quad \text{for } W/h \to \infty, \tag{5.69}$$

where these equations apply:

$$R_s = \sqrt{\frac{\pi f \mu_0}{\sigma}}. \tag{5.70}$$

$$\alpha_c = \frac{8.68 R_s P}{2\pi Z_0 h}\left[1 + \frac{h}{W_{eff}} + \frac{h}{\pi W_{eff}}\left(\ln\frac{4\pi W}{t} + \frac{t}{W}\right)\right] \quad \text{for } W/h \leq 1/2\pi. \tag{5.71}$$

$$\alpha_c = \frac{8.68 R_s}{2\pi Z_0 h} PQ \qquad \text{for} \frac{1}{2}\pi < W/h \leq 2. \tag{5.72}$$

$$\alpha_c = \frac{8.68 R_s Q}{Z_0 h}\left\{\frac{W_{eff}}{h} + \frac{2}{\pi}\ln\left[2\pi e\left(\frac{W_{eff}}{2h} + 0.94\right)\right]\right\}^{-2} \left[\frac{W_{eff}}{h} + \frac{W_{eff}/\pi h}{(W_{eff}/2h) + 0.94}\right] \text{for } W/h \geq 2. \tag{5.73}$$

In equations 5.69 through 5.73:

$$P = 1 - \left(\frac{W_{eff}}{4h}\right)^2 \tag{5.74}$$

and

$$Q = 1 + \frac{h}{W_{eff}} + \frac{h}{\pi W_{eff}}\left(\ln\frac{2h}{t} - \frac{t}{h}\right). \tag{5.75}$$

In dielectric substrates, the dielectric losses are normally smaller than conductor losses. Dielectric losses in silicon substrates, however, can be of the same order or larger than conductor losses.

5.7 Slot Line

A **slot line** is another planar waveguide that is used above X-band. The basic configuration of a slot line is shown in Figure 5.9.

The line consists of a dielectric substrate and a narrow slot on one side of the substrate, the other side is without metallization. In a slot line, the wave propagates along the slot with major electric field component oriented across the slot in the plane of metallization. The mode of propagation is non-TEM and almost transverse electric in nature. However, unlike the conventional waveguide, there is no low frequency cutoff because the slotline is a two-conductor structure. The most widely used method of slotline analysis is the one given by Cohn and employs a transverse resonance approach. Most methods used to find the wavelength and impedance for this type of waveguide are based on numerical formulation, and they do not provide closed form expressions. This becomes a serious handicap for circuit analysis and design. Closed form expression has been obtained by curve-fitting the results based on Cohn's analysis. These expressions have an accuracy of the order of 2% for the following set of parameters:

$$\begin{aligned} 9.7 \leq \varepsilon_r &\leq 20 \\ 0.02 \leq W/h &\leq 1.0 \\ 0.01 \leq h/\lambda_0 &\leq (h/\lambda_0)_c \end{aligned} \tag{5.76}$$

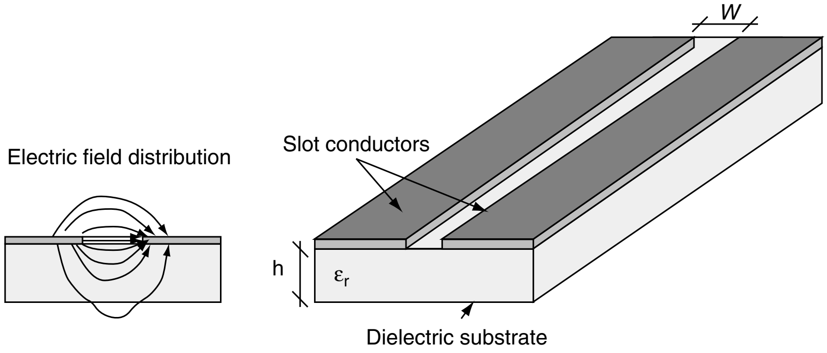

FIGURE 5.9 Slot Line Geometry

The $(h/\lambda_0)c$ is equal to the cutoff value for the TE_{10} surface wave mode on the slot line and is given by:

For $0.02 \leq \varepsilon_r \leq 0.2$:

$$\begin{aligned}\lambda_s/\lambda_0 &= 0.923 - 0.448\log\varepsilon_r \\ &\quad + 0.2W/h - (0.29W/h + 0.047)\log(h/\lambda_0 10^2).\end{aligned} \tag{5.77}$$

$$\begin{aligned}Z_{0s} &= 72.62 - 35.19\log\varepsilon_r + 50\frac{(W/h - 0.02)(W/h - 0.1)}{W/h} \\ &\quad + \log(W/h - 10^2) \times (44.28 - 19.58\log\varepsilon_r) + [0.32\log\varepsilon_r - 0.11 \\ &\quad + W/h(1.07\log\varepsilon_r + 1.44)] \times (11.4 - 6.07\log\varepsilon_r - h/\lambda_0 10^{-2})^2.\end{aligned} \tag{5.78}$$

for $0.2 \leq \varepsilon_r \leq 1.0$:

$$\begin{aligned}\lambda_s/\lambda_0 &= 0.987 - 0.4483\log\varepsilon_r + W/h(0.111 - 0.0022\varepsilon_r) \\ &\quad - (0.121 - 0.094W/h + -0.0032\varepsilon_r) \times \log(h/\lambda_0 10^2).\end{aligned} \tag{5.79}$$

$$\begin{aligned}Z_{0S} &= 113.19 - 353.55\log\varepsilon_r + 1.25W/h(114.59 - 51.88\log\varepsilon_r) \\ &\quad + 20(W/h - 0.2) \times (1 - W/h) - [0.15 + 0.23\log\varepsilon_r \\ &\quad + W/h(-0.79 + 2.07\log\varepsilon_r)] \times [10.25 - 5\log\varepsilon_r \\ &\quad + W/h(2.1 - 1.42\log\varepsilon_r) - h/\lambda_0 10^2]^2.\end{aligned} \tag{5.80}$$

Note the all the logarithms are assumed to be with respect to base 10.

5.8 Coplanar Waveguide

A **coplanar waveguide** consists of a center strip with two ground planes located parallel to and in the plane of the strip, as shown in Figure 5.10.

Quasistatic analysis formulation for CPW is available (Gupta, 1979). The synthesis formulas take the following closed-form expressions.

When the following equations result:

$$\frac{S}{H} \leq \frac{10}{3(1 + \ln\varepsilon_r)} \text{ and } \frac{W}{H} \leq \frac{80}{3(1 + \ln\varepsilon_r)},$$

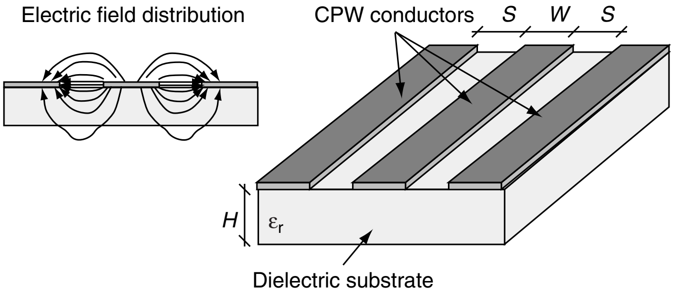

FIGURE 5.10 Coplanar Line Geometry

Then:

$$W = S \cdot G(\varepsilon_r, H, Z_0, S), \tag{5.81}$$

with:

$$G = \begin{cases} \left[\frac{1}{4}\exp\left(\frac{\pi}{4\varepsilon_{re}}\frac{\eta_0}{Z_0}\right) + \exp\left(-\frac{\pi}{4\varepsilon_{re}}\frac{\eta_0}{Z_0}\right) - 1\right] & \text{for } Z_0 < \frac{\eta_0}{\sqrt{2(\varepsilon_r+1)}}. \\ \left[\frac{1}{8}\exp\left(2\pi\sqrt{\varepsilon_{re}}\frac{Z_0}{\eta_0}\right) - \frac{1}{2}\right]^{-1} & \text{for } Z_0 \geq \frac{\eta_0}{\sqrt{2(\varepsilon_r+1)}}. \end{cases} \tag{5.82}$$

The ε_{re} is a relative effective dielectric constant:

$$\varepsilon_{re} = \varepsilon_{re}(\varepsilon_r, H, Z_0, S) = AB, \tag{5.83}$$

with these equations:

$$A = 1 + \sqrt{2}(\varepsilon_r - 1)\sqrt{\varepsilon_r + 1}\frac{Z_0}{\eta_0}\frac{K(k)}{K(k')}. \tag{5.84}$$

$$\begin{aligned}B = \operatorname{sech}&\left\{\frac{\varepsilon_r^5}{4\pi(\varepsilon_r + 1)^6}\left(\frac{\eta_0}{Z_0}\right)^2.\right. \\ &\left.\exp\left[\left(1 + 0.0016\varepsilon_r Z_0\frac{S}{H}\right)\ln\left(0.6 + \frac{S}{H}\right)\right]\right\}.\end{aligned} \tag{5.85}$$

$$k = \frac{\exp\left(\frac{\pi(1+g)S}{2H}\right) - \exp\left(\frac{\pi S}{2H}\right)}{\exp\left(\frac{\pi(2+g)S}{2H}\right) - 1}. \tag{5.86}$$

$$k' = \sqrt{1 - k^2}. \tag{5.87}$$

$$g = G|_{\varepsilon_{re}} = \frac{\varepsilon_r + 1}{2}. \tag{5.88}$$

$$\eta_0 = 120\,\pi\ \Omega. \tag{5.89}$$

The $K(k)/K(k')$ is the ratio of complete elliptic integrals of the first kind (Abramowitz and Stegun, 1972). Therefore, in a CPW wave guide design, for a given substrate (ε_r, H) and a required characteristic impedance Z_0, the central conductor width W can be evaluated immediately by choosing an appropriate gap width S.

5.9 Dielectric Circular Waveguide and Optical Fiber

Optical fiber is a guiding structure consisting of a core and a cladding that have a circular cross section, as illustrated in Figure 5.11.

The core (radius a) is made of a material with permittivity greater than that of the cladding (radius b) so that a critical angle exists for waves inside the core incident on the interface between the core and the cladding. Hence, **waveguiding** is made possible in the core by total internal reflection. Although

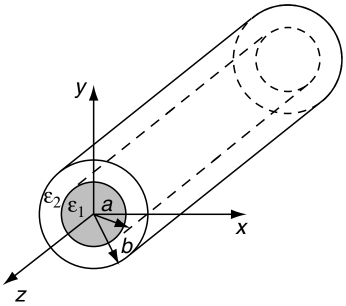

FIGURE 5.11 Circular Optical Fiber Waveguide Structure

the cladding is not necessary for the purpose of waveguiding, since the permittivity of the air is smaller than the permittivity of the fiber, it avoids scattering by the supporting structure of the fiber because the field decays exponentially outside the core, hence, it is very small outside the cladding. Moreover, the cladding allows a single-mode propagation for a larger value of the radius of the core than permitted in the absence of it. A common approach to simplify the analysis of this type of structure is to consider the cladding region to extend to infinity, having relative dielectric constant equal to one (air). From the application of Maxwell's equations to the problem illustrated, it turns out that TE and TM modes are not supported by this structure because there is no metal to separate the core from the outside dielectric. It is important to identify two modes for the structure, the ones inside the rod ($\rho < a$) and the ones outside the rod ($\rho > a$). For this structure to act as a waveguide, the fields outside the rod must vanish and exhibit a decay in the radial direction. The diameter of the rod in this structure is very important: an increase in the diameter reduces the attenuation of the field inside the rod, increases the distance to which the fields outside the rod extend, while producing a propagation constant slightly higher to the one of free space. The field distribution inside a dielectric waveguide is a combination of TE (or H) and TM (or E) modes. One way to designate hybrid modes is to denote them as HE when the TE modes predominate or EH when TM modes predominate. Pure TE or TM modes exhibit cutoff frequencies below which attenuating modes cannot propagate. The cutoff frequency is determined by the minimum electrical radius (a/λ) of the rod. For small values of a/λ, the modes cannot propagate unattenuated in the rod. There is, however, one hybrid mode called the HE_{11} that does not have a cutoff frequency. This mode is called the **dominant mode** or **dipole mode** because it is used in end-fire antennas. The field components of the modes in the internal rod are given in these equations:

$$E_\rho = -j\frac{1}{\beta_\rho^2}\left[m\omega\mu A_m \frac{J_m(\beta_\rho\rho)}{\rho} + \beta_z\beta_\rho B_m J_m(\beta_\rho\rho)\right]\cos(m\phi)e^{-j\beta_z z}. \quad (5.90)$$

$$E_\phi = j\frac{1}{\beta_\rho^2}\left[\omega\beta_\rho\mu A_m J_m(\beta_\rho\rho) + m\beta_z B_m \frac{1}{\rho} J_m(\beta_\rho\rho)\right]\sin(m\phi)e^{-j\beta_z z}. \quad (5.91)$$

$$E_z = B_m J_m(\beta_\rho\rho)\cos(m\phi)e^{-j\beta_z z} \quad (5.92)$$

$$H_\rho = -j\frac{1}{\beta_\rho^2}\left[m\omega\varepsilon B_m \frac{J_m(\beta_\rho\rho)}{\rho} + \beta_z\beta_\rho A_m J_m(\beta_\rho\rho)\right]\sin(m\phi)e^{-j\beta_z z}. \quad (5.93)$$

$$H_\phi = -j\frac{1}{\beta_\rho^2}\left[\omega\beta_\rho\varepsilon B_m J_m(\beta_\rho\rho) + m\beta_z A_m \frac{1}{\rho} J_m(\beta_\rho\rho)\right]\cos(m\phi)e^{-j\beta_z z}. \quad (5.94)$$

$$H_z = A_m J_m(\beta_\rho\rho)\sin(m\phi)e^{-j\beta_z z}. \quad (5.95)$$

In equations 5.90 through 5.95:

$$\beta_\rho^2 + \beta_z^2 = \beta^2 = \omega^2\varepsilon\mu. \quad (5.96)$$

$$A_m = -j\frac{\beta_\rho^2}{\omega\varepsilon\mu}A_{mn}D_2. \quad (5.97)$$

$$\begin{aligned} B_m &= -j\frac{\beta_\rho^2}{\omega\varepsilon\mu}B_{mn}C_2 \\ &= \frac{\partial}{\partial(\beta_\rho\rho)} \end{aligned} \quad (5.98)$$

Note that in equations 5.97 and 5.98, the coefficients A_m and B_m are dependent of each other, and their dependence can be found by applying the proper boundary conditions. To find the propagating mode in the rod for a given radius of the rod, it is necessary to write the field expression outside the rod and impose that this field decays for increasing radius. Upon application of this procedure, it is possible to determine an eigenvalue equation for the rod that gives a relationship between the fiber parameters and the minimum radius of the rod capable of supporting guided modes. The relationship is expressed as:

$$(\beta_\rho a)_{\max} = \omega a\sqrt{\varepsilon_0\mu_0(\varepsilon_r - 1)}. \quad (5.99)$$

5.10 Line-Type Waveguide

A transmission line can also be considered as a guiding structure because it forces propagation of the electromagnetic field in a specific direction. The fundamental mode in the transmission lines illustrated in Figure 5.12 is the transverse electric and magnetic mode (TEM).

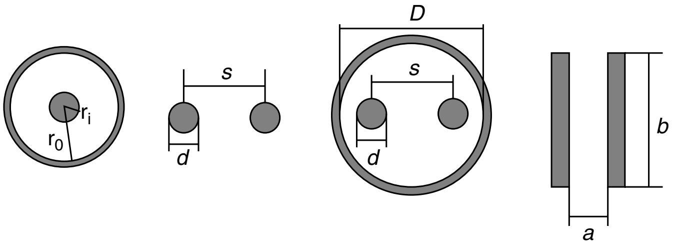

FIGURE 5.12 Fundamental Mode TEM: Transmission Lines

TABLE 5.4 Basic Parameters of Line-Type Waveguide

Capacitance [farad/meter]	$\frac{2\pi}{\ln(r_0/r_i)}$	$\frac{\pi\varepsilon}{\cosh^{-1}(s/d)}$	*Not defined*	$\frac{\varepsilon b}{a}$
Inductance (external) [henry/meter]	$\frac{\mu}{2\pi}\ln(r_0/r_i)$	$\frac{\mu}{\pi}\cosh^{-1}(s/d)$	*Not defined*	$\frac{\mu a}{b}$
Conductance [siemens/meter]	$\frac{2\pi\omega\varepsilon''}{\ln(r_0/r_i)}$	$\frac{\pi\omega\varepsilon''}{\cosh^{-1}(s/d)}$	*Not defined*	$\frac{\omega\varepsilon'' b}{a}$
Resistivity [ohms per meter]	$\frac{R_s}{2\pi}\left(\frac{1}{r_0}+\frac{1}{r_i}\right)$	$\frac{2R_s}{\pi d}\left[\frac{s/d}{\sqrt{(s/d)^2-1}}\right]$	*See note*	$\frac{2R_s}{b}$
High frequency internal inductance [henry/meter]	R/ω	R/ω	R/ω	R/ω
Characteristic impedance [ohms]	$\frac{\eta}{2\pi}\ln(r_0/r_i)$	$\frac{\eta}{\pi}\cosh^{-1}(s/d)$	*See note*	$\eta\frac{a}{b}$
Conductor attenuation α_c	$R/2Z_0$	$R/2Z_0$	$R/2Z_0$	$R/2Z_0$
Dielectric attenuation α_d	$\frac{\pi}{\lambda}\frac{\varepsilon''}{\varepsilon'}$	$\frac{\pi}{\lambda}\frac{\varepsilon''}{\varepsilon'}$	$\frac{\pi}{\lambda}\frac{\varepsilon''}{\varepsilon'}$	$\frac{\pi}{\lambda}\frac{\varepsilon''}{\varepsilon'}$
Total attenuation [decibels/meter]	$8.686(\alpha_c+\alpha_d)$	$8.686(\alpha_c+\alpha_d)$	$8.686(\alpha_c+\alpha_d)$	$8.686(\alpha_c+\alpha_d)$
Propagation constant β (for low-loss case)	$\omega\sqrt{\mu\varepsilon'}=2\pi/\lambda$	$\omega\sqrt{\mu\varepsilon'}=2\pi/\lambda$	$\omega\sqrt{\mu\varepsilon'}=2\pi/\lambda$	$\omega\sqrt{\mu\varepsilon'}=2\pi/\lambda$

Note: Assume $p = s/d$ and $q = s/D$.
Note: All the units in Table 5.4 are in the MKS system, and R_S is the surface resistance of the conductor due to the skin effect.

For this type of waveguide, it is important to evaluate the capacitance and the inductance per unit length, respectively. These two parameters enable the computation of the characteristic impedance of the line. To characterize the propagation, the propagation constant can be identified for the line, whereas the loss is divided in dielectric loss (α_d) and conductor loss (α_c). Table 5.4 illustrates the fundamental parameters of four different types of transmission line that are used in practice. The **first type of line** is the coaxial transmission line. This line is made out of a central conductor surrounded by a grounded one. The separation between the two conductors can be simple air or dielectric. Air-filled coaxial lines are very attractive because of very low dielectric loss. They are, however, difficult to manufacture since the central conductor must be suspended in air.

The **second line** presented in Table 5.4 is made out of two wires (signal-ground) running parallel to each other. The diameter of the conductor is indicated with d and the separation with s. There are several variations of this simple transmission line, among them the most common is called '**twisted pair**', and it consists of two wires twisted with each other, forming a helix.

The **third line** is a combination of the first two and consists of two parallel conductors shielded by a circular shaped electric shell that is usually grounded.

The **last line** is made of two parallel thin plates facing each other, having air or dielectric as the separation medium.

$$\begin{aligned}\text{Resistivity[ohm]} = {}& \frac{2R_{s2}}{\pi d}\left[1+\frac{1+2p^2}{4p^4}\left(1-4q^2\right)\right] \\ &+\frac{8R_{s3}}{\pi D}q^2\left[1+q^2-\frac{1+4p^2}{8p^4}\right].\end{aligned} \tag{5.100}$$

$$\begin{aligned}\text{Char impedance[ohm]} = {}& \frac{\eta}{\pi}\left\{\ln\left[2p\left(\frac{1-q^2}{1+q^2}\right)\right]\right. \\ &\left.-\frac{1+4p^2}{16p^4}\left(1-4q^2\right)\right\}.\end{aligned} \tag{5.101}$$

Antenna Fundamentals

6.1 Introduction

An **antenna** is a device used for transmission or reception of **electromagnetic waves**, allowing **radio-frequency** communication between distant locations across empty space or other material media. Antennas are fabricated using conducting and/or dielectric materials, are designed with desirable radiation or reception characteristics, and employ suitable coupling arrangements to an external port for an input/output (I/O) connection. The **I/O** may be used for exciting the antenna from a radio-frequency **signal source** or for coupling any radio-frequency signal received by the antenna to an output load, respectively, when operated as a **transmitter** or a **receiver**. Depending on the particular application and technical requirements, an antenna can be a very simple form, like a piece of metal wire or rod used in a **car or home radio**, or can be much more complex in shape and size for more sophisticated applications in **wireless communication** and **radar**. This chapter studies the fundamental operation of a general antenna structure, independent of its specific configuration and application, and device basic performance parameters commonly used in antenna technology.

Specifically, this discussion analyzes basic antenna parameters under four operating conditions: (1) antenna as a transmitter, (2) antenna as a receiver, (3) antenna in a transmit–receive communication link, and (4) antenna as a scatterer. For related studies on fundamental antenna parameters or for information on more advanced concepts of antenna theory, one may refer to some of the standard antenna books such as those by Balanis (1997), Kraus and Fleisch (1999), Kraus (1950), Jasik (1961), Collin and Zucker (1969), and Schelkunoff and Friis (1952).

6.2 Antenna as a Transmitter

6.2.1 Basic Far-Field Relations

Figure 6.1 shows the geometry of a general radiating antenna placed at the origin of a spherical co-ordinate system (r, θ, ϕ). The electric field $\bar{E}$ and the magnetic field $\bar{H}$ of any arbitrary antenna, as observed in the far-field region, can be expressed in a general form as follows. It is assumed that the antenna is excited from a time-harmonic source and that the field expressions represent the corresponding complex phasors:

$$\bar{E}(r, \theta, \phi) = \hat{\theta}E_\theta(r, \theta, \phi) + \hat{\phi}E_\phi(r, \theta, \phi). \tag{6.1}$$

$$\bar{H}(r, \theta, \phi) = \hat{\theta}H_\theta(r, \theta, \phi) + \hat{\phi}H_\phi(r, \theta, \phi). \tag{6.2}$$

$$|\bar{E}(r, \theta, \phi)| = \sqrt{|E_\theta(r, \theta, \phi)|^2 + |E_\phi(r, \theta, \phi)|^2}. \tag{6.3}$$

$$\bar{H} = \frac{\hat{r} \times \bar{E}}{\eta_0}, \ \frac{|\bar{E}|}{|\bar{H}|} = \frac{E_\theta}{H_\phi} = -\frac{E_\phi}{H_\theta} = \eta_0 = \sqrt{\frac{\mu_0}{\varepsilon_0}} = 120\pi \tag{6.4}$$

The far-field region may be loosely defined to be sufficiently far away from the antenna (i.e., $r \rightarrow \infty$). In this region, the radiating fields behave like a uniform plane wave, having no field component along the radial direction ($\hat{r}$). Using the basic principles of a plane wave (Cheng, 1993; Rao, 2000; Ramo *et al.*, 1993), one can relate the magnetic field $\bar{H}$ in the far-field region to the corresponding electric field $\bar{E}$ in a quite simple manner, as given in equation 6.4. Therefore, it may be convenient and sufficient to use only the electric field $\bar{E}$ to model various far-field antenna parameters.

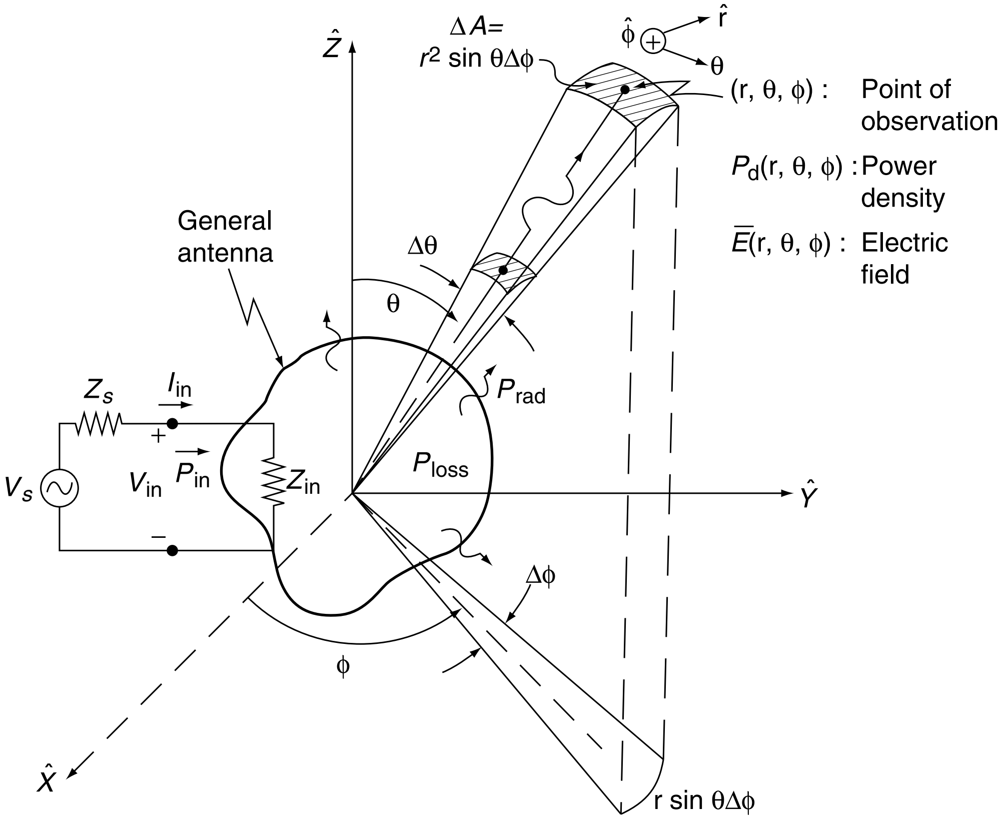

FIGURE 6.1 A General Antenna Geometry in a Spherical Coordinate System, Showing its Radiation Fields and Input Excitation

6.2.2 Radiation Power Density

The electromagnetic power flows in radial direction $\hat{r}$. The power density of radiation, P_d, is defined as the time-average power flow per unit area, ΔA, perpendicular to the power flow:

$$\Delta P = \bar{S}(r, \theta, \phi) \cdot \hat{n}\,\Delta A = P_d(r, \theta, \phi)\hat{r} \cdot \hat{n}\,\Delta A, \qquad (6.5)$$

where the vector $\bar{S}(r, \theta, \phi) = \hat{r}P_d(r, \theta, \phi)$ is called the power-flow vector or the Poynting vector and where $\hat{n}$ is normal to the surface ΔA. The power density, P_d, is related to the electric-field magnitude:

$$P_d(r, \theta, \phi) = P_{d\theta}(r, \theta, \phi) + P_{d\phi}(r, \theta, \phi) = \frac{|\bar{E}|^2}{2\eta_0}. \qquad (6.6)$$

$$P_{d\theta} = \frac{|E_\theta|^2}{2\eta_0},\ P_{d\phi} = \frac{|E_\phi|^2}{2\eta_0}. \qquad (6.7)$$

It is assumed that the magnitude of a complex phasor quantity, such as $|E_\theta|$ or $|E_\phi|$, refers to the peak value of the respective time-harmonic quantity.

6.2.3 Power per Solid Angle

The **solid angle**, $\Delta\Omega$, sometimes referred to as the **cone angle**, is produced by a surface element $\overline{\Delta A} = \Delta A\hat{n}$ and is defined as follows:

$$\Delta\Omega = \frac{\overline{\Delta A} \cdot \hat{r}}{r^2} = \frac{(\Delta A\hat{n}) \cdot \hat{r}}{r^2}. \qquad (6.8)$$

The unit of a solid angle is **Steradian** or *Sr* for short. The solid angle formed by the angle segments $(\Delta\theta, \Delta\phi)$, shown in Figure 6.1, can be expressed as:

$$\Delta\Omega = \frac{\Delta A}{r^2} = \frac{r^2 \sin\theta\Delta\theta\Delta\phi}{r^2} = \sin\theta\Delta\theta\Delta\phi. \qquad (6.9)$$

Using equations 6.8 and 6.9 in 6.5, one may rewrite the power flow ΔP through the cone angle $\Delta\Omega$ formed by the angle segments $(\Delta\theta, \Delta\phi)$ (see Figure 6.1):

$$\Delta P = P_d(r, \theta, \phi)r^2\Delta\Omega = P_d(r, \theta, \phi)r^2 \sin\theta\Delta\theta\Delta\phi. \qquad (6.10)$$

$$\frac{\Delta P}{\Delta\Omega} = P_d(r, \theta, \phi)r^2 = [P_{d\theta}(r, \theta, \phi) + P_{d\phi}(r, \theta, \phi)]r^2. \quad (6.11)$$

The power ΔP is conserved while propagating in empty space through the cone angle $\Delta\Omega$. Therefore, from equation 6.10, $P_d(r, \theta, \phi)r^2$ should be independent of *r*. In other words, $P_d(r, \theta, \phi)$ and its constituent parts $P_{d\theta}(r, \theta, \phi)$ and $P_{d\phi}(r, \theta, \phi)$ should be inversely proportional to r^2:

$$P_{d\theta}(r, \theta, \phi) = \frac{p_{d\theta}(\theta, \phi)}{r^2}, P_{d\phi}(r, \theta, \phi) = \frac{p_{d\phi}(\theta, \phi)}{r^2},$$
$$P_d(r, \theta, \phi) = \frac{p_d(\theta, \phi)}{r^2}. \qquad (6.12)$$

$$p_d(\theta, \phi) = p_{d\theta}(\theta, \phi) + p_{d\phi}(\theta, \phi). \qquad (6.13)$$

$$\frac{\Delta P}{\Delta\Omega} = p_d(\theta, \phi). \qquad (6.14)$$

The $p_d(\theta, \phi)$ is called the **power per solid angle**, with W/Sr as its unit. The $p_d(\theta, \phi)$ consists of two parts, $p_{d\theta}(\theta, \phi)$ and $p_{d\phi}(\theta, \phi)$, that correspond to the $\hat{\theta}$ and $\hat{\phi}$ components of the radiated electric field, respectively.

Now, from equations 6.12, 6.6, and 6.7, the magnitudes of the total electric field $\bar{E}$ and its components E_θ and E_ϕ should be inversely proportional to *r*:

$$|E_\theta(r, \theta, \phi)| = \frac{f_\theta(\theta, \phi)}{r},\ |E_\phi(r, \theta, \phi)| = \frac{f_\phi(\theta, \phi)}{r},$$
$$|\bar{E}(r, \theta, \phi)| = \frac{f(\theta, \phi)}{r}. \qquad (6.15)$$

$$p_{d\theta} = \frac{f_\theta^2}{2\eta_0},\ p_{d\phi} = \frac{f_\phi^2}{2\eta_0},\ p_d = \frac{f^2}{2\eta_0};\ f^2 = f_\theta^2 + f_\phi^2. \qquad (6.16)$$

6.2.4 Radiation Pattern

The r-independent parts of the corresponding power density functions are p_d, $p_{d\theta}$, and $p_{d\phi}$. The r-independent parts of the corresponding electric field functions are f, f_θ, f_ϕ. These power density and field functions may be normalized with respect to their maximum total values $p_{d\max}$ and $f_{\max}$ respectively:

$$\underline{p}_d(\theta, \phi) = \frac{p_d(\theta, \phi)}{p_{d\max}},\ \underline{p}_{d\theta}(\theta, \phi) = \frac{p_{d\theta}(\theta, \phi)}{p_{d\max}},$$
$$\underline{p}_{d\theta}(\theta, \phi) = \frac{p_{d\phi}(\theta, \phi)}{p_{d\max}}. \qquad (6.17)$$

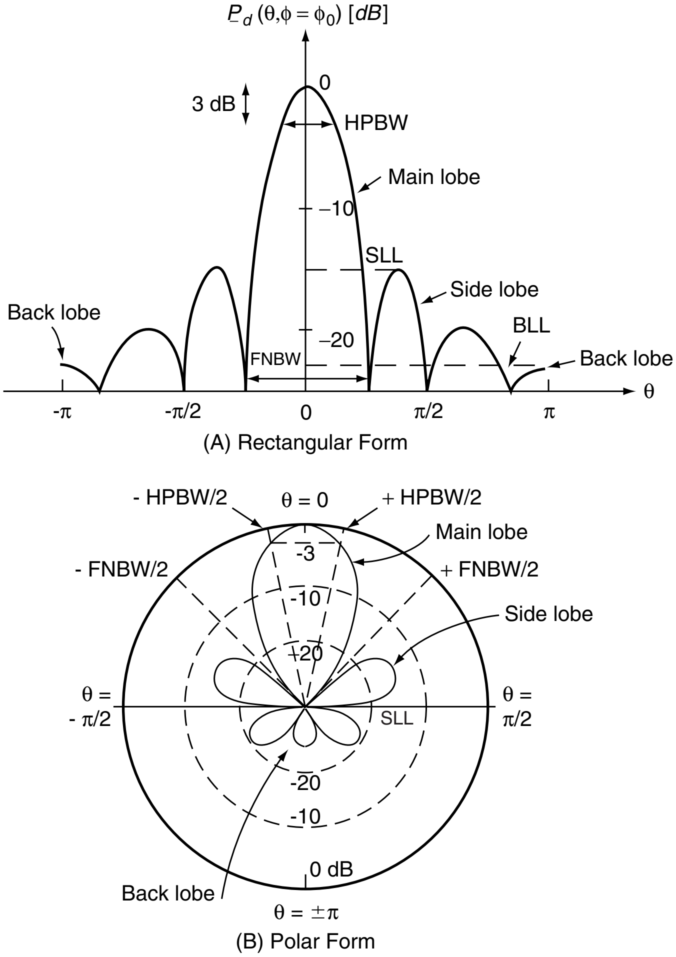
$$\underline{f}(\theta, \phi) = \frac{f(\theta, \phi)}{f_{\max}},\ \underline{f}_\theta(\theta, \phi) = \frac{f_\theta(\theta, \phi)}{f_{\max}},\ \underline{f}_\phi(\theta, \phi) = \frac{f_\theta(\theta, \phi)}{f_{\max}}. \quad (6.18)$$

$$\underline{p}_d = \underline{p}_{d\theta} + \underline{p}_{d\phi} \leq 1;\ \underline{f} = \sqrt{\underline{f}_\theta^2 + \underline{f}_\phi^2} \leq 1;$$
$$\underline{p}_d = \underline{f}^2,\ \underline{p}_{d\theta} = \underline{f}_\theta^2,\ \underline{p}_{d\phi} = \underline{f}_\phi^2. \qquad (6.19)$$

The normalized functions $\underline{p}_d$, $\underline{p}_{d\theta}$, and $\underline{p}_{d\phi}$, are called the total-, theta-, and phi-power radiation patterns, respectively. Similarly, $\underline{f}$, $\underline{f}_\theta$, and $\underline{f}_\phi$ are called the total-, theta-, and phi-field radiation patterns, respectively. An example of a total power-radiation pattern, $\underline{p}_d(\theta, \phi = \phi_0)$, is shown in Figure 6.2 in both rectangular and polar forms. Radiation patterns are normally plotted with respect to one angle variable, θ or ϕ, keeping the other variable fixed. Alternatively, the radiation pattern may be plotted using a three-dimensional (3-D) graph, including both θ and ϕ variables.

6.2.5 Beam Width and Side Lobe Level

As shown in Figure 6.2, an antenna has a direction of maximum radiation, such that $\underline{p}_d(\theta_{\max}, \phi = \phi_0) = 1$ (in Figure 6.2, $\theta_{\max}$ is assumed 0^0). The lobe surrounding the maximum



(A) Rectangular Form

(B) Polar Form

FIGURE 6.2 Examples of a Power Radiation Pattern $\underline{P}_d$, are Plotted in Rectangular and Polar Forms as a Function of θ for a Fixed Value of $\phi = \phi_0$. The half-power beam width (HPBW), first-null beam width (FNBW), side lobe level (SLL), and back lobe level (BLL) are shown, indicating the main lobe, side lobe, and back lobe of radiation.

radiation is called the **main lobe** or the **main beam**. The width of the main beam, defined using the angles of first nulls in both sides of $\theta_{\max}$, is called the **first-null beam width** (FNBW). Sometimes it is more useful to define the beam width using the angles of half-power radiation relative to the maximum radiation. The beam width defined in such manner is called the **half-power beam width** (HPBW). The lobes of the radiation pattern in both sides of the main lobe are called the **side lobes**, and the maximum level of radiation in the side lobes is called the **side lobe level** (SLL). In many applications, it is desirable to have a sufficiently low SLL to minimize unwanted interference away from the main lobe of communication. Low SLL also helps in efficient use of radiated power by using most of the radiated power in the desired main lobe of communication. Antennas also often radiate to the direction opposite the main beam, and the corresponding lobe is called the **back lobe**. The level of maximum radiation in the back lobe is called the **back lobe level** (BLL). A low BLL may be desirable to minimize interference to the back side to allow for efficient use of the radiated power.

It may be noted, depending on the specific application in mind, that the desired radiation pattern may take many different forms. In addition to the total power radiation pattern, one may be interested in the theta- or phi-power patterns to evaluate the polarization properties of radiation. The polarization properties are discussed separately in the following section.

6.2.6 Polarization Unit Vector

Equation 6.15 indicates that the magnitude of the electric field is inversely proportional to *r*. Assuming linearity, the electric field should be proportional to the antenna input current I_{in}. In addition, the phase of the electric field must vary as $e^{-jk_0 r}$ to account for the wave propagation in the $\hat{r}$ direction, where $k_0 = 2\pi/\lambda_0 = 2\pi f/c$ is called the wave number in free space, λ_0 is the free-space wavelength, $c = 3 \times 10^8$ m/s is the velocity of the electromagnetic wave in free space, and *f* is the frequency of operation. Accordingly, the complete phasor of the *E*-field vector may be expressed in the following form:

$$\bar{E}(r, \theta, \phi) = I_{\text{in}} \frac{e^{-jk_0 r}}{r} \bar{e}(\theta, \phi) = I_{\text{in}} \frac{e^{-jk_0 r}}{r} [\hat{\theta} e_\theta(\theta, \phi) + \hat{\phi} e_\phi(\theta, \phi)] \tag{6.20}$$

$$E_\theta(r, \theta, \phi) = I_{\text{in}} \frac{e^{-jk_0 r}}{r} e_\theta(\theta, \phi),\ E_\phi(r, \theta, \phi) = I_{\text{in}} \frac{e^{-jk_0 r}}{r} e_\phi(\theta, \phi) \tag{6.21}$$

$$p_d = \frac{|I_{\text{in}}|^2 |\bar{e}|^2}{2\eta_0},\ p_{d\theta} = \frac{|I_{\text{in}}|^2 |\bar{e}_\theta|^2}{2\eta_0},\ p_{d\phi} = \frac{|I_{\text{in}}|^2 |\bar{e}_\phi|^2}{2\eta_0}. \tag{6.22}$$

$$k_0 = \frac{2\pi}{\lambda_0},\ \lambda_0 = \frac{c}{f},\ c = 3 \times 10^8 \text{ m/s} \tag{6.23}$$

The (θ, ϕ)-dependent part, $\bar{e}(\theta, \phi)$, of the *E*-field is a complex vector called the **transmit vector**, which is separated into its magnitude and a complex unit vector $\hat{\rho}$:

$$\bar{e}(\theta, \phi) = |\bar{e}(\theta, \phi)| \hat{\rho}(\theta, \phi). \tag{6.24}$$

$$|\bar{e}(\theta, \phi)| = \sqrt{[|e_\theta(\theta, \phi)|^2 + |e_\phi(\theta, \phi)|^2]}. \tag{6.25}$$

The complex unit vector $\hat{\rho}$ is called the **transmit polarization unit vector** or simply the **polarization unit vector**, $\hat{\rho}$ contains information about the phase and direction of the transmit radiation. The ρ has $\hat{\theta}$ and $\hat{\phi}$ components and has a unit magnitude:

$$\hat{\rho}(\theta, \phi) = \hat{\theta} \rho_\theta(\theta, \phi) + \hat{\phi} \rho_\phi(\theta, \phi);\ |\hat{\rho}(\theta, \phi)| = 1. \tag{6.26}$$

$$\rho_\theta = \frac{e_\theta}{|\bar{e}|} = \frac{E_\theta}{|\bar{E}|}, \rho_\phi = \frac{e_\phi}{|\bar{e}|} = \frac{E_\phi}{|\bar{E}|}. \tag{6.27}$$

$$\arg(\rho_\theta) = \arg(e_\theta) = \alpha_\theta,\ \arg(\rho_\phi) = \arg(e_\phi) = \alpha_\phi, \\ \alpha_\phi\text{-}\alpha_\theta = \Delta\phi. \tag{6.28}$$

6.2.7 Polarization Ellipse and Axial Ratio

The polarization unit vector, $\hat{\rho}$, is originally expressed in the (θ, ϕ) coordinates. The locus of the vector, with time, is in general an ellipse with its major and minor axes oriented along $\hat{\theta}'$ and $\hat{\phi}'$, respectively, as shown in Figure 6.3. The polarization vector $\hat{\rho}(\theta, \phi)$ may be transformed into the new coordinate system (θ', ϕ'):

$$\begin{aligned}\hat{\rho}(\theta, \phi) &= e^{j\alpha(\theta,\phi)}\hat{\rho}'(\theta, \phi) = e^{j\alpha(\theta,\phi)}[\hat{\theta}'\hat{\alpha}(\theta, \phi) \\ &+ \zeta(\theta, \phi)\hat{\phi}' jb(\theta, \phi)]; \quad a, b \geq 0,\ a \geq b,\ \hat{\theta}' \times \hat{\phi}' = \hat{r}.\end{aligned} \tag{6.29}$$

$$\begin{aligned}\zeta &= +1 \text{ for CW wave;} \\ \zeta &= \text{-}1 \text{ for CCW wave.}\end{aligned} \tag{6.30}$$

The ζ is the rotational parameter of the wave, indicating in which manner the polarization ellipse rotates with time. In Figure 6.3, $\zeta = +1$ when the polarization ellipse of the particular wave turns clockwise (CW), and $\zeta = \text{-}1$ when the polarization ellipse turns counterclockwise (CCW). The CW and CCW waves are also referred to, respectively, as left-hand polarized (LHP) and right-hand polarized (RHP) when the wave propagates in the $\hat{r} = \hat{\theta}' \times \hat{\phi}$ direction (which is the case here). A more standardized convention may be followed to describe the rotation of the polarization vector, which is independent of the coordinate system one chooses to use. A wave is called an RHP wave when the direction of wave propagation corresponds to the thumb of the right hand as the wave polarization vector spins around in the directions of the fingers of the right hand (with fingers curved in a rotational orientation). Alternately, the wave is called an LHP wave when the left hand matches the directions and orientations just described.

Using simple trigonometry for rotating the coordinates by an angle γ (see Figure 6.3), the following transformation equations can be written as:

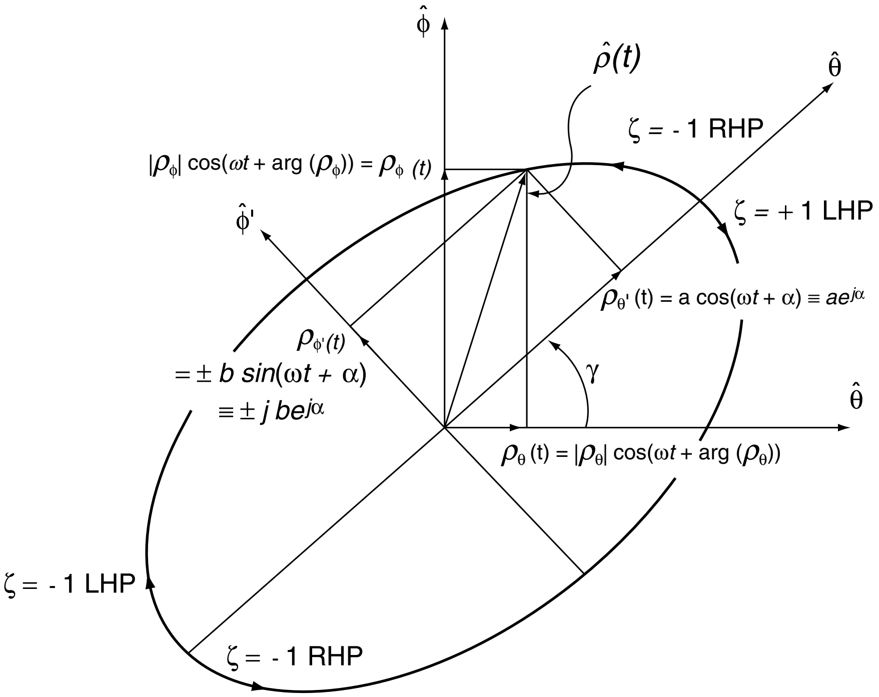
$$e^{j\alpha} a = \rho_\theta \cos\gamma + \rho_\phi \sin\gamma. \tag{6.31}$$

$$e^{j\alpha} jb\zeta = \text{-}\rho_\theta \sin\gamma + \rho_\phi \cos\gamma. \tag{6.32}$$

The unknown parameters a, b, γ, and α, as well as the rotational parameter ζ, can be solved in terms of ρ_θ and ρ_ϕ, using the pair of complex equations 6.31 and 6.32. The γ is called the tilt angle, a the major axis, b the minor axis, and α the phase of the ellipse. The ratio of the major and minor axes is called the axial ratio (AR):

$$AR = \frac{a}{b} \equiv 20\log\frac{a}{b}.[\text{dB}] \tag{6.33}$$

The parameters of the polarization ellipse are expressed in the following and are conditional upon the phase difference between ρ_θ and $\rho_\phi(\arg(\rho_\phi)\text{-}\arg(\rho_\theta) = \Delta\phi$. In the following, it is assumed that $\text{-}\pi/2 \leq \gamma \leq \pi/2$, and $a \geq b$. It is also assumed that one represents the phase difference, $\Delta\phi$, in the domain $\text{-}\pi < \Delta\phi \leq \pi$.



$\hat{\phi}$
$\hat{\rho}(t)$
$\hat{\theta}$
ζ = - 1 RHP
$|\rho_\phi| \cos(\omega t + \arg(\rho_\phi)) = \rho_\phi\ (t)$
$\hat{\phi}'$
ζ = + 1 LHP
$\rho_{\theta'}$ (t) = a cos($\omega t + \alpha$) $\equiv ae^{j\alpha}$
$\rho_{\phi'}(t)$
$= \pm\, b\, sin(\omega t + \alpha)$
$\equiv \pm\, j\, be^{j\alpha}$
γ
$\hat{\theta}$
ρ_θ (t) = $|\rho_\theta|$ cos(ωt + arg (ρ_θ))
ζ = - 1 LHP
ζ = - 1 RHP

FIGURE 6.3 Vector $\hat{\rho}$ is Shown in Two Coordinate Systems: the Original Coordinate System (θ, ϕ) and a Rotated Coordinate System (θ', ϕ'). The locus of the unit vector $\hat{\rho}(t)$ is in general an ellipse, with its major axis aligned along $\hat{\theta}'$, which is in general tilted by an angle γ with respect to the original axis $\hat{\theta}$.

Case A: Linearly Polarized Wave

In case A, $\Delta\phi = 0$ or π, or $Im(\rho_\phi \rho_\theta^*) = 0$:

$$\begin{aligned}
&a = \sqrt{|\rho_\theta|^2 + |\rho_\phi|^2} = 1,\ b = 0,\ AR = \infty,\ \alpha = \alpha_\theta,\\
&\gamma = \arctan\left(\frac{|\rho_\phi|}{|\rho_\theta|}\right)\ \text{if}\ \Delta\phi = 0,\\
&\gamma = \text{-}\arctan\left(\frac{|\rho_\phi|}{|\rho_\theta|}\right)\ \text{if}\ \Delta\phi = \pi,\\
&\zeta = \text{undefined}.
\end{aligned} \tag{6.34}$$

In this case, the polarization ellipse becomes a straight line, with $b = 0$ and $AR = \infty$, and the rotational parameter ζ becomes irrelevant.

Case B: Circularly Polarized Wave

In case B, $\Delta\phi = \pm\pi/2$ (or equivalently $Re(\rho_\phi \rho_\theta^*) = 0$) and $|\rho_\theta| = |\rho_\phi|$:

$$a = b = |\rho_\theta| = |\rho_\phi|,\ \gamma = 0,\ \alpha = \alpha_\theta,\ \zeta = Im\left(\frac{\rho_\phi}{\rho_\theta}\right),\ AR = 1 \equiv 0\ \text{dB}. \tag{6.35}$$

In this case, the polarization ellipse becomes a circle with $a = b$, and axial ratio $AR = 1(\equiv 0\text{dB})$. The wave is called a **circularly polarized** wave (CP). The tilt angle is arbitrary and is chosen to be zero. When the wave is RHP ($\zeta = -1$), it is called **right-hand circularly polarized** (RHCP), and on the other hand, when the wave is LHP ($\zeta = +1$), it is called **left-hand circularly polarized** (LHCP).

Case C: Elliptically Polarized Wave with $\gamma = 0$ or $\pi/2$

In case C, $\Delta\phi = \pm\pi/2$ (or equivalently $Re(\rho_\phi \rho_\theta^*) = 0$) but $|\rho_\theta| \neq |\rho_\phi|$:

$$\text{if}|\rho_\theta| > |\rho_\phi| \left\{ \begin{array}{l} a = |\rho_\theta|,\ b = |\rho_\phi|,\ \gamma = 0,\ \alpha = \alpha_\theta, \\ \zeta = +1\ \text{if}\ \Delta\phi = +\pi/2;\ \zeta = \text{-}1\ \text{if}\ \Delta\phi = \text{-}\pi/2. \end{array} \right. \tag{6.36}$$

$$\text{if}|\rho_\theta| < |\rho_\phi| \left\{ \begin{array}{l} a = |\rho_\phi|,\ b = |\rho_\theta|,\ \gamma = +\pi/2,\ \alpha = \alpha_\phi, \\ \zeta = +1\ \text{if}\ \Delta\phi = +\pi/2;\ \ \zeta = \text{-}1\ \text{if}\ \Delta\phi = \text{-}\pi/2. \end{array} \right. \tag{6.37}$$

Case C is the special situation of an elliptical wave with the major and minor axes coinciding with the original coordinates. Depending on the relative magnitudes of ρ_θ and ρ_ϕ however, one needs to choose the tilt angle as 0 or $\pi/2$ degrees, as indicated.

Case D: General Elliptically Polarized Wave

Case D includes all cases other than A, B, and C, when $\Delta\phi \neq 0,\ \pm\pi/2,\ \pi$, (irrespective of $|\rho_\theta|$ and $|\rho_\phi|$):

$$\begin{aligned}
&\zeta = +1(\text{LHP})\ \text{if}\ Im(\rho_\phi \rho_\theta^*) > 0(\text{or}\sin\Delta\phi > 0);\\
&\zeta = \text{-}1(\text{RHP})\ \text{if}\ Im(\rho_\phi \rho_\theta^*) < 0(\text{or}\sin\Delta\phi < 0).
\end{aligned} \tag{6.38}$$

When $\zeta = +1$, the wave is called **left-hand elliptically polarized** (LHEP), and when $\zeta = -1$, the wave is called **right-hand elliptically polarized** (RHEP):

$$\tan 2\gamma = \frac{2Re(\rho_\phi \rho_\theta^*)}{|\rho_\theta|^2\text{-}|\rho_\phi|^2} = \frac{2|\rho_{\theta|}|\rho_{\phi|}|\cos\Delta\phi}{|\rho_\theta|^2\text{-}|\rho_\phi|^2};\ \text{-}\frac{\pi}{2} \leq \gamma \leq +\frac{\pi}{2}. \tag{6.39}$$

Note that there can be two values of $\text{-}\pi/2 \leq \gamma \leq \pi/2$ satisfying equation 6.39. One needs to eliminate one value as follows:

$$\begin{aligned}
&0 < \gamma < \pi/2\ \text{if}\ Re(\rho_\phi \rho_\theta^*) > 0(\text{or}\cos\Delta\phi > 0);\\
&\text{-}\pi/2 < \gamma < 0\ \text{if}\ Re(\rho_\phi \rho_\theta^*) < 0(\text{or}\cos\Delta\phi < 0).
\end{aligned} \tag{6.40}$$

$$\begin{aligned}
a &= \sqrt{|\rho_\theta|^2\cos^2\gamma + |\rho_\phi|^2\sin^2\gamma + 2|\rho_\theta||\rho_\phi|\sin\gamma\cos\gamma\cos\Delta\phi}\\
&= \sqrt{\frac{1}{2}[|\rho_\theta|^2 + |\rho_\phi|^2 + \{|\rho_\theta|^4 + |\rho_\phi|^4 + 2|\rho_\theta|^2|\rho_\phi|^2\cos(2\Delta\phi)\}^{1/2}}.
\end{aligned} \tag{6.41}$$

$$\begin{aligned}
b &= \sqrt{|\rho_\theta|^2\sin^2\gamma + |\rho_\phi|^2\cos^2\gamma\text{-}2|\rho_\theta||\rho_\phi|\sin\gamma\cos\gamma\cos\Delta\phi}\\
&= \sqrt{\frac{1}{2}[|\rho_\theta|^2 + |\rho_\phi|^2\text{-}\{|\rho_\theta|^4 + |\rho_\phi|^4 + 2|\rho_\theta|^2|\rho_\phi|^2\cos(2\Delta\phi)\}^{1/2}}.
\end{aligned} \tag{6.42}$$

$$\begin{aligned}
\alpha &= \arg(\rho_\theta\cos\gamma + \rho_\phi\sin\gamma)\\
&= \alpha_\theta + \arctan\left[\frac{|\rho_\phi|\sin\gamma\sin\Delta\phi}{|\rho_\phi|\sin\gamma\cos\Delta\phi + |\rho_\theta|\cos\gamma}\right].
\end{aligned} \tag{6.43}$$

It should be remembered that all parameters a, b, γ, α, ζ, and AR as well as the unit vectors $\hat{\theta}'$ and $\hat{\phi}'$ in equations 6.40 to 6.43 are functions of (θ, ϕ). Figure 6.4 shows a four-quadrant chart for $\Delta\phi$ that may be used to determine the type of polarization (linear, circular or elliptical, left-handed or right-handed) and the corresponding tilt angle γ. The other parameters a, b, AR, and α can then be determined from cases A through D as appropriate.

6.2.8 Total Radiated Power and Radiation Efficiency

From equations 6.10 and 6.12, the total radiated power can be determined by integrating the power density function $P_d(r, \theta, \phi)$ over a closed spherical surface.

$$P_{\text{rad}} = \int_{\theta=0}^{\pi}\int_{\phi=0}^{2\pi} P_d(r, \theta, \phi)r^2\sin\theta d\phi d\theta = \int_{\theta=0}^{\pi}\int_{\phi=0}^{2\pi} p_d(\theta, \phi)\sin\theta\ d\phi\ d\theta. \tag{6.44}$$

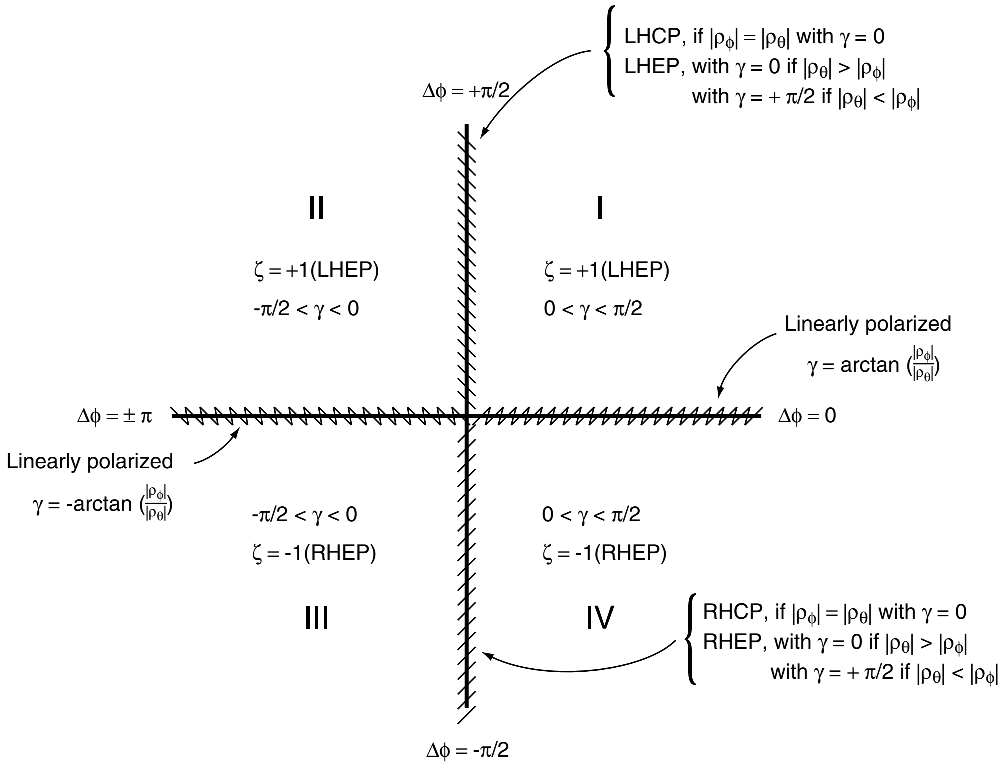


FIGURE 6.4 Different Quadrants of the Phase Difference $\Delta\phi = \arg(\rho_\phi) - \arg(\rho_\theta)$ Determine the Tilt Angle γ and Rotational Parameter ζ

The total radiated power, P_{rad}, is less than or equal to the input power, P_{in}, supplied at the input of the antenna. A part of the input power, P_{loss}, is dissipated as heat in the material (conductor or dielectric) of the antenna itself.

$$P_{\text{rad}} = P_{\text{in}}\text{-}P_{\text{loss}} = P_{\text{in}}\left(1\text{-}\frac{P_{\text{loss}}}{P_{\text{in}}}\right) \tag{6.45}$$

$$\eta_r = 1\text{-}\frac{P_{\text{loss}}}{P_{\text{in}}}. \tag{6.46}$$

The parameter η_r, is called the radiation efficiency. A part of the P_{loss} is dissipated as dielectric loss (P_{ld}), a part as conductor loss (P_{lc}), and a part is sometimes lost as unwanted surface wave in the antenna substrate material (P_{sw}), with efficiencies associated with the individual loss mechanisms as η_d, η_c, and η_{sw}, respectively:

$$P_{\text{loss}} = P_{ld} + P_{lc} + P_{sw}. \tag{6.47}$$

$$\eta_d = 1\text{-}\frac{P_{ld}}{P_{\text{in}}},\ \eta_c = 1\text{-}\frac{P_{lc}}{P_{\text{in}}},\ \eta_{sw} = 1\text{-}\frac{P_{sw}}{P_{\text{in}}}. \tag{6.48}$$

If the individual losses are small, the total radiation efficiency can be approximated as the product of individual parts:

$$\eta_r = 1\text{-}\frac{P_{ld} + P_{lc} + P_{sw}}{P_{\text{in}}} \simeq \left(1\text{-}\frac{P_{ld}}{P_{\text{in}}}\right)\left(1\text{-}\frac{P_{lc}}{P_{\text{in}}}\right)\left(1\text{-}\frac{P_{sw}}{P_{\text{in}}}\right) = \eta_c\eta_d\eta_{sw}. \tag{6.49}$$

6.2.9 Antenna Input Impedance and Radiation Resistance

An antenna is seen by the input source as an equivalent impedance Z_{in} (see Figure 6.1) with real and imaginary parts R_{in} and X_{in}, respectively. The imaginary part is produced due to stored energy in the antenna field. The real part R_{in} consists of two parts, R_{rad} and R_{loss} respectively contributed due to the radiated power P_{rad} and the power loss P_{loss} in the antenna:

$$Z_{\text{in}} = R_{\text{in}} + jX_{\text{in}} = R_{\text{rad}} + R_{\text{loss}} + jX_{\text{in}},\ R_{\text{in}} = R_{\text{rad}} + R_{\text{loss}}. \tag{6.50}$$

$$\begin{aligned} P_{\text{rad}} &= \frac{|I_{\text{in}}|^2 R_{\text{rad}}}{2},\ P_{\text{loss}} = \frac{|I_{\text{in}}|^2 R_{\text{loss}}}{2}, \\ P_{\text{in}} &= \frac{|I_{\text{in}}|^2 (R_{\text{rad}} + R_{\text{loss}})}{2},\ \eta_r = \frac{R_{\text{rad}}}{R_{\text{rad}} + R_{\text{loss}}}. \end{aligned} \tag{6.51}$$

The R_{rad} is called the **radiation resistance**, and R_{loss} is called the **loss resistance** of the antenna.

6.2.10 Resonant Frequency and Bandwidth

The input impedance Z_{in} of the antenna is a function of the frequency of operation. Figure 6.5 shows the magnitude of the input impedance of an example antenna as a function of

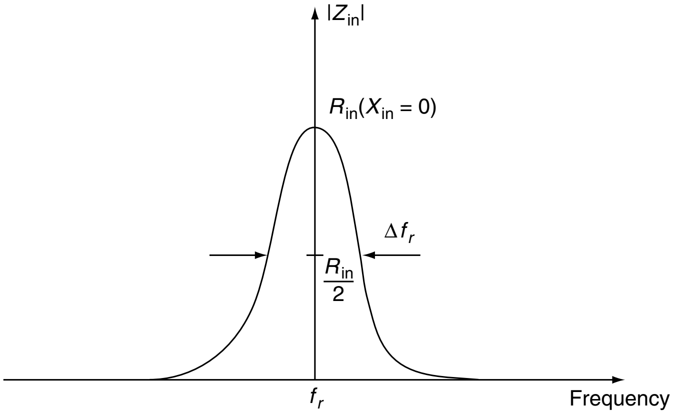

FIGURE 6.5 The frequency dependence of impedance magnitude of an example antenna is shown with the resonant frequency f_r and the bandwidth Δf_r of the antenna

frequency. In this case, the antenna impedance looks like a parallel RLC resonant circuit. The frequency, f_r, for which the impedance magnitude is maximum, or equivalently the reactance is zero, is often defined as the **resonant frequency**. It is desirable to operate the antenna at this resonant frequency so that it can be easily matched to an input transmission line with a real characteristic impedance. The frequency span Δf_r, beyond which the impedance magnitude falls below half of the resonant value, may be defined as the **impedance bandwidth** of the antenna. The antenna may be usable in this frequency band. Outside the antenna's bandwidth, the input power to the antenna would be significantly reflected due to impedance mismatch, resulting in poor radiation.

It may be noted that Figure 6.5 shows only an example case. Depending on the type of the antenna and its application, the resonance frequency and bandwidth may be defined based on the performance parameter one desires for the particular application, such as the gain, directivity, axial ratio. In such cases, the resonant frequency is defined as the frequency of best performance and the bandwidth as the frequency span over which the performance can be tolerated, as dictated by the application. It is meaningful to call the resonant frequency and the bandwidth of an antenna with an appropriate parameter prefix, such as the impedance–resonant frequency, the impedance–bandwidth, gain–resonant frequency, the gain–bandwidth, the axial–ratio–resonant frequency, or the axial–ratio–bandwidth. Often, the definitions based on the different performance parameters have strong correlations with each other.

6.2.11 Directivity

How well an antenna directs the radiation in a particular angle is quantified by comparing the radiation intensity with that of an ideal isotropic radiator. An isotropic radiator is defined as an antenna that radiates uniformly in all angles. Let the total radiated power from a given antenna, P_{rad}, also be radiated from the ideal isotropic radiator. The resulting power density, $P_{d(iso)}$, at a given distance r is independent of θ and ϕ:

$$P_{d(\text{iso})} = \frac{P_{\text{rad}}}{4\pi r^2}. \tag{6.52}$$

The ratio of the power density $P_d(r, \theta, \phi)$ from the actual antenna, in a given direction (θ, ϕ) with that from the isotropic radiator $P_{d(\text{iso})}$, is called the **directive gain function** $D_g(\theta, \phi)$:

$$D_g(\theta, \phi) = \frac{P_d(r, \theta, \phi)}{P_{d(iso)}} = \frac{4\pi r^2 P_d(r, \theta, \phi)}{P_{\text{rad}}} = \frac{4\pi p_d(\theta, \phi)}{P_{\text{rad}}}. \tag{6.53}$$

$$P_d(r, \theta, \phi) = \frac{P_{\text{rad}}}{4\pi r^2} D_g(\theta, \phi),\ p_d(\theta, \phi) = \frac{P_{\text{rad}}}{4\pi} D_g(\theta, \phi). \tag{6.54}$$

The maximum value of $D_g(\theta, \phi)$, occurring along the main beam direction $(\theta_{\max}, \phi_{\max})$, is called the **directivity** (D).

$$\text{Directivity} = D = D_g(\theta, \phi)_{\max} = D_g(\theta_{\max}, \phi_{\max}). \tag{6.55}$$

Now, using equation 6.44 in equation 6.53 $D_g(\theta, \phi)$ can be expressed using either $p_d(\theta, \phi)$ or the power pattern $\underline{P}_d(\theta, \phi)$:

$$\begin{aligned} D_g(\theta, \phi) &= \frac{4\pi p_d(\theta, \phi)}{\int\limits_{\phi=0}^{2\pi}\int\limits_{\theta=0}^{\pi} \underline{p}_d(\theta, \phi)\sin\theta d\theta d\phi} \\ &= \frac{4\pi p_d(\theta, \phi)}{\int\limits_{\phi=0}^{2\pi}\int\limits_{\theta=0}^{\pi} \underline{P}_d(\theta, \phi)\sin\theta d\theta d\phi}. \end{aligned} \tag{6.56}$$

- ***D_g, R_{rad}, and $\bar{e}$ Relationship***: Combining the equations (6.22, 6.51, and 6.54), a useful relationship results between the field vector $\bar{e}(\theta, \phi)$, directive gain function $D_g(\theta, \phi)$, and the radiation resistance R_{rad}:

$$\frac{|I_{\text{in}}|^2 |\bar{e}(\theta, \phi)|^2}{2\eta_0} = \frac{|I_{\text{in}}|^2 R_{\text{rad}}}{8\pi} D_g(\theta, \phi),\ |\bar{e}(\theta, \phi)| = \sqrt{\frac{\eta_0 R_{\text{rad}}}{4\pi} D_g(\theta, \phi)}. \tag{6.57}$$

6.2.12 Gain

It may also be useful to find the ratio of the power density $P_d(r, \theta, \phi)$ from a given antenna to that $(= P'_{d(\text{iso})})$ from an ideal isotropic radiator when supplied by the same input power P_{in} in both cases (unlike the same P_{rad} considered in the last section.) The ratio of $P_d(r, \theta, \phi)$ to $P'_{d(\text{iso})}$ is called the **gain function** $G(\theta, \phi)$:

$$P'_{d(\text{iso})} = \frac{P_{\text{in}}}{4\pi r^2}. \tag{6.58}$$

$$G(\theta, \phi) = \frac{P_d(r, \theta, \phi)}{P'_{d(\text{iso})}} = \frac{4\pi r^2 P_d(r, \theta, \phi)}{P_{\text{in}}} = \frac{4\pi p_d(\theta, \phi)}{P_{\text{in}}}. \tag{6.59}$$

$$P_d(r, \theta, \phi) = \frac{P_{\text{in}}}{4\pi r^2} G(\theta, \phi) = \frac{P_{\text{rad}}}{4\pi r^2 \eta_r} G(\theta, \phi);$$
$$p_d(\theta, \phi) = \frac{P_{\text{in}}}{4\pi} G(\theta, \phi). \quad (6.60)$$

Comparing equations 6.59 and 6.53, and using the efficiency relationship of equation 6.45 a simple relationship is obtained between $G(\theta, \phi)$ and $D_g(\theta, \phi)$:

$$G(\theta, \phi) = \eta_r D_g(\theta, \phi). \quad (6.61)$$

The maximum value of the gain function is referred to as the maximum gain or simply the **gain G**:

$$\text{Gain} = G = G(\theta, \phi)_{\max} = G(\theta_{\max}, \phi_{\max}) = \eta_r D. \quad (6.62)$$

- ***G*, *R*$_{\text{in}}$, and $\bar{\mathbf{e}}$ Relationship**: Combining equations (6.22, 6.51, 6.60) leads to a useful relationship between the field vector $\bar{e}(\theta, \phi)$, gain function $G(\theta, \phi)$, and the antenna input resistance R_{in}:

$$\frac{|I_{\text{in}}|^2 |\bar{e}(\theta, \phi)|^2}{2\eta_0} = \frac{|I_{\text{in}}|^2 R_{\text{in}}}{8\pi} G(\theta, \phi), \; |\bar{e}(\theta, \phi)| = \sqrt{\frac{\eta_0 R_{\text{in}}}{4\pi} G(\theta, \phi)}. \quad (6.63)$$

6.2.13 Beam Efficiency

The **beam efficiency $\boldsymbol{\eta}_{\text{beam}}$** of an antenna is defined as the ratio of the radiated power, P_{mainbeam}, confined in the antenna main lobe to the total radiated power P_{rad}. This quantifies how well the antenna uses the total radiated power in the desired main beam.

$$\eta_{\text{beam}} = \frac{P_{\text{mainbeam}}}{P_{\text{rad}}} = \frac{\int\int_{\text{mainbeam}} p_d(\theta, \phi) \sin\theta \; d\theta \; d\phi}{\int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} p_d(\theta, \phi) \sin\theta \; d\theta \; d\phi}. \quad (6.64)$$

6.3 Antenna as a Receiver

This section treats an antenna as a receiving element. Before a receiving antenna can be modeled, a uniform plane wave must first be modeled incident on the antenna placed at the origin of a spherical coordinate system (see Figure 6.6).

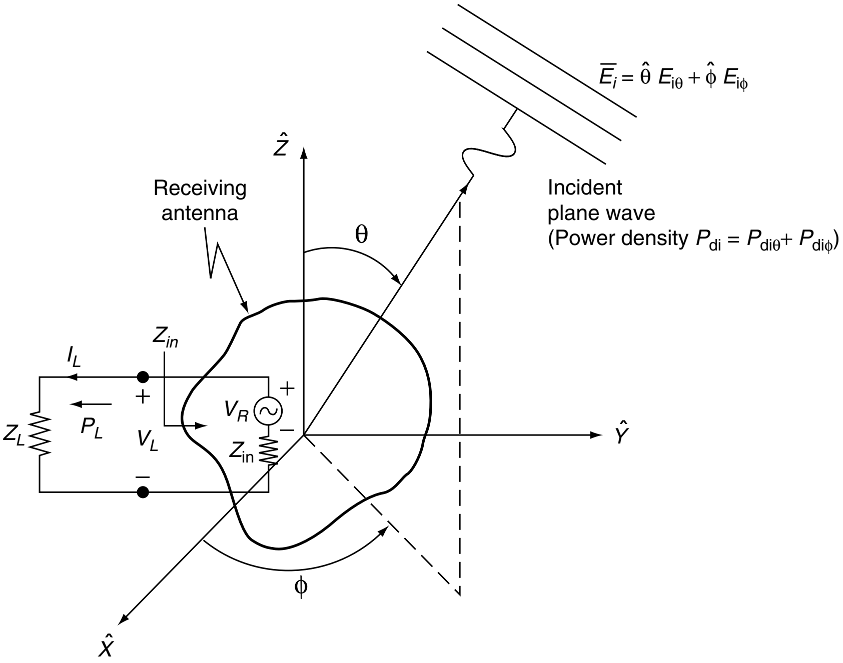
6.3.1 Incident Plane Wave

The incident plane wave has both $\hat{\theta}$ and $\hat{\phi}$ components with arbitrary amplitudes and phases. Unlike a radiating wave propagating radially away from the origin, the incident plane wave is propagating toward the origin with a $e^{+jk_0 r}$ phase factor:

$$\bar{E}_i = \hat{\theta} E_{i\theta} + \hat{\phi} E_{i\phi} = \bar{e}_i e^{+jk_0 r} = (\hat{\theta} e_{i\theta} + \hat{\phi} e_{i\phi}) e^{+jk_0 r}. \quad (6.65)$$

$$\bar{e}_i = \hat{\theta} e_{i\theta} + \hat{\phi} e_{i\phi} = |e_i| \hat{\rho}_i = |\bar{e}_i| (\hat{\theta} \rho_{i\theta} + \hat{\phi} \rho_{i\phi}). \quad (6.66)$$

$$|\bar{e}_i| = \sqrt{|e_{i\theta}|^2 + |e_{i\phi}|^2}, \; \rho_{i\theta} = \frac{e_{i\theta}}{|\bar{e}_i|}, \; \rho_{i\phi} = \frac{e_{i\phi}}{|\bar{e}_i|}. \quad (6.67)$$



$\bar{E}_i = \hat{\theta}\, E_{i\theta} + \hat{\phi}\, E_{i\phi}$

FIGURE 6.6 A General Antenna System in a Receiving Mode of Operation Shows an Incident Plane Wave and a Thevenin's Equivalent Model at the Input Terminals

$$|\hat{\rho}_i| = \sqrt{|\rho_{i\theta}|^2 + |\rho_{i\phi}|^2} = \frac{\sqrt{|e_{i\theta}|^2 + |e_{i\phi}|^2}}{|\bar{e}_i|} = 1. \qquad (6.68)$$

$$P_{dinc} = \frac{|\bar{E}_i|^2}{2\eta_0} = \frac{|\bar{e}_i|^2}{2\eta_0}. \qquad (6.69)$$

The $\hat{\rho}_i$ is the polarization unit vector of the incident wave. Like the radiating polarization unit vector $\hat{\rho}$, the incident polarization unit vector $\hat{\rho}_i$ may be transformed to a new coordinate system $(\hat{\theta}'_i, \hat{\phi}'_i)$ aligned with the major and minor axes of the incident polarization ellipse, respectively. The angle between the $\hat{\theta}$ and $\hat{\theta}'_i$ axes is the tilt angle γ_i:

$$\hat{\rho}_i = e^{j\alpha_i}\hat{\rho}'_i = e^{j\alpha_i}(a_i\hat{\theta}'_i\text{-}\zeta_i jb_i\hat{\phi}'_i); \quad a_i,\, b_i \geq 0,\; a_i \geq b_i,\; \theta'_i \times \hat{\phi}'_i = \hat{r}. \qquad (6.70)$$

$$\begin{aligned} \zeta_i &= +1 \text{ for LHP wave;} \\ \zeta_i &= \text{-}1 \text{ for RHP wave.} \end{aligned} \qquad (6.71)$$

The equations in Section 6.2.7 may be used here to determine the various parameters of the incident wave. The major and minor axes a_i and b_i, axial ratio AR_i, tilt angle γ_i, the rotation parameter ζ_i, and the phase angle α_i should be replaced for the corresponding variables in Section 6.27: a, b, AR, γ, ζ, and α, respectively. However, it may be noted that, in contrast with equation 6.29, equation 6.70 has a negative sign before ζ_i. This takes into account the propagation of the incident wave in the -$\hat{r}$ direction instead of the $+\hat{r}$ direction of propagation for the outgoing radiated field. The change in the direction of propagation, by definition, automatically switches the "handedness" (right- or left-hand) of the wave.

6.3.2 Receive Voltage Vector

As shown in Figure 6.6, the receiving antenna is modeled as a Thevenin's equivalent circuit at its output terminals. The open-circuit voltage V_R can be written as a linear combination of the θ and the ϕ components of the incident fields:

$$\begin{aligned} V_R(\theta, \phi) = V_{R\theta}(\theta, \phi) + V_{R\phi}(\theta, \phi) = e_{\theta i}\nu_{R\theta}(\theta, \phi) \\ + e_{\phi i}\nu_{R\phi}(\theta, \phi) = \bar{e}_i \cdot \bar{\nu}_R(\theta, \phi). \end{aligned} \qquad (6.72)$$

$$\bar{\nu}_R(\theta, \phi) = \hat{\theta}\nu_{R\theta}(\theta, \phi) + \hat{\phi}\nu_{R\phi}(\theta, \phi) = |\bar{\nu}_R(\theta, \phi)|\hat{\rho}_R(\theta, \phi). \qquad (6.73)$$

$$\hat{\rho}_R(\theta, \phi) = \hat{\theta}\rho_{R\theta}(\theta, \phi) + \hat{\phi}\rho_{R\phi}(\theta, \phi). \qquad (6.74)$$

$$|\bar{\nu}_R| = \sqrt{|\nu_{R\theta}|^2 + |\nu_{R\phi}|^2},\; \rho_{R\theta} = \frac{\nu_{R\theta}}{|\bar{\nu}_R|},\; \rho_{R\phi} = \frac{\nu_{R\phi}}{|\bar{\nu}_R|}. \qquad (6.75)$$

$$|\hat{\rho}_R| = \sqrt{|\rho_{R\theta}|^2 + |\rho_{R\phi}|^2} = \frac{\sqrt{|\nu_{R\theta}|^2 + |\nu_{R\phi}|^2}}{|\bar{\nu}_R|} = 1. \qquad (6.76)$$

The $\bar{\nu}_R(\theta, \phi)$ is called the **receive vector**, and the unit vector $\hat{\rho}_R(\theta, \phi)$ is called the **receive polarization unit vector**. Like the radiation and incident polarization unit vectors $\hat{\rho}$ and $\hat{\rho}_i$, the receive polarization unit vector may be transformed to a new coordinate system $(\hat{\theta}_R, \hat{\phi}_R)$ aligned with the major and minor axes of the receive polarization ellipse. The angle between the $\hat{\theta}$ and $\hat{\theta}_R$ axes is the tilt angle γ_R:

$$\begin{aligned} &\hat{\rho}_R = e^{j\alpha_R}\hat{\rho}'_R = e^{j\alpha_R}(a_R\hat{\theta}'_R + \zeta_R jb_R\hat{\phi}'_R); \\ &a_R,\, b_R \geq 0,\; a_R \geq b_R,\; \hat{\theta}'_R \times \hat{\phi}'_R = \hat{r}. \end{aligned} \qquad (6.77)$$

$$\begin{aligned} \zeta_R &= +1 \text{ for LHP receiver;} \\ \zeta_R &= \text{-}1 \text{ for RHP receiver.} \end{aligned} \qquad (6.78)$$

Like the incident polarization unit vector in equation 6.70, the equations in Section 6.2.7 may also be used here to determine the various parameters for the receive polarization unit vector $\hat{\rho}_R$. It may be noted that, in contrast with equation 6.70, equation 6.77 has a positive sign before ζ_R. The rotational parameter ζ_R as a rule follows the same convention as for ζ, which is different from the rule for the incident wave ζ_i

6.3.3 Received Power and Effective Area

Once the Thevenin's voltage V_R of the receiving antenna is known, the load power P_L delivered to a load impedance Z_L can be easily obtained (see Figure 6.6):

$$V_R = \bar{e}_i \cdot \bar{\nu}_R = |\bar{e}_i||\bar{\nu}_R|\hat{\rho}_i \cdot \hat{\rho}_R. \qquad (6.79)$$

$$V_L = \frac{V_R Z_L}{Z_L + Z_{\text{in}}},\; I_L = \frac{V_R}{Z_L + Z_{\text{in}}},\; P_L = \frac{1}{2}\left|\frac{V_R}{Z_L + Z_{\text{in}}}\right|^2 R_L. \qquad (6.80)$$

The effective area A_e of a receiving antenna is defined as the ratio of the load power P_L and the incident power density P_{dinc}. The receiving antenna is seen as an equivalent capture area for the incident wave. The equivalent area A_e of an antenna may be clearly distinguished from the physical area of an antenna because, in general, they can be significantly different from each other. For example, a commonly used wire antenna has a nonzero effective area allowing a fairly good reception, whereas its physical area is very small—practically zero:

$$A_e = \frac{P_L}{P_{\text{dinc}}} = \frac{R_L\eta_0}{|\bar{e}_i|^2}\left|\frac{V_R}{Z_L + Z_{\text{in}}}\right|^2. \qquad (6.81)$$

$$A_e = \frac{R_L\eta_0}{|\bar{e}_i|^2}\frac{|\bar{\nu}_R|^2|\bar{e}_i|^2|\hat{\rho}_i \cdot \hat{\rho}_R|^2}{|Z_L + Z_{\text{in}}|^2} = \frac{R_L\eta_0|\bar{\nu}_R|^2|\hat{\rho}_i \cdot \hat{\rho}_R|^2}{|Z_L + Z_{\text{in}}|^2}. \qquad (6.82)$$

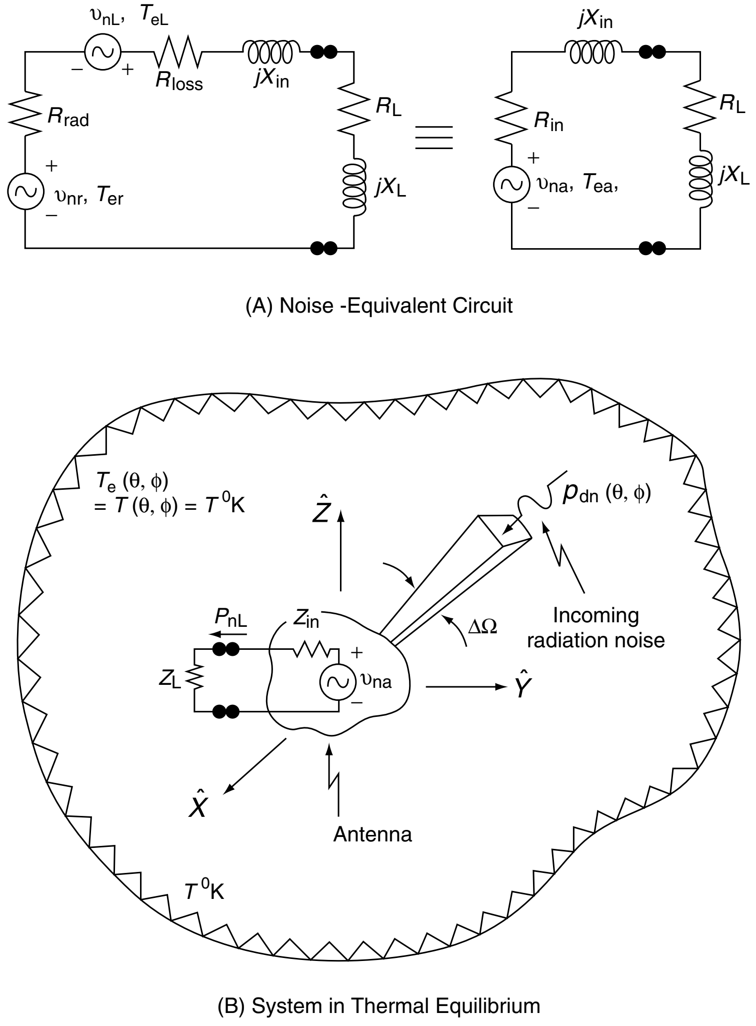
The effective area can be maximized in two ways: (1) by matching the load impedance for maximum power transfer, which requires $Z_L = Z^*_{\text{in}}$ or (2) by adjusting the incident and receive polarization vectors such that $|\hat{\rho}_i \cdot \hat{\rho}_R| = 1 = |\hat{\rho}_i \cdot \hat{\rho}_R|$ whenever possible. Under these conditions, the maximum effective area A_{em} can be derived from equation 6.82:

$$A_{em}(\theta, \phi) = \frac{\eta_0 |\bar{v}_R(\theta, \phi)|^2}{4R_{\text{in}}}; \; Z_L = Z_{\text{in}}^*, \; |\hat{\rho}_i \cdot \hat{\rho}_R| = 1 = |\hat{\rho}_i' \cdot \hat{\rho}_R'|. \tag{6.83}$$

The element $|\hat{\rho}_i \cdot \hat{\rho}_R|$ is called the **polarization match factor** between the incident wave and the receiving antenna. It can be shown that the polarization match factor is at the maximum possible (unity) only when $\gamma_i = \gamma_r$, $\zeta_i = \zeta_r$, and $AR_i = AR_r$ ($a_i = a_R$, $b_i = b_R$). From equations 6.70 and 6.77, one can see that the above condition established when $\hat{\rho}_i = \hat{\rho}_R^*$. Other possible practical situations may be considered. First, for a given receiving antenna (given ζ_r and AR_r), a given incident plane wave (given ζ_i and AR_i), and a given load impedance Z_L, the receive power P_L can be maximized by just turning the antenna about the $\hat{r}$ axis, such that the major axes of the incident and receive polarization vectors are aligned ($\gamma_i = \gamma_R$). Second, every other parameter remaining the same, the received power is larger if the rotational parameters are matched ($\zeta_i = \zeta_r$) compared to when they are mismatched ($\zeta_i \neq \zeta_r$).

6.3.4 Received Noise Temperature

Figure 6.7(A) shows the noise-equivalent circuit model of an antenna. Like an ohmic resistance, the input resistance of the antenna, R_{in} is associated with a noise source v_{na}, with equivalent noise temperature T_{ea} (Pozar, 1998). Unlike an ohmic resistance, however, T_{ea} is not the physical temperature of the antenna. The v_{na} consists of two parts, v_{nL} and v_{nr}, with noise temperatures, T_a and T_{er}, respectively associated with the loss resistance R_{loss} and radiation resistance R_{rad} of the antenna. The v_{nL} is generated due to the thermal process in the antenna itself, and therefore T_a is equal to the physical temperature of



(A) Noise -Equivalent Circuit

(B) System in Thermal Equilibrium

FIGURE 6.7 Noise Model for a Receiving Antenna. (A) This noise-equivalent circuit of an antenna shows noise voltage v_{nr} received through radiation and v_{nl} produced by the antenna itself due to material-loss resistance R_{loss}. (B) The antenna is placed in a closed "perfectly absorbing" chamber at temperature $T^0 K(p_{dn}$ = noise power per unit solid angle, as seen by an ideal isotropic antenna).

the antenna. In comparison, T_{er} is associated with the incoming radiation noise that depends on the temperature distribution of the surrounding objects that generate it:

$$\bar{v}_{nL}^2 = 4kT_a R_{\text{loss}},\ \bar{v}_{nr}^2 = 4kT_{er}R_{\text{rad}},\ \bar{v}_{na}^2 = 4kT_{ea}R_{\text{in}};\ \ \bar{v}_{na}^2 = \bar{v}_{nL}^2 + \bar{v}_{nr}^2. \tag{6.84}$$

The bar over the v represents root-mean-square (rms) values per unit bandwidth. Let the total noise–power per unit bandwidth, delivered by the antenna to a conjugate-matched load $Z_L = Z_{\text{in}}^*$ be P_{na}. The respective constituent parts delivered by v_{nL} and v_{nR} are P_{nL} and P_{nr}. These noise powers can be expressed using the respective noise temperatures and antenna radiation efficiency η_r (from equation 6.51), which would then provide a relationship between T_{ea}, T_a, and T_{er}:

$$P_{nL} = \frac{\bar{v}_{nL}^2}{4R_{\text{in}}} = kT_a\frac{R_{\text{loss}}}{R_{\text{in}}} = kT_a(1\text{-}\eta_r). \tag{6.85}$$

$$P_{nr} = \frac{\bar{v}_{nr}^2}{4R_{\text{in}}} = kT_{er}\frac{R_{\text{rad}}}{R_{\text{in}}} = kT_{er}\eta_r. \tag{6.86}$$

$$P_{na} = \frac{\bar{v}_{na}^2}{4R_{\text{in}}} = kT_{ea} = P_{nL} + P_{nr};\ \ T_{ea} = \eta_r T_{er} + (1\text{-}\eta_r)T_a. \tag{6.87}$$

Relationship Between T_{er} and Radiation–Noise Density

Let $p_{dn}(\theta, \phi)$ be the noise–power density of the incoming radiation per unit solid angle and per unit bandwidth, as seen by an ideal, matched "isotropic" antenna (gain function $G_{iso}(\theta, \phi) = 1$, matched effective area $= A_{em(iso)}$). The matched radiation noise P_{nr} received by an arbitrary antenna can be expressed in terms of $p_{dn}(\theta, \phi)$ and the antenna's effective area $A_{em}(\theta, \phi)$ relative to $A_{em(iso)}$:

$$\begin{aligned} P_{nr} &= \int_\Omega p_{dn}(\theta, \phi)\frac{A_{em}(\theta, \phi)}{A_{em(iso)}}d\Omega = \int_\Omega p_{dn}(\theta, \phi)\frac{G(\theta, \phi)}{G_{iso}}d\Omega \\ &= \int_\Omega p_{dn}(\theta, \phi)G(\theta, \phi)d\Omega. \end{aligned} \tag{6.88}$$

It may be noted that equation 6.88 uses the $G(\theta, \phi) \sim A_{em}(\theta, \phi)$ relationship, to be developed in 6.110. Then, using equations 6.86 and 6.61 in 6.88, we can relate the radiation noise–temperature T_{er} with $p_{dn}(\theta, \phi)$ and the directive gain function $D_g(\theta, \phi)$:

$$\begin{aligned} \mathrm{r}_r kT_{er} &= \int_\Omega p_{dn}(\theta, \phi)G(\theta, \phi)d\Omega; \\ T_{er} &= \int_\Omega \frac{p_{dn}(\theta, \phi)}{k}D_g(\theta, \phi)d\Omega. \end{aligned} \tag{6.89}$$

Relationship Between T_{er} and Spatial Temperature Distribution $T_e(\theta, \phi)$

Consider first the special situation when the antenna is surrounded by perfect absorbers, and the entire system is in thermal equilibrium at the temperature $T = T_a$, as shown in Figure 6.7(B). Under this condition, the noise–temperature of the antenna should be equal to the surrounding temperature. Consequently, using equation 6.87, the radiation–noise temperature of the antenna can be shown to be the temperature of the surrounding objects T:

$$T_{ea} = T = T_a = \eta_r T_{er} + (1\text{-}\eta_r)T_a;\ \ T_{er} = T. \tag{6.90}$$

Due to symmetry of the situation, $p_{dn}(\theta, \phi)$ is independent of the angle of arrival (θ, ϕ). With this assumption, and using equations 6.56 and 6.90 in equation 6.89 a relationship between p_{dn} and the absorber temperature T results:

$$\begin{aligned} T_{er} = T &= \int_\Omega \frac{p_{dn}(\theta, \phi)}{k}D_g(\theta, \phi)d\Omega \\ &= \frac{p_{dn}}{k}\int_\Omega D_g(\theta, \phi)d\Omega = \frac{4\pi p_{dn}}{k};\ p_{dn} = \frac{kT}{4\pi}. \end{aligned} \tag{6.91}$$

Equation 6.91 can be extended to arbitrary situations when the surrounding objects are at different physical temperatures $T(\theta, \phi)$, or the objects can be modeled with noise-equivalent temperatures $T_e(\theta, \phi)$. This will relate $p_{dn}(\theta, \phi)$ to $T(\theta, \phi)$ or $T_e(\theta, \phi)$. Then, using equation 6.89 T_{er} can be related to the surrounding temperature profile $T_e(\theta, \phi)$ via $D_g(\theta, \phi)$:

$$p_{dn}(\theta, \phi) = \frac{kT_e(\theta, \phi)}{4\pi},\ T_{er} = \frac{1}{4\pi}\int_\Omega T_e(\theta, \phi)D_g(\theta, \phi)d\Omega. \tag{6.92}$$

6.4 Transmit–Receive Communication Link

Figure 6.8(A) shows a communication link between two antennas, with their antenna parameters indicated by a subscript 1 or 2. Each antenna is described with respect to its own spherical coordinate system, represented with subscripts 1 or 2, having an origin at the center of the corresponding antenna. First, antenna 1 can be treated as the transmit antenna. The transmit field, $\bar{E}$, radiated from antenna 1 is viewed as the incident wave, $\bar{e}_i$, for the receiving antenna 2:

$$\bar{E}_1(r_1, \theta_1, \phi_1) = I_1\frac{e^{-jk_0 r_1}}{r_1}\bar{e}_1(\theta_1, \phi_1) = \bar{e}_i. \tag{6.93}$$

$$|\bar{e}_i| = \frac{|I_1||\bar{e}_1(\theta_1, \phi_1)|}{r_1},\ \hat{\rho}_i = e^{j(\arg(I_1) - k_0 r_1)}\hat{\rho}_1(\theta_1, \phi_1). \tag{6.94}$$

(A) Communication Link

(B) Two-Port Circuit

FIGURE 6.8 A Communication Link Between Two Antennas, Shown with Antenna 1 Used as the Transmitter and Antenna 2 as the Receiver. The Link can be Viewed as a Two-Port Circuit as Shown in (B).

Note that the incident polarization unit vector $\hat{\rho}_i$, as seen by receiving antenna 2, is equal to the transmit polarization unit vector $\hat{\rho}_1$ of antenna 1 multiplied by the phase factor $e^{j(\arg(I_1)-k_0 r_1)}$ due to propagation over distance r_1 and the phase of the input current I_1. The magnitude of the incident wave in equation 6.94 may be expressed in terms of the input impedance $R_{\text{in}1}$ of antenna 1 (or alternately the input power $P_{\text{in}1}$ of antenna 1) using equation 6.63:

$$|\bar{e}_i| = |I_1|\sqrt{\frac{\eta_0 R_{\text{in}1}}{4\pi r_1^2} G(\theta_1, \phi_1)} = \sqrt{\frac{2\eta_0 P_{\text{in}1}}{4\pi r_1^2} G(\theta_1, \phi_1)}. \quad (6.95)$$

The Thevenin's voltage, or the open-circuit voltage V_{R2}, at the terminals of antenna 2 can now be written in different forms using equations 6.79, 6.93, 6.94, and 6.95:

$$V_{R2} = I_1 \frac{e^{-jk_0 r_1}}{r_1} \bar{e}_1(\theta_1, \phi_1) \cdot \bar{v}_{R2}(\theta_2, \phi_2). \quad (6.96)$$

$$V_{R2} = \frac{|I_1||\bar{e}_1(\theta_1,\phi_1)||\bar{v}_{R2}(\theta_2,\phi_2)|}{r_1} e^{j(\arg(I_1)\text{-}k_0 r_1)} \hat{\rho}_1(\theta_1,\phi_1) \cdot \hat{\rho}_{R2}(\theta_2,\phi_2). \quad (6.97)$$

$$V_{R2} = \left[\sqrt{\frac{2\eta_0 P_{\text{in}1}}{4\pi r_1^2} G_1(\theta_1,\phi_1)}\right] |\bar{v}_{R2}(\theta_2,\phi_2)| e^{j(\arg(I_1)\text{-}k_0 r_1)} \hat{\rho}_1(\theta_1,\phi_1) \cdot \hat{\rho}_{R2}(\theta_2,\phi_2). \quad (6.98)$$

6.4.1 Transmit–Receive Link as a Two-Port Circuit

If antenna 2 is also excited by an input current I_2, antenna 1 will receive a Thevenin's terminal voltage V_{R1}. Repeating the procedure described in the previous paragraphs, V_{R1} may be expressed by interchanging the subscripts 1 and 2:

$$V_{R1} = I_2 \frac{e^{-jk_0 r_2}}{r_2} \bar{e}_2(\theta_2,\phi_2) \cdot \bar{v}_{R1}(\theta_1,\phi_1). \quad (6.99)$$

The link between antennas 1 and 2 may be seen as a two-port circuit, as illustrated in Figure 6.8(B). The total input voltages V_1 and V_2, respectively across the terminals of antennas 1 and 2 may be expressed as a superposition of the receive voltage and the transmit voltage:

$$V_1 = I_1 Z_{\text{in}1} + V_{R1},\ V_2 = I_2 Z_{\text{in}2} + V_{R2}. \tag{6.100}$$

$$Z_{12} = \frac{V_{R1}}{I_2} = \frac{e^{-jk_0 r_2}}{r_2} \bar{e}_2(\theta_2, \phi_2) \cdot \bar{v}_{R1}(\theta_1, \phi_1). \tag{6.101}$$

$$Z_{21} = \frac{V_{R2}}{I_1} = \frac{e^{-jk_0 r_1}}{r_1} \bar{e}_1(\theta_1, \phi_1) \cdot \bar{v}_{R2}(\theta_2, \phi_2);\ r_1 = r_2. \tag{6.102}$$

If the circuit is assumed to be reciprocal, then $Z_{12} = Z_{21}$ (Pozar, 1998). Hence, the following is true:

$$\bar{e}_1(\theta_1, \phi_1) \cdot \bar{v}_{R2}(\theta_2, \phi_2) = \bar{e}_2(\theta_2, \phi_2) \cdot \bar{v}_{R1}(\theta_1, \phi_1). \tag{6.103}$$

Equation 6.103 shows an important relationship in antenna theory called the **antenna reciprocity relationship**.

6.4.2 Relationship Between Transmit and Receive Vectors of an Arbitrary Antenna

Using equation 6.103, one can relate the transmit and receive vectors of any arbitrary antenna (replaced for antenna 1), once the transmit and receive vectors of one specific known antenna can be substituted for antenna 2.

A small dipole antenna with unit input current and length l can be used as the reference antenna 2. Let this dipole current be oriented in the -$\hat{\theta}_1$ direction, such that the radiation from the dipole antenna 2 is maximum toward the antenna 1. Alternately, one may visualize the current of the dipole antenna 2 to be oriented along the $\hat{Z}_2$ axis (see Figure 6.8(A)). Then, let the $\hat{z}_2$ axis be turned to align in the $-\hat{\theta}_1$ direction so that in the line of communication $\hat{\theta}_1 = \hat{\theta}_2$ and $\hat{\theta}_2 = 90°$. Under this situation, using the results from Das (2004) in Section 6.2.1, the transmit and receive vectors of the dipole antenna 2 are found as:

$$\bar{I} = I_2 \hat{z}_2 = \text{-}\hat{\theta}_1, I_2 = 1. \tag{6.104}$$

$$\bar{e}_2(\theta_2,\ \phi_2) = \frac{j\eta_0 l}{2\lambda_0} \hat{\theta}_2 = \frac{j\eta_0 l}{2\lambda_0} \hat{\theta}_1,\ \bar{v}_{R2}(\theta_2,\ \phi_2) = l\hat{\theta}_2 = l\theta_1,\ \theta_1 = \theta_2. \tag{6.105}$$

Now, using equation 6.105 in equation 6.103, the relationship between the $\hat{\theta}$ components of the transmit and receive vectors of the arbitrary antenna 1 is established as follows:

$$\begin{aligned} \bar{e}_1(\theta_1, \phi_1) \cdot \hat{\theta}_1 l &= \frac{j\eta_0 l}{2\lambda_0} \theta_1 \cdot \bar{v}_{R1}(\theta_1, \phi_1), e_{1\theta}(\theta_1, \phi_1) \\ &= \frac{j\eta_0}{2\lambda_0} v_{R1\theta}(\theta_1, \phi_1). \end{aligned} \tag{6.106}$$

One may repeat the above procedure by reorienting the dipole antenna 2 such that the current is in the -$\hat{\phi}_1$ direction. This would provide the relationship between the $\hat{\phi}$ components of the transmit and receive vectors:

$$e_{1\phi}(\theta_1, \phi_1) = \frac{j\eta_0}{2\lambda_0} v_{R1\phi}(\theta_1, \phi_1). \tag{6.107}$$

Combining equations 6.106 and 6.107, the relationship between the complete transmit and receive vectors becomes:

$$\bar{e}_1(\theta_1, \phi_1) = \frac{j\eta_0}{2\lambda_0} \bar{v}_{R1}(\theta_1, \phi_1). \tag{6.108}$$

Because an arbitrary antenna is being considered for antenna 1, and the direction of consideration (θ_1, ϕ_1) is arbitrary, it can be generalized that for any antenna and any direction of radiation-reception the following is true:

$$\begin{aligned} \bar{e}(\theta, \phi) &= \frac{j\eta_0}{2\lambda_0} \bar{v}_R(\theta, \phi), \\ |\bar{e}(\theta, \phi)| &= \frac{\eta_0}{2\lambda_0} |\bar{v}_R(\theta, \phi)|,\ \hat{\rho}(\theta, \phi) = j\hat{\rho}_R(\theta, \phi). \end{aligned} \tag{6.109}$$

Equation 6.109 is a useful universal relationship between the transmit and receive vectors of any antenna.

$G \sim A_{em}$ Relationship

Consider now the relationship between the magnitudes of the transmit and receive vectors in equation 6.109. Then use equation 6.63 to relate $|\bar{e}|$ to G and equation 6.83 to relate $|\bar{v}_R|$ to maximum effective area A_{em}. Thus, an equivalent universal relationship between $G(\theta, \phi)$ and $A_{em}(\theta, \phi)$ results:

$$\frac{|\bar{e}(\theta, \phi)|^2}{|\bar{v}_R(\theta, \phi)|^2} = (\frac{\eta_0}{2\lambda_0})^2 = \frac{G(\theta, \phi)}{A_{em}(\theta, \phi)} \frac{\eta_0^2}{16\pi},\ \frac{G(\theta, \phi)}{A_{em}(\theta, \phi)} = \frac{4\pi}{\lambda_0^2}. \tag{6.110}$$

6.4.3 Friis Transmission Formula

Using the universal $\bar{e} \sim \bar{v}_R$ relationship of equation 6.109 in the equation 6.96, the received Thevenin's voltage at the antenna 2 terminals can be expressed using transmit vectors of the two antennas:

$$V_{R2} = I_1 \frac{e^{-jk_0 r_1}}{r_1} \bar{e}_1(\theta_1, \phi_1) \cdot \bar{e}_2(\theta_2, \phi_2) \frac{2\lambda_0}{j\eta_0}. \tag{6.111}$$

$$|V_{R2}| = \frac{|I_1|}{r_1} |\bar{e}_1(\theta_1, \phi_1)||\bar{e}_2(\theta_2, \phi_2)| \frac{2\lambda_0}{\eta_0} |\hat{\rho}_1(\theta_1, \phi_1) \cdot \hat{\rho}_2(\theta_2, \phi_2)|. \tag{6.112}$$

Equation 6.63 may be used to relate the multiple $|\bar{e}|$s of equation 6.112 to corresponding Gs:

$$|V_{R2}|^2 = \left(\frac{\lambda_0}{4\pi r_1}\right)^2 4|I_1|^2 R_{\text{in}1} R_{\text{in}2} G_1(\theta_1, \phi_1) G_2(\theta_2, \phi_2) |\hat{\rho}_1(\theta_1, \phi_1) \cdot \hat{\rho}_2(\theta_2, \phi_2)|^2. \tag{6.113}$$

$$|V_{R2}|^2 = \left(\frac{\lambda_0}{4\pi r_1}\right)^2 8 P_{\text{in}1} R_{\text{in}2} G_1(\theta_1, \phi_1) G_2(\theta_2, \phi_2) |\hat{\rho}_1(\theta_1, \phi_1) \cdot \hat{\rho}_2(\theta_2, \phi_2)|^2. \tag{6.114}$$

Once V_{R2} is known, the load voltage V_{L2} and load power P_{L2}, when the antenna 2 is loaded by an arbitrary load impedance Z_{L2}, are found from equation 6.80:

$$P_{L2} = \frac{8R_{\text{in2}}R_{L2}}{2|Z_{L2} + Z_{\text{in2}}|^2}\left(\frac{\lambda_0}{4\pi r_1}\right)^2 P_{\text{in1}}G_1(\theta_1, \phi_1)G_2(\theta_2, \phi_2)|\hat{\rho}_1(\theta_1, \phi_1) \cdot \hat{\rho}_2(\theta_2, \phi_2)|^2. \tag{6.115}$$

$$P_{L2\,\max} = \left(\frac{\lambda_0}{4\pi r_1}\right)^2 P_{\text{in1}}G_1(\theta_1, \phi_1)G_2(\theta_2, \phi_2);\ Z_{L2} = Z^*_{\text{in2}}, |\hat{\rho}_1 \cdot \hat{\rho}_2| = 1. \tag{6.116}$$

$$P_{L2} = P_{L2\,\max}\left(\frac{4R_{\text{in2}}R_{L2}}{|Z_{L2} + Z_{\text{in2}}|^2}\right)|\hat{\rho}_1(\theta_1, \phi_1) \cdot \hat{\rho}_2(\theta_2, \phi_2)|^2. \tag{6.117}$$

Equations 6.115, 6.116, and 6.117 are called the **Friis transmission formula**, which relates the received load power to the input power through the antenna and load parameters.

6.4.4 Polarization Match Factor

The element $\hat{\rho}_1(\theta_1, \phi_1) \cdot \hat{\rho}_2(\theta_2, \phi_2)$ in the above Friis formulas is the **polarization match factor** M_p.

$$M_p = \hat{\rho}_1(\theta_1, \phi_1) \cdot \hat{\rho}_2(\theta_2, \phi_2). \tag{6.118}$$

Using equation 6.29 (also see Figure 6.3), M_p may be alternately represented in the coordinates of the respective polarization ellipses:

$$M_p = e^{j\alpha_1}\hat{\rho}'_1(\theta_1, \phi_1) \cdot \hat{\rho}'_2(\theta_2, \phi_2)e^{j\alpha_2}. \tag{6.119}$$

It should be remembered, however, that equation 6.118 applies for general conditions, where the polarization unit vectors are referenced with respect to the coordinate systems of the corresponding antennas (see Figure 6.8) that in general can have arbitrary relative orientation with respect to each other. It may be useful to express M_p for a simpler situation, when the axes $(\hat{x}_1, \hat{y}_1, \hat{z}_1)$ and $(\hat{x}_2, \hat{y}_2, \hat{z}_2)$ are respectively aligned with each other (with different origins). With this situation, in the direction of communication between the antennas, $\hat{\theta}_1 \cdot \hat{\theta}_2 = 1$, but $\hat{\phi}_1 \cdot \hat{\phi}_2 =$ -1:

$$M_p = \hat{\rho}_1 \cdot \hat{\rho}_2 = (\rho_{1\theta}\hat{\theta}_1 + \rho_{1\phi}\hat{\phi}_1) \cdot (\rho_{2\theta}\hat{\theta}_2 + \rho_{2\phi}\hat{\phi}_2) = \rho_{1\theta}\rho_{2\theta}\text{-}\rho_{1\phi}\rho_{2\phi}. \tag{6.120}$$

M_p Using $\hat{\rho}$ Vectors in Common Coordinates

Consider again the just described situation of aligned coordinates for the two antennas of a communication link. However, consider that the polarization unit vectors of the two antennas, $\hat{\rho}_1$ and $\hat{\rho}_2$, are expressed while the two antennas are placed in a common coordinate system (r, θ, ϕ) with origin at the antenna center:

$$\hat{\rho}_1 = \rho_{1\theta}\hat{\theta} + \rho_{1\phi}\hat{\phi}, \hat{\rho}_2 = \rho_{2\theta}\hat{\theta} + \rho_{2\phi}\hat{\phi}. \tag{6.121}$$

With this situation, one may see that the polarization mismatch factor, $M_p = \rho_{1\theta}\rho_{2\theta} - \rho_{1\phi}\rho_{2\phi}$, is no longer equal to $\hat{\rho}_1 \cdot \hat{\rho}_2$. The correct expression for M_p is as follows:

$$\begin{aligned} M_p &= \rho_{1\theta}\rho_{2\theta} - \rho_{1\phi}\rho_{2\phi} = \hat{\rho}_{1s} \cdot \hat{\rho}_2 = \hat{\rho}_1 \cdot \hat{\rho}_{2s}; \\ \hat{\rho}_{1s} &= \hat{\rho}_1|_{\hat{\phi} \to -\hat{\phi}}, \hat{\rho}_{2s} = \hat{\rho}_2|_{\hat{\phi} \to -\hat{\phi}}. \end{aligned} \tag{6.122}$$

$$|M_p| = |\hat{\rho}_{1s} \cdot \hat{\rho}_2| = |\hat{\rho}_1 \cdot \hat{\rho}_{2s}|, \tag{6.123}$$

where the unit vectors with subscript s refer to original vectors with $-\hat{\phi}$ switched for $\hat{\phi}$. As may be noted, this essentially switches the "handedness" of the coordinates.

6.5 Antenna as a Scatterer

Figure 6.9 shows a plane wave, $\bar{E}_i$, being scattered from an arbitrary antenna. $\bar{E}_i$ is incident from angle (θ_i, ϕ_i), which in general has both $\hat{\theta}$ and $\hat{\phi}$ components of the electric field:

$$\bar{E}_i = e^{jk_0 r}(e_{i\theta}\hat{\theta} + e_{i\phi}\hat{\phi}), P_{di} = P^{\theta}_{di} + P^{\phi}_{di};\ P^{\theta}_{di} = \frac{|e_{i\theta}|^2}{2\eta_0}, P^{\phi}_{di} = \frac{|e_{i\phi}|^2}{2\eta_0}. \tag{6.124}$$

The scattered field $\bar{E}_s(r, \theta, \phi;\ \theta_i, \phi_i)$ in the far-field region can be decomposed into two parts. The first part, $\bar{E}_{so}(r, \theta, \phi;\ \theta_i, \phi_i)$, is the scattering with the antenna input terminals open-circuited ($I_L = 0$). The second part, $\bar{E}_r(r, \theta, \phi;\ \theta_i, \phi_i)$, is the reradiated field due to the load current I_L = -I_{in} when the antenna is loaded with a finite impedance:

$$\bar{E}_s = \bar{E}_{so} + \bar{E}_r = \frac{e^{-jk_0 r}}{r}[e_{i\theta}\bar{e}^{\theta}_s(\theta,\ \phi;\ \ \theta_i,\ \phi_i) + e_{i\phi}\bar{e}^{\phi}_s(\theta,\ \phi;\ \theta_i,\ \phi_i)]. \tag{6.125}$$

The scattered field is a linear combination of the incident field components $e_{i\theta}$ and $e_{i\phi}$. As for a radiating antenna, the scattered field also has the $e^{-jk_0 r}$-dependence, in the far-field region, that account for the propagation phase and the free-space loss. The $\bar{e}^{\theta}_s$ and $\bar{e}^{\phi}_s$ may respectively be referred to as the θ- and ϕ-scattering vectors and are the r-independent part of the scattered field due to one unit of $e_{i\theta}$ and $e_{i\phi}$, respectively.

The part due to the open-circuited antenna may be separately expressed in the following form, where the subscript refers to the corresponding values in the open-circuited condition:

$$\bar{E}_{so} = \frac{e^{-jk_0 r}}{r}[e_{i\theta}\bar{e}^{\theta}_{so}(\theta,\ \phi;\ \ \theta_i,\ \phi_i) + e_{i\phi}\bar{e}^{\phi}_{so}(\theta,\ \phi;\ \theta_i,\ \phi_i)]. \tag{6.126}$$

Using equations 6.20, 6.72, and 6.80, the reradiated part can be expressed in terms of the input current I_{in} = -I_L, the transmit vector $\bar{e}(\theta,\ \phi)$, and the receive vector $\bar{v}_R(\theta_i,\ \phi_i)$. The

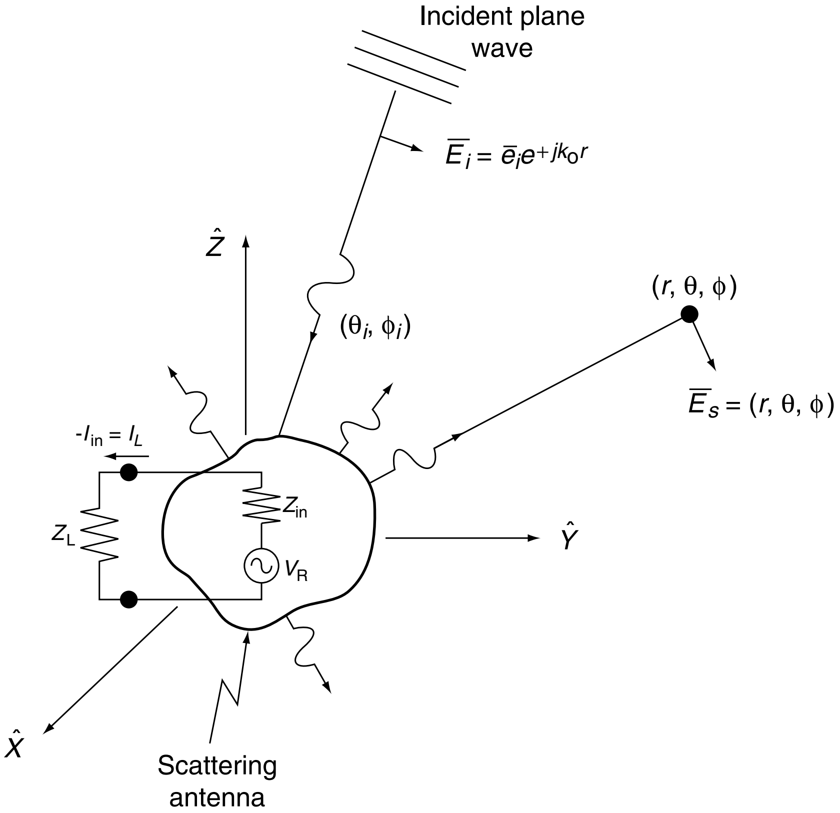

FIGURE 6.9 A Plane Wave Incident From Angle (θ_i, ϕ_i) is Scattered from an Antenna. The scattered signal $\overline{E}_s(r, \theta, \phi)$ is observed at a point $(r,\ \theta,\ \phi)$. The scattered signal is affected by the load impedance Z_L.

input/load current is induced by the incident field and related by the receive vector $\bar{v}_R$:

$$\bar{E}_r = \frac{e^{-jk_0 r}}{r} I_{\text{in}}(\theta_i,\ \phi_i)\bar{e}(\theta, \phi) = -\frac{e^{-jk_0 r}}{r}\left[\frac{\bar{e}_i \cdot \bar{v}_R(\theta_i,\ \phi_i)}{Z_{\text{in}} + Z_L}\bar{e}(\theta,\ \phi)\right]. \quad (6.127)$$

Now the individual parts in equations 6.126 and 6.127 may be combined with equation 6.125 to obtain the following relationships:

$$\bar{e}_s^\theta = \bar{e}_{so}^\theta - \frac{v_{R\theta}(\theta_i, \phi_i)}{Z_{\text{in}} + Z_L}\bar{e}(\theta,\ \phi), \bar{e}_s^\phi = \bar{e}_{so}^\phi - \frac{v_{R\phi}(\theta_i, \phi_i)}{Z_{\text{in}} + Z_L}\bar{e}(\theta,\ \phi). \quad (6.128)$$

6.5.1 Intercepted Power and Radar Cross Section

First consider a θ-polarized incident field ($e_{i\phi} = 0$). With this condition, the power–density, P_{ds}^θ, of the scattered field at a given location $(r,\ \theta, \phi)$ can be expressed using the resulting scattered E-field (from equations 6.124 and 6.125). For brevity of presentation, the angle of incidence (θ_i, ϕ_i) and the observation point $(r,\ \theta,\ \phi)$ can be considered as implicit variables, as appropriate:

$$P_{ds}^\theta(r,\ \theta,\ \phi;\ \theta_i,\ \phi_i) = \frac{|e_{i\theta}|^2|\bar{e}_s^\theta|^2}{2\eta_0 r^2} = \frac{P_{di}^\theta|\bar{e}_s^\theta|^2}{r^2} = \frac{P_{di}^\theta[|e_{s\theta}^\theta|^2 + |e_{s\phi}^\theta|^2]}{r^2}. \quad (6.129)$$

An **effective intercept power**, P_{int}^θ, is defined as associated with a scatterer. The P_{int}^θ is the equivalent power intercepted by the scattering antenna that when reradiated by an isotropic antenna provides the same power density at the observation location as the scattering wave. The P_{int}^θ is a function of the angle of observation $(\theta,\ \phi)$. The corresponding **radar cross section**, σ^θ, is defined as the ratio of the intercept power and the incident power density P_{di}^θ:

$$P_{ds}^\theta = \frac{P_{int}^\theta(\theta,\ \phi;\ \theta_i, \phi_i)}{4\pi r^2} = \frac{P_{di}^\theta \sigma^\theta}{4\pi r^2};$$
$$\sigma^\theta(\theta,\ \phi;\ \ \theta_i,\ \phi_i) = \frac{P_{int}^\theta}{P_{di}^\theta} = \frac{4\pi r^2 P_{ds}^\theta}{P_{di}^\theta}. \quad (6.130)$$

Using equations 6.129 in 6.130, the relationship is created between the θ-radar cross section σ^θ and the θ-scattering vector $\bar{e}_s^\theta$. σ^θ is further decomposed into σ_θ^θ and σ_ϕ^θ which respectively correspond to the θ and ϕ components of $\bar{e}_s^\theta = \hat{\theta} e_{s\theta}^\theta + \hat{\phi} e_{s\phi}^\theta$:

$$\sigma^\theta(\theta, \phi;\ \ \theta_i, \phi_i) = 4\pi|\bar{e}_s^\theta|^2 = 4\pi[|e_{s\theta}^\theta|^2 + |e_{s\phi}^\theta|^2]$$
$$= \sigma_\theta^\theta(\theta,\ \phi;\ \ \theta_i, \phi_i) + \sigma_\phi^\theta(\theta,\ \phi;\ \ \theta_i, \phi_i). \quad (6.131)$$

Similarly, the radar cross section may be defined for the ϕ-polarized incident field, with the θ-superscripts exchanged for ϕ:

$$\begin{aligned} P_{ds}^{\phi}(r,\ \theta,\ \phi;\ \theta_i,\ \phi_i) &= \frac{P_{int}^{\phi}(\theta,\ \phi;\ \ \theta_i,\ \phi_i)}{4\pi r^2} \\ &= \frac{P_{di}^{\phi}|\bar{e}_s^{\phi}|^2}{r^2} = \frac{P_{di}^{\phi}[|e_{s\theta}^{\phi}|^2 + |e_{s\phi}^{\phi}|^2]}{r^2}. \end{aligned} \tag{6.132}$$

$$\begin{aligned} \sigma^{\phi}(\theta,\ \phi;\ \ \theta_i,\ \phi_i) &= \frac{4\pi r^2 P_{ds}^{\phi}}{P_{di}^{\phi}} = 4\pi[|e_{s\theta}^{\phi}|^2 + |e_{s\theta}^{\phi}|^2] \\ &= \sigma_{\theta}^{\phi}(\theta,\ \phi;\ \ \theta_i,\ \phi_i) + \sigma_{\phi}^{\phi}(\theta,\ \phi;\ \ \theta_i,\ \phi_i). \end{aligned} \tag{6.133}$$

II
Antenna Elements and Arrays

6.6 Introduction

One can envision literally infinite possible antenna geometries that can be designed to achieve a variety of performance features. Among these diverse configurations, one may identify a few **basic antenna elements** that are often used for general-purpose wireless applications. The following sections analyze the radiation/reception mechanism in selected basic antenna geometries: (1) dipole antenna, (2) monopole antenna, (3) wire-loop antenna, (4) slot antenna, and (5) microstrip antenna. Selected other types of antennas in use will also be introduced.

An **antenna array** is made of a number of individual antenna elements each located at a different position in space, with independent excitation to each input. Such an array may provide many practical advantages over a single antenna element. By properly designing for the individual locations and input excitations, one can achieve radiation characteristics that might not be normally feasible using a single antenna. If one can also control the input excitations to the individual elements in the real-time, the radiation characteristics of the array, such as the pointing direction or radiation pattern, can be changed in a dynamic manner. This will allow significant flexibility for adjusting to a dynamically changing situation. This chapter will analyze the basic theory of a general antenna array and derive results for specific situations of a one-dimensional array and a two-dimensional array.

6.7 Antenna Elements

This section presents a number of basic antenna elements, starting with a small dipole antenna that is considered the most fundamental radiating structure. Behaviors only in the far-field region are emphasized, and various radiation and impedance parameters of the specific antennas are derived from them. For general definitions and notations used in this study, the reader is referred to Das (2004). Some useful parameters of the antenna elements covered in this section are summarized in Table 6.1.

6.7.1 Dipole Antennas

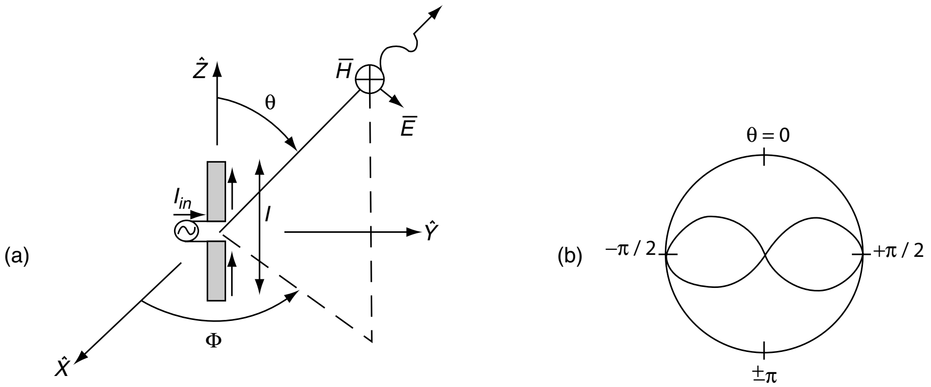
Small Dipole Antenna

A **small dipole antenna** may be visualized as a small length of current $\bar{I} = \hat{z}I_{in}$, excited by connecting a pair of small metal wires or rods to a radio frequency source. This is shown in Figure 6.10. It is considered small when the length l is significantly smaller than the wavelength ($l \ll \lambda_0$) of operation. This basic element is often used in many radio communication systems as a **whip antenna**. For communication in a relatively

TABLE 6.1 Summary of Antenna Parameters of Basic Antenna Types

Antenna type		Polarization	Power pattern $P_{-d}(\theta, \pi)$	Directivity D	Radiation resistance $R_{\text{rod}}(\Omega)$
Dipole antennas (current along $\hat{z}$)	Short dipole (length $= l$)	$E_\theta(TM_z)$	$\sin^2\theta$	1.5	$80\pi^2(l/\lambda_0)^2$
	Half-wave dipole (length $= \lambda_0/2$)	$E_\theta(TM_z)$	$\dfrac{\cos^2(\pi/2\cos\theta)}{\sin^2\theta}$	1.64	73
	Half-wave folded dipole (length $= \lambda_0/2$)	$E_\theta(TM_z)$	$\dfrac{\cos^2(\pi/2\cos\theta)}{\sin^2\theta}$	1.64	292
Monopole antennas (current along $\hat{z}$)	Short monopole (length $= l$)	$E_\theta(TM_z)$	$\sin^2\theta$ (only half space, $0 \leq \theta \leq \pi/2$)	3.0	$160\pi^2(l/\lambda_0)^2$
	Half-wave monopole (length $= \lambda_0/4$)	$E_\theta(TM_z)$	$\dfrac{\cos^2(\pi/2\cos\theta)}{\sin^2\theta}$ (only half space, $0 \leq \theta \leq \pi/2$)	3.28	36.5
	Half-wave folded monopole (length $= \lambda_0/4$)	$E_\theta(TM_z)$	$\dfrac{\cos^2(\pi/2\cos\theta)}{\sin^2\theta}$ (only half space, $0 \leq \theta \leq \pi/2$)	3.28	146
Loop antenna (loop on x–y plane)	Small loop antenna (loop area $= S$)	$E_\phi(TE_z)$	$\sin^2\theta$	1.5	$320\pi^4(S/\lambda_0^2)^2$
Slot antennas (slot length along $\hat{z}$)	Short slot antenna (length $= l$)	$E_\phi(TE_z)$	$\sin^2\theta$	1.5	$45(\lambda_0/l)^2$
	Half-wave slot antenna (length $= \lambda_0/2$)	$E_\phi(TE_z)$	$\dfrac{\cos^2(\pi/2\cos\theta)}{\sin^2\theta}$	1.64	485
Microstrip antenna (antenna current along $\hat{x}$, patch on the x–y plane)	Rectangular, edge fed (length $= \lambda_0/(2\sqrt{\varepsilon_r})$	Both E_θ and $E_\phi(TM_x)$	See Section 6.2.5	No analytical results, depending on several parameters: d, L, W, ε_r, λ_0.	

Refer to appropriate sections in the text for the geometry of the specific antennas.



(A) A Basic Dipole Antenna

(B) Power Radiation Pattern

FIGURE 6.10 (A) This Basic Dipole antenna is excited by an Input Current I_{in} and the Figure Shows the Directions of the Electric $\bar{E}$ and Magnetic $\bar{H}$ Fields in the Far-Field Region. (B) The Power Radiation Pattern $\underline{p}_d(\theta, \phi)$ in the Elevation Plane (θ) for a Given ϕ is Shown Here. The pattern is uniform in the azimuth (ϕ) plane.

low frequency range (such as a short-wave radio), where the wavelength of radiation is quite long, a whip antenna of any reasonable length can be safely approximated as a small dipole antenna. The metal wire or rod is ideally made of a perfect metal when the ohmic loss in the metal is zero. In practical situations when the wire is made from a very good conductor, unless the wire is too thin (which results in very high ohmic resistance), only a small fraction of the input power is dissipated as ohmic loss. Most of the input power is thus radiated into the free space, resulting in a good radiation efficiency.

Transmitting Mode of Operation

The rigorous electric and magnetic fields of this dipole antenna can be derived using Maxwell's equations (Cheng, 1993; Ramo *et al.*, 1993). The final expressions in the far-field region are provided here and are used to derive the various basic parameters. The radiated far-fields of the dipole antenna can be expressed in the following form:

$$\bar{E}(r,\,\theta,\,\phi) = \hat{\theta} I_{\text{in}} \frac{e^{-jk_0 r}}{r} \frac{j\eta_0 l}{2\lambda_0} \sin\theta = I_{\text{in}} \frac{e^{-jk_0 r}}{r} \bar{e}(\theta,\,\phi). \tag{6.134}$$

$$\begin{aligned} \bar{H}(r,\,\theta,\,\phi) &= \frac{\hat{r} \times \bar{E}(r,\,\theta,\,\phi)}{\eta_0} = \hat{\phi} I_{\text{in}} \frac{e^{-jk_0 r}}{r} \frac{jl}{2\lambda_0} \sin\theta \\ &= I_{\text{in}} \frac{e^{-jk_0 r}}{r} \frac{jl}{2\lambda_0} (\hat{z} \times \hat{r}). \end{aligned} \tag{6.135}$$

$$\bar{e}(\theta,\,\phi) = \hat{\theta} \frac{j\eta_0 l}{2\lambda_0} \sin\theta,\; \hat{\rho}(\theta,\,\phi) = j\hat{\theta}. \tag{6.136}$$

The dipole does not radiate in the vertical directions $(\theta = 0,\ \pi)$ and produces maximum radiation perpendicular to the current $(\theta = \pi/2)$ with uniform variation in the azimuth. There is a $\sin\theta$ factor for variation of the radiation fields in the elevation in proportion to the projection of the input current in the particular direction. The magnetic field $\bar{H}$ is in the $\hat{\phi}$ direction and, thus, revolves around the wire in analogy to a magnetostatic field, due to a linear current. The electric field $\bar{E}$ and, accordingly, the polarization vector of the dipole antenna, are in the $\hat{\theta}$ direction. Once the far-field expressions are known, then the power density P_d and power per unit solid angle p_d of the radiation can be derived using the theory of Das (2004):

$$\begin{aligned} P_d(r,\,\theta,\,\phi) &= \frac{|\bar{E}|^2}{2\eta_0} = \frac{|I_{\text{in}}|^2 \eta_0}{8r^2} \left(\frac{l}{\lambda_0}\right)^2 \sin^2\theta,\; p_d(\theta,\,\phi) \\ &= r^2 P_d(r,\,\theta,\,\phi) = \frac{|I_{in}|^2 \eta_0}{8} \left(\frac{l}{\lambda_0}\right)^2 \sin^2\theta. \end{aligned} \tag{6.137}$$

The power radiation pattern $\underline{p}_d(\theta,\,\phi)$ of the dipole antenna is a $\sin^2\theta$ function in elevation and uniform in the azimuth:

$$\underline{p}_d(\theta,\,\phi) = \frac{p_d(\theta,\,\phi)}{p_{\text{dmax}}} = \sin^2\theta. \tag{6.138}$$

The total radiated power from the dipole antenna for a given input current I_{in} can be obtained by integrating $p_d(\theta,\,\phi)$ over the entire sphere:

$$\begin{aligned} P_{\text{rad}} &= \int\limits_{\phi=0}^{2\pi} \int\limits_{\theta=0}^{\pi} p_d(\theta,\,\phi) \sin\theta d\theta d\phi \\ &= \frac{|I_{\text{in}}|^2 \eta_0 \pi}{3} \left(\frac{l}{\lambda_0}\right)^2 = \frac{|I_{\text{in}}|^2 R_{\text{rad}}}{2}. \end{aligned} \tag{6.139}$$

$$R_{\text{rad}} = \frac{2\eta_0 \pi}{3} \left(\frac{l}{\lambda_0}\right)^2 = 80\pi^2 \left(\frac{l}{\lambda_0}\right)^2,\; R_{\text{in}} = R_{\text{rad}};\; \eta_r = 1. \tag{6.140}$$

The directive gain and directivity of the dipole antenna are obtained from $p_d(\theta,\,\phi)$ or $\underline{p}_d(\theta,\,\phi)$ Das (2004):

$$\begin{aligned} D_g(\theta,\,\phi) &= \frac{4\pi p_d(\theta,\,\phi)}{\int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} p_d(\theta,\,\phi) \sin\theta d\theta d\phi} \\ &= \frac{4\pi \underline{p}_d(\theta,\,\phi)}{\int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} \underline{P}_d(\theta,\,\phi) \sin\theta d\theta d\phi}. \end{aligned} \tag{6.141}$$

$$D_g(\theta,\,\phi) = \frac{4\pi \sin^2\theta}{\int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} \sin^3\theta d\theta d\phi} = \frac{3\sin^2\theta}{2};\; D = 1.5. \tag{6.142}$$

In an ideal situation, when the ohmic loss is zero or radiation efficiency is one, the antenna gain is equal to the directivity. In practical cases using good conductors, the ohmic loss can be calculated using the metal conductivity, shape of the wire, and the current distribution:

$$G(\theta,\,\phi) = \eta_r \frac{3\sin^2\theta}{2} \simeq \frac{3\sin^2\theta}{2},\; G \simeq 1.5;\; \eta_r \simeq 1. \tag{6.143}$$

Receiving Mode of Operation

Figure 6.11 shows the dipole antenna in the **receiving mode** of operation. The Thevenin's voltage excited at the antenna terminals can be obtained by taking the tangential component of the incident electric field and multiplying it with the antenna length:

$$\begin{aligned} V_R &= -lE_{\text{zinc}} = le_{i\theta} \sin\theta = \bar{v}_R(\theta,\,\phi) \cdot \bar{e}_i \\ &= v_{R\theta}(\theta,\,\phi) e_{i\theta} + v_{R\phi}(\theta,\,\phi) e_{i\phi}. \end{aligned} \tag{6.144}$$

$$\begin{aligned} v_{R\theta}(\theta,\,\phi) &= l\sin\theta,\; v_{R\phi}(\theta,\,\phi) = 0; \\ \bar{v}_R(\theta,\,\phi) &= \hat{\theta} l \sin\theta,\; \hat{\rho}_R(\theta,\,\phi) = \hat{\theta}. \end{aligned} \tag{6.145}$$

(A) Antenna in Receiving Mode

(B) Thevenin's Equivalent Circuit

FIGURE 6.11 (A) A Small Dipole Antenna in its Receiving Mode of Operation (B) Thevenin's Equivalent Circuit of the Receiving Dipole Antenna

The receiving vector $\bar{v}_R$ is linearly polarized, with the receiving polarization unit vector in the $\hat{\theta}$ direction. From the magnitude of the receiving vector, the maximum effective area A_{em} can be found using the theory of Das (2004):

$$A_{em}(\theta, \phi) = \frac{\eta_0 |\bar{v}_R(\theta, \phi)|^2}{4R_{in}} = \frac{3\lambda_0^2 \sin^2 \theta}{8\pi}. \qquad (6.146)$$

Notice that the ratio of $A_{em}(\theta, \phi)$ and $G(\theta, \phi)$ is equal to $\frac{\lambda_0^2}{4\pi}$, which is a constant independent of (θ, ϕ). This is the universal constant applicable for any arbitrary antenna, as derived in Das (2004):

$$\frac{A_{em}(\theta, \phi)}{G(\theta, \phi)} = \frac{3\lambda_0^2 \sin^2 \theta}{8\pi(1.5 \sin^2 \theta)} = \frac{\lambda_0^2}{4\pi}. \qquad (6.147)$$

Dipole Antenna of Arbitrary Length

If the length of the dipole antenna is not electrically small, then one can derive the radiation fields by slicing it into small pieces and then superposing (integrating) the individual fields, if the current distribution is known. This is shown in Figure 6.12. Each piece can be modeled as a small dipole with a different current of excitation and a different location.

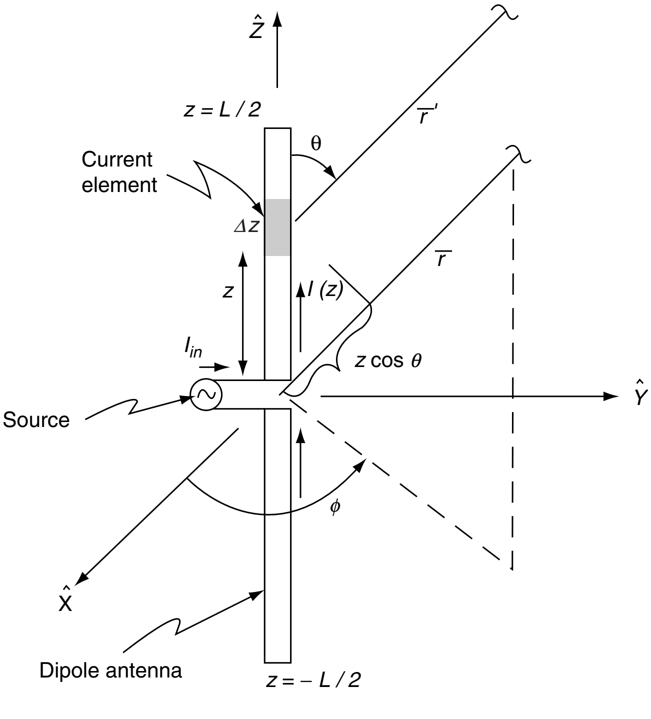

FIGURE 6.12 A Linear Dipole Antenna of Arbitrary Length *L*. This antenna can be treated as a number of "slices" of small dipole elements. The total field can be obtained by superposing the fields due to the individual small dipole slices having current $I(z)$, having length Δz, and being located at distance z from the center.

The elemental field $\Delta\bar{E}$ produced by a current element of length Δz, located at distance z from the center, with a current I_z, can be written using equations 6.134 through 6.136:

$$\Delta\bar{E} = \hat{\theta} I(z) \frac{e^{-jk_0 r'}}{r'} \frac{j\eta_0}{2\lambda_0} \sin\theta \Delta z; \; r' = r - z\cos\theta. \qquad (6.148)$$

Assuming that $z \ll r$ in the far-field, equation 6.148 can be simplified by approximating the r' in the denominator as r:

$$\Delta\bar{E} \simeq \hat{\theta} I(z) \frac{e^{-jk_0 r} e^{jk_0 z\cos\theta}}{r} \frac{j\eta_0}{2\lambda_0} \sin\theta \Delta z. \qquad (6.149)$$

The total field can be obtained by integrating equation 6.149 with respect to z, from $z = -L/2$ to $z = +L/2$:

$$\bar{E} = \hat{\theta} \frac{e^{-jk_0 r}}{r} \frac{j\eta_0}{2\lambda_0} \sin\theta \int_{z=-L/2}^{L/2} I(z) e^{jk_0 z\cos\theta} dz. \qquad (6.150)$$

If the current distribution $I(z)$ is known or can be approximated by a known function, then the far-field of the total antenna can be obtained using equation 6.150. One would expect the current distribution to exhibit a standing wave pattern, with zero current at the ends of the line ($z = \pm L/2$) and $I = I_{\text{in}}$ at the center. This behavior is similar to the current distribution along an open-circuited transmission line, having propagation constant k_0:

$$I(z) = I_{\text{in}} \frac{\sin[k_0(L/2 - |z|)]}{\sin(k_0 L/2)}; \; I(z=0) = I_{\text{in}}. \qquad (6.151)$$

Using the current distribution of equation 6.151 in 6.150 and then performing the integration over z, one can obtain a close-form expression for the far-field distribution:

$$\begin{aligned}\bar{E}(r, \theta, \phi) &= \hat{\theta} \frac{e^{-jk_0 r}}{r} \frac{j\eta_0}{2\lambda_0} \sin\theta \int_{z=-L/2}^{L/2} I_{\text{in}} \frac{\sin[k_0(L/2 - |z|)}{\sin(k_0 L/2)} e^{jk_0 z\cos\theta} dz \\ &= \hat{\theta} \frac{e^{-jk_0 r}}{r} \frac{j\eta_0 I_{\text{in}}}{2\pi} \left(\frac{\cos(k_0 L/2 \cos\theta) - \cos(k_0 L/2)}{\sin(k_0 L/2)\sin\theta} \right).\end{aligned} \qquad (6.152)$$

Once the electric field is obtained, then basic antenna parameters can be derived using steps similar to those used for a small dipole antenna (Das, 2004). The radiated power is obtained by integrating the power-density function over the sphere, as usual, from which the radiation resistance can be derived. The necessary spherical integration involving equation 6.152 cannot be easily expressed in closed form, requiring numerical integration.

Half-Wave Dipole Antenna

A dipole antenna with $L = \lambda_0/2$, called a **half-wave dipole**, is often useful because it operates close to a resonant condition of its input impedance. This results in an almost real value of the input impedance, which can be easily matched to an input source having a real source impedance for maximum power transfer. For this case, the equations 6.151 and 6.152 can be simplified:

$$I(z) = I_{\text{in}} \cos(k_0 z) = I_{\text{in}} \cos\frac{2\pi z}{\lambda_0}. \tag{6.153}$$

$$\begin{aligned} \bar{E}(r,\,\theta,\,\phi) &= \hat{\theta}\,\frac{e^{-jk_0 r}}{r}\,\frac{j\eta_0 I_{\text{in}}}{2\pi}\left(\frac{\cos\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\right) \\ &= \hat{\theta}\,\frac{e^{-jk_0 r}}{r}\,j60 I_{\text{in}}\left(\frac{\cos\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\right). \end{aligned} \tag{6.154}$$

The polarization vector is in the $\hat{\theta}$ direction, which is the same as that for a small dipole. The power density P_d and power per unit solid angle p_d can be expressed using equation 6.154 (Das, 2004):

$$\begin{aligned} P_d(r,\,\theta,\,\phi) &= \frac{|E_\theta|^2}{2\eta_0} = \frac{15|I_{\text{in}}|^2}{\pi r^2}\left(\frac{\cos\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\right)^2, \\ p_d(\theta,\,\phi) &= \frac{15|I_{\text{in}}|^2}{\pi}\left(\frac{\cos\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\right)^2. \end{aligned} \tag{6.155}$$

The direction of maximum radiation is along $\theta = \frac{\pi}{2}$, which is perpendicular to the direction of the antenna current. The power radiation pattern $\underline{p}_d(\theta,\,\phi)$ has the following form with respect to θ, having a uniform variation in the azimuth:

$$\underline{p}_d(\theta,\,\phi) = \frac{p_d(\theta,\,\phi)}{p_{d\max}} = \left(\frac{\cos\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\right)^2. \tag{6.156}$$

Now, by following steps similar to those used for a small dipole, the radiated power P_{rad}, radiation resistance R_{rad}, directive gain $D_g(\theta,\,\phi)$, and directivity D for a half-wave dipole antenna can be derived. This will require integrations involving the pattern function of equation 6.156:

$$P_{\text{rad}} = \int_{\phi=0}^{2\pi}\int_{\theta=0}^{\pi} p_d(\theta,\,\phi)\sin\theta\, d\theta\, d\phi = 30|I_{\text{in}}|^2 \int_{\theta=0}^{\pi} \frac{\cos^2\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\, d\theta. \tag{6.157}$$

$$R_{\text{rad}} = \frac{2P_{\text{rad}}}{|I_{\text{in}}|^2} = 60\int_{\theta=0}^{\pi} \frac{\cos^2\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\, d\theta. \tag{6.158}$$

$$D_g(\theta,\,\phi) = \frac{4\pi \underline{p}_d(\theta,\,\phi)}{\int_{\phi=0}^{2\pi}\int_{\theta=0}^{\pi}\underline{p}_d(\theta,\,\phi)\sin\theta\, d\theta\, d\phi} = \frac{2\left(\frac{\cos\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\right)^2}{\int_{\theta=0}^{\pi}\frac{\cos^2\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\, d\theta}. \tag{6.159}$$

$$D = D_g(\theta,\,\phi)_{\max} = \frac{2}{\int_{\theta=0}^{\pi}\frac{\cos^2\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\, d\theta}. \tag{6.160}$$

The θ integral that identically appears in the above equations 6.157 through 6.160 may be computed numerically and has an approximate value of 1.22. Using this value, the antenna parameters can be approximated as follows:

$$\begin{aligned} &P_{\text{rad}} = 36.6|I_{\text{in}}|^2,\ D_g(\theta,\,\phi) = 1.64\left(\frac{\cos\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}\right)^2, \\ &D = 1.64,\ R_{\text{rad}} = 73.2\ \Omega \end{aligned} \tag{6.161}$$

Notice that the directivity D of a half-wave dipole (= 1.64) is not significantly different from that of a small dipole (= 1.5).

Folded Dipole Antenna

Figure 6.13 shows the geometry of a **folded dipole antenna**. It consists of a source (V_{in}) connected to the ends of a wire of total length $2L$ and folded once as a rectangular loop of height L and width $\delta \ll L$. The length L can have any value but is often designed to be about $\lambda_0/2$ for a resonant operation. This antenna configuration can be viewed as a superposition of an **odd mode** and an **even mode**, having dual excitations at the center of the two arms of the antenna with odd and even symmetry. The odd mode represents a transmission line mode of operation without any radiation. Here, the top and bottom sections are two identical transmission-line stubs of length $L/4$ connected in series, as shown in Figure 6.13. The input current I_t in this mode can then be related to V_{in} as follows:

$$I_t = \frac{V_{\text{in}}}{2Z_t} = \frac{V_{\text{in}}}{2jZ_0\tan(k_0 L/2)}, \tag{6.162}$$

where Z_0 is the characteristic impedance of a two-wire transmission line having the same wire diameter as that of the folded dipole and having a line-to-line separation δ. In contrast, the even mode represents an antenna mode of operation with $I = 0$ at the top and bottom ends to satisfy the symmetry condition. The antenna mode operates very much as two dipole antennas of length L that are placed close to each other. The current distribution along the wire is the same as that for an equivalent dipole antenna and, therefore, has the same radiation pattern and gain. The input current I_a for the antenna mode can be related to the input voltage V_{in} using the input impedance Z_{dipole} of an equivalent dipole antenna of length L:

$$Z_{\text{dipole}} = \frac{V_{\text{in}}/2}{2I_a},\ I_a = \frac{V_{\text{in}}}{4Z_{\text{dipole}}}. \tag{6.163}$$

Now, using superposition, the input impedance of the folded dipole can be expressed as a parallel combination of two parts:

$$I_{\text{in}} = I_a + I_t = \frac{V_{\text{in}}}{4Z_{\text{dipole}}} + \frac{V_{\text{in}}}{2jZ_0\tan(k_0 L/27)}. \tag{6.164}$$

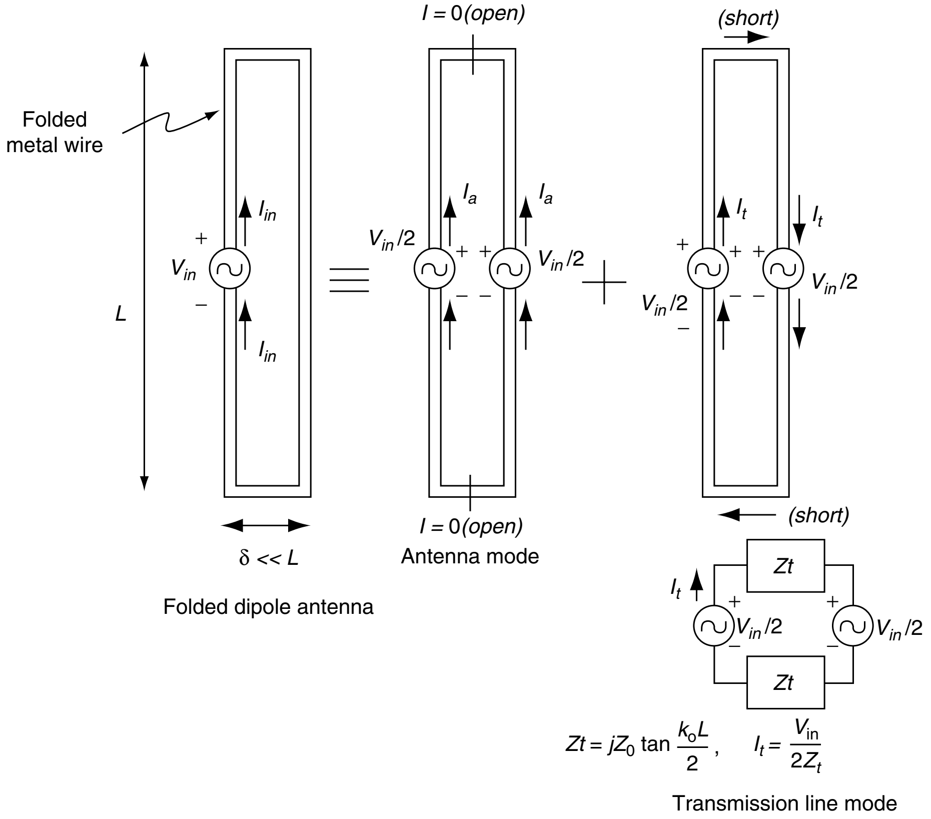

FIGURE 6.13 A Folded Dipole Antenna of Vertical Length L. The antenna can be treated as a superposition of an **even mode** that radiates as a regular dipole antenna of length L and an **odd mode** that can be viewed as two transmission line stubs of length $L/2$, each connected in series.

$$Z_{\text{in}}=\frac{V_{\text{in}}}{I_{\text{in}}}=\frac{1}{\frac{1}{4Z_{\text{dipole}}}+\frac{1}{2jZ_0\tan(k_0L/2)}}=(4Z_{\text{dipole}})\,\|\,(2jZ_0\tan(k_0L/2)). \tag{6.165}$$

If the length L is a half wavelength, or $k_0L/2=\pi/2$, then the input impedance of the folded dipole antenna is four times that of a half-wave dipole antenna:

$$Z_{\text{in}}(L=\lambda_0/2)=4Z_{\text{dipole}}(L=\lambda_0/2)=4\times 73=292\,\Omega. \tag{6.166}$$

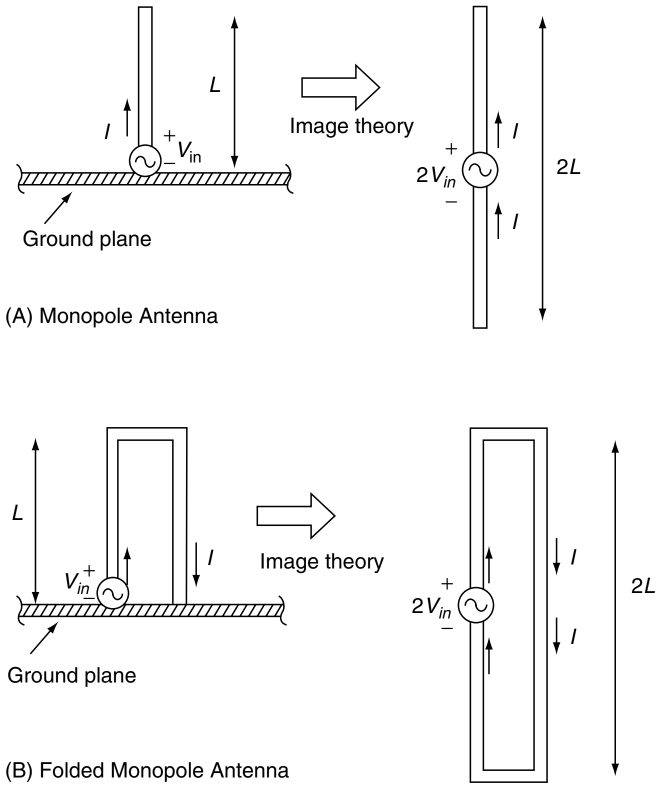
So, a folded-dipole antenna is a derivative of a regular dipole antenna with the same radiation pattern, polarization, and directivity, except with a different input impedance. For the half-wave case, the folded-dipole antenna simply produces an impedance transformation by a factor of four. The resulting 292 Ω impedance is convenient to match to 300 Ω systems used in some broadcast applications.

6.7.2 Monopole Antennas

Monopole antennas, as shown in Figure 6.14, constitute a group of derivatives of dipole antennas. Here, only half of the dipole antenna is needed for operation. A metal ground plane (ideally of infinite size) is used, with respect to which the excitation voltage is applied to the half structure. The half structure for a regular dipole antenna is called a monopole antenna, in reference to the presence of only one physical side. A similar half structure for a folded dipole antenna is called a folded monopole antenna. The presence of the ground plane allows the monopole antenna to operate as electrically equivalent to a dipole antenna. The ground plane equivalently replaces the lower half by an imaging principle, similar to creating an optical image through a mirror. Notice in Figure 6.14 that for the currents in the monopole and dipole structures to be the same, one needs the source voltage of the equivalent dipole antenna to be twice that of the monopole antenna. As a result, the input impedance of the monopole structure is half that of the corresponding dipole structure:

$$Z_{\text{monopole}}=\frac{1}{2}Z_{\text{dipole}};\ Z_{\text{monopole}}=\frac{V_{\text{in}}}{I_{\text{in}}},\ Z_{\text{dipole}}=\frac{2V_{\text{in}}}{I_{\text{in}}}. \tag{6.167}$$

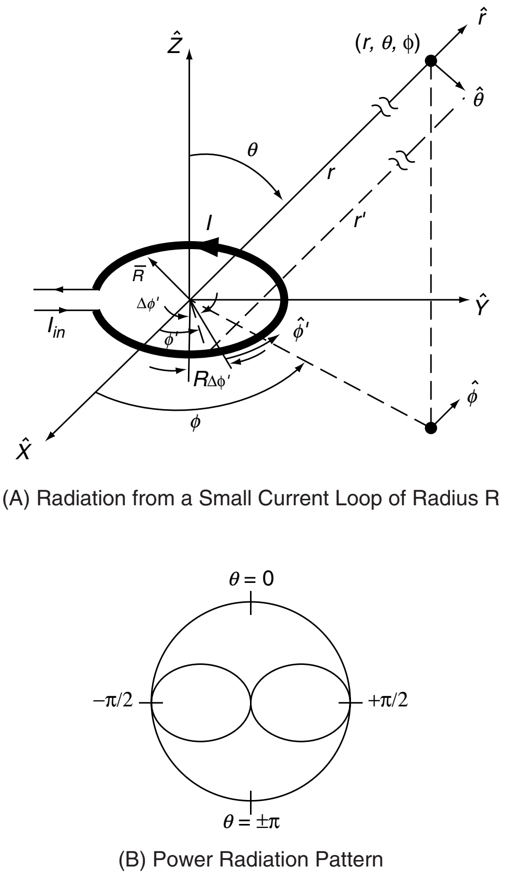
For example, if the length of the monopole antenna $L=\lambda_0/4$, such that the corresponding length of the equivalent dipole antenna is $\lambda_0/2$, the following values of the radiation impedances result:



(A) Monopole Antenna

(B) Folded Monopole Antenna

FIGURE 6.14 The Corresponding Equivalent Dipole Structures Employing Image Theory



(A) Radiation from a Small Current Loop of Radius R

(B) Power Radiation Pattern

FIGURE 6.15 Circular Loop Antenna

$$
\begin{aligned}
Z_{\text{monopole}} &= \frac{1}{2} Z_{\text{dipole}} = 36.5\,\Omega; \\
Z_{\text{foldedmonopole}} &= \frac{1}{2} Z_{\text{foldeddipole}} = 146\,\Omega.
\end{aligned}
\tag{6.168}
$$

Due to the imaging principle, the polarization of radiation and radiation patterns of a monopole antenna is the same as that of its equivalent dipole antenna. However: the monopole antenna has a field only in the top half of the space, having zero radiation below the ground plane. In contrast, the equivalent dipole structure has fields in both sides, with the radiation to the bottom side symmetric to that above. In this situation, the expression of the directive gain functions in equations 6.141, 6.142, 6.159, and 6.160 (Das, 2004) can be used to show that the directivity D of a monopole antenna is twice that of its equivalent dipole structure.

$$
\begin{aligned}
D_{\text{monopole}} = 2D_{\text{dipole}};\ D_{\text{short monopole}} &= 3.0, \\
D_{\text{half-wave monopole}} &= 3.28.
\end{aligned}
\tag{6.169}
$$

6.7.3 Loop Antenna

A **loop antenna** consists of a wire loop of arbitrary shape fed by an input current I_{in}. A circular loop, as shown in Figure 6.15, is the shape most commonly used. The radius of the loop, R, could be electrically small or large. If the current distribution along the wire loop is known, or can at least be closely approximated based on some physical insight, then the radiated fields of the loop antenna can be derived analytically or computed numerically. This is possible by treating the loop as a superposition of small current elements with known amplitudes, physical location, and orientation. The far-field quantities for a small dipole antenna, as presented in Section 6.7.1, with suitable transformation of its coordinates to account for different physical location and orientation, can be used here to model the elemental radiation.

If the current loop is small ($R \ll \lambda_0$), the far-field quantities can be derived into a simple final form. In this case, the current along the loop $I(\phi')\hat{\phi}'$ can be assumed to be independent of $\hat{\phi}'$, with a magnitude equal to the input current I_{in}. With reference to Figure 6.15, consider the small current element of length $R\Delta\phi'$ carrying a current along the direction $\hat{\phi}'$. The radiation fields due to this current element can be expressed using results from Section 6.7.1, equations 6.134 and 6.135. One must properly adjust these equations, however, to account for the orientation of the current element along $\hat{\phi}'$ and its location at (R, ϕ'), defined by a position vector $\bar{R} = R\hat{R}$.

For simplicity of analysis, one should first use equation 6.135 to express the radiating magnetic field $\bar{H}$ due to the current element:

$$\Delta\bar{H}(r,\,\theta,\,\phi;\,\phi') = \frac{jI_{\text{in}}R\Delta\phi'}{2\lambda_0}\frac{e^{-jk_0r'}}{r'}(\hat{\phi}'\times\hat{r}). \qquad (6.170)$$

$$\hat{\phi}' = \cos(\phi-\phi')\hat{\phi} + \sin\theta\sin(\phi-\phi')\hat{\theta}. \qquad (6.171)$$

$$\bar{R} = R\hat{R} = R[\sin\theta\cos(\phi-\phi')\hat{r} + \cos\theta\cos(\phi-\phi')\hat{\theta} - \sin(\phi-\phi')\hat{\phi}]. \qquad (6.172)$$

$$r' = r - \bar{R}\cdot\hat{r} = r - R\sin\theta\cos(\phi-\phi'). \qquad (6.173)$$

$$(\hat{\phi}'\times\hat{r}) = \cos(\phi-\phi')\hat{\theta} - \sin\theta\sin(\phi-\phi')\hat{\phi}. \qquad (6.174)$$

Using the coordinate relationships of equations 6.171 through 6.174, equation 6.170 can be rewritten in the following form:

$$\Delta\bar{H}(r,\,\theta,\,\phi;\,\phi') \simeq \frac{jI_{\text{in}}R\Delta\phi'}{2\lambda_0}\frac{e^{-jk_0r}e^{jk_0R\sin\theta\cos(\phi-\phi')}}{r} \times[\cos(\phi-\phi')\hat{\theta} - \sin\theta\sin(\phi-\phi')\hat{\phi}]. \qquad (6.175)$$

In the far-field region, $r \gg R$. This condition has been used in equation 6.175 to approximate r' in the denominator by r. In addition, for a small loop, $R \ll \lambda_0 = \frac{2\pi}{k_0}$, which is equivalent to $Rk_0 \ll 1$. This condition can be used to further approximate equation 6.175 by approximating one of the exponential functions in the numerator:

$$\Delta\bar{H}(r,\,\theta,\,\phi;\,\phi') \simeq \frac{jI_{in}R\Delta\phi'}{2\lambda_0}\frac{e^{-jk_0r}[1 + jk_0R\sin\theta\cos(\phi-\phi')]}{r} \times[\cos(\phi-\phi')\hat{\theta} - \sin\theta\sin(\phi-\phi')\hat{\phi}]. \qquad (6.176)$$

The total magnetic field can be obtained by integrating equation 6.176 over $0 < \hat{\phi}' < 2\pi$ to cover the entire current loop. The $\hat{\phi}$ component of equation 6.176 can be shown to integrate to zero, whereas the $\hat{\theta}$ component will be nonzero:

$$\bar{H}(r,\,\theta,\,\phi) = \int_{\phi'=0}^{2\pi}\Delta\bar{H}(r,\,\theta,\,\phi;\,\hat{\phi}') = \frac{jI_{\text{in}}R}{2\lambda_0}\frac{e^{-jk_0r}}{r}(jk_0R\sin\theta)(\pi\hat{\theta})$$
$$= -\frac{I_{\text{in}}(\pi R^2)}{\lambda_0^2}\frac{e^{-jk_0r}}{r}(\pi\sin\theta)\hat{\theta} = -\frac{e^{-jk_0r}}{4\pi r}I_{\text{in}}Sk_0^2\sin\theta\hat{\theta};\; S = \pi R^2. \qquad (6.177)$$

Once the total radiating magnetic field is known, the radiating electric field can be obtained from it using their far-field relationship:

$$\bar{E}(r,\,\theta,\,\phi) = \hat{\phi}\frac{\eta_0k_0^2(I_{\text{in}}S)\sin\theta e^{-jk_0r}}{4\pi r} = \eta_0\bar{H}(r,\,\theta,\,\phi)\times\hat{r}. \qquad (6.178)$$

If there are N number of loops in the form of a coil instead of a single loop shown in Figure 6.15, then the corresponding field quantities would have to be multiplied by N. One may view the far-field of a small loop antenna as **dual** to that of a small dipole antenna. This is because the loop antenna has H_θ and E_ϕ far-field components, as shown in equations 6.177 and 6.178, in contrast to which a small dipole antenna has E_θ and H_ϕ components. Both the small loop and the small dipole antennas have the same $\sin\theta$ field pattern, thus having the same directive gain $D_g(\theta,\,\phi) = 1.5\sin^2\theta$ and directivity $D = 1.5$. Once the radiation fields are known, using a procedure similar to that used for a small dipole antenna in Section 6.7.1, one can derive the total radiated power, P_{rad}, and the radiation resistance, R_{rad}.

$$P_{\text{rad}} = \frac{\eta_0k_0^4(S|I_{\text{in}}|)^2}{12\pi},\; R_{\text{rad}} = \frac{2P_{\text{rad}}}{|I_{\text{in}}|^2} = \frac{\eta_0k_0^4S^2}{6\pi} = 20k_0^4S^2. \qquad (6.179)$$

It may be noted, that equation 6.179 needs to be multiplied by N^2 for a N-loop coil antenna.

6.7.4 Slot Antenna

A **slot antenna**, as shown in Figure 6.16, is considered another basic radiating element. It is realized by removing a small area of metal from an infinite ground plane. For a practical design, however, the ground plane may be finite but large in size. The open area, or the ‘slot,’ can be of any shape and size, but is shown in Figure 6.16 to be rectangular, as is often done for simplicity. As shown in this figure, a slot antenna may be excited by applying a voltage source across the slot.

Babinet’s Principle

One may view a slot antenna to be physically *complementary* to a **strip dipole antenna** consisting of a metal strip of the same

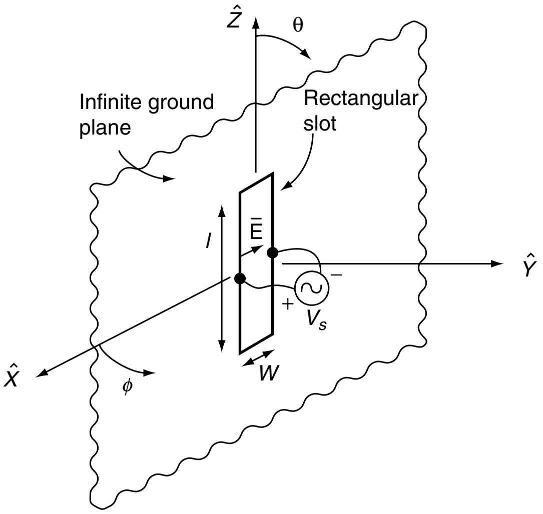


FIGURE 6.16 A Slot Antenna. This antenna is produced by a rectangular opening at the center of an infinite ground plane.

shape and size as that of the slot. The complementary strip dipole is to be excited by a voltage gap, breaking across the strip at the same position where the slot antenna is excited. If the slot antenna is superimposed on its complementary dipole antenna structure, one would obtain an infinite conducting plane. Interestingly, employing certain symmetry in Maxwell's equations and realizing the complementary nature of the above two structures, it can be shown that the fields of a slot antenna and that of a complementary dipole antenna are related to each other in a simple manner. This theory is called **Babinet's principle** (Balanis, 1997), which consequently relates the various transmit/receive characteristics, such as the pattern, gain, and input impedance of the two complementary antennas.

According to Babinet's principle, the fields produced by a slot antenna can be obtained directly from the corresponding complementary strip dipole antenna using the following substitutions:

- For the front side of the slot antenna of ($0 < \phi < \pi$; see Figure 6.16), replace $\bar{E}$ of the dipole with $-\bar{H}$ for the slot antenna, $\bar{H}$ with $\bar{E}$, ε_0 with μ_0, μ_0 with ε_0, and η_0 with $1/\eta_0$, but replace the input current I_{in} of the strip dipole with twice the source voltage V_s for the slot antenna.
- For the back side ($\pi < \phi < 2\pi$), one needs the same substitutions as for the front side, except the signs for the field expressions are reversed.

The above substitutions also lead to a simple relationship between the complex input impedances of the complementary antennas. If Z_{sl} is the complex input impedance as seen across the input of an arbitrary slot antenna and Z_{cd} is that of its complementary dipole antenna, then using the substitutions prescribed in Babinet's principle, one can show:

$$4\frac{Z_{cd}}{\eta_0} = \frac{\eta_0}{Z_{sl}}, \; Z_{cd}Z_{sl} = \frac{\eta_0^2}{4}. \tag{6.180}$$

Small Slot Antenna

As an example, let us apply Babinet's principle to a **small rectangular slot antenna**, whose complementary structure is a small dipole antenna studied in Section 6.7.1. Employing the substitutions prescribed in the previous subsection, the far-field expressions for the small slot antenna can be obtained from those in equations 6.134 and 6.135 for a short dipole antenna:

$$\bar{H}(r, \theta, \phi) = \begin{cases} -\hat{\theta} V_s \frac{e^{-jk_0 r}}{r} \frac{jl}{\eta_0 \lambda_0} \sin\theta; & 0 < \phi < \pi. \\ \hat{\theta} V_s \frac{e^{-jk_0 r}}{r} \frac{jl}{\eta_0 \lambda_0} \sin\theta; & \pi < \phi < 2\pi. \end{cases} \tag{6.181}$$

$$\bar{E}(r, \theta, \phi) = \begin{cases} \hat{\phi} V_s \frac{e^{-jk_0 r}}{r} \frac{jl}{\lambda_0} \sin\theta; & 0 < \phi < \pi. \\ -\hat{\phi} V_s \frac{e^{-jk_0 r}}{r} \frac{jl}{\lambda_0} \sin\theta; & \pi < \phi < 2\pi. \end{cases} \tag{6.182}$$

Using these field expressions described previously, one can obtain the antenna parameters for the small slot antenna following similar steps to Section 6.7.1 for a complementary dipole antenna:

$$P_d(r, \theta, \phi) = \frac{|V_s|^2}{2\eta_0 r^2}\left(\frac{l}{\lambda_0}\right)^2 \sin^2\theta, \; p_d(\theta, \phi) = \frac{|V_s|^2}{2\eta_0}\left(\frac{l}{\lambda_0}\right)^2 \sin^2\theta. \tag{6.183}$$

$$\underline{p}_d(\theta, \phi) = \frac{p_d(\theta, \phi)}{p_{d\max}} = \sin^2\theta. \tag{6.184}$$

$$P_{\text{rad}} = \int_{\phi=0}^{2\pi}\int_{\theta=0}^{\pi} p_d(\theta, \phi)\sin\theta d\theta d\phi = \frac{|V_s|^2 4\pi}{3\eta_0}\left(\frac{l}{\lambda_0}\right)^2 = \frac{|V_s|^2}{2R_{\text{rad}}}. \tag{6.185}$$

$$G_{\text{rad}} = \frac{1}{R_{\text{rad}}} = \frac{8\pi}{3n_0}\left(\frac{l}{\lambda_0}\right)^2 = \frac{1}{45}\left(\frac{l}{\lambda_0}\right)^2. \tag{6.186}$$

$$D_g(\theta, \phi) = \frac{3\sin^2\theta}{2}; \; D = 1.5. \tag{6.187}$$

Comparing the radiation resistances of a small slot in equation 6.186 to that of a small dipole antenna in equation 6.140, one sees that $R_{\text{rad}}(\text{dipole}) \times R_{\text{rad}}(\text{slot}) = \frac{\eta_0^2}{4}$, which is consistent with the general impedance relationship of equation 6.180. As shown in equation 6.184, a narrow slot antenna (see Figure 6.16) has the same $\sin^2\theta$ power pattern as that of a small dipole antenna. The small slot antenna has E_ϕ and H_θ radiation fields, in contrast with the E_θ and H_ϕ radiation fields of its complementary small dipole antenna.

Similar procedures can be extended to a half-wave slot antenna or, in general, to a rectangular slot antenna of any arbitrary length. This will allow derivation of the far fields, as well as radiation/impedance parameters of a long slot antenna, by relating to those of the complementary dipole structures in Section 6.2.1 under Dipole Antenna of Arbitrary Length.

6.7.5 Microstrip Antenna

The **microstrip antenna** is a relatively modern invention. It was invented to allow convenient integration of an antenna and other driving circuitry of a communication system on a common printed-circuit board or a semiconductor chip (Carver and Mink, 1981; Pozar, 1992). Besides other resulting advantages, the integrated-circuit technology for the antenna fabrication allowed high dimensional accuracy, which was otherwise difficult to achieve in traditional fabrication methods. The geometry of a microstrip antenna consists of a dielectric substrate of certain thickness d, having a complete metalization on one of its surfaces and of a metal "patch" on the other side. The substrate is usually thin ($d \ll \lambda$). The metal patch on the front surface can have various shapes, although a rectangular shape, as shown in Figure 6.17, is commonly used. The antenna may be excited using various methods (Pozar, 1992; Pozar and Schawbert, 1995). One common approach is to feed from a microstrip line, connecting the microstrip antenna at the center of one of its edges. The microstrip line

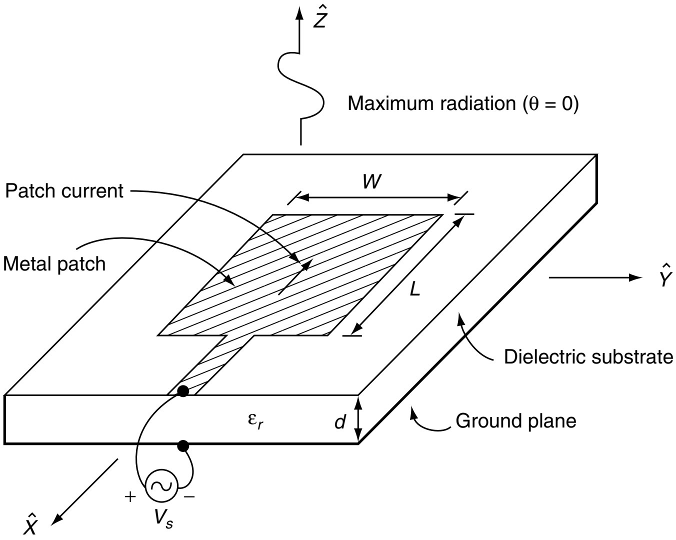

FIGURE 6.17 Geometry of a Rectangular Microstrip Antenna. It consists of a rectangular metal patch on a dielectric substrate and is excited by a voltage source across the metal patch and the bottom ground plane of the substrate. The microstrip antenna produces maximum radiation in the broadside direction ($\theta = 0$), with ideally no radiation along the substrate edges ($\theta = 90^\circ$).

may be connected to a feeding circuitry or directly fed by connecting a signal source across the microstrip line and the ground plane.

The microstrip antenna produces maximum radiation in the broadside (perpendicular to the substrate) direction and ideally no radiation in the end-fire (along the surface of the substrate) direction. The size of the antenna is usually designed such that the antenna resonates at the operating frequency, producing a real input impedance. For a rectangular microstrip antenna, this requires the length of the antenna, L, to be about half a wavelength in the dielectric medium. The width of the antenna, W, on the other hand, determines the level of the input impedance. The microstrip antenna can be thought of as a rectangular cavity with open sidewalls. The fringing fields through the open sidewalls are responsible for the radiation. However, the structure is principally a resonant cavity, with only limited fringing radiation. Therefore, the bandwidth of the radiation is poor compared to the bandwidth of antennas discussed earlier. The small bandwidth, however, is adequate in a large class of communication applications. Readers may refer to Balanis (1997) and Carver and Mink (1981) for some analytical modeling of a microstrip antenna. Simple and approximate expressions for the radiated electric field components of a microstrip antenna are given by Carver and Mink (1981):

$$E_\theta = \frac{-jV_o k_0 W e^{-jk_0 r}}{\pi r} \cos\phi \cos(k_0 \sqrt{\varepsilon_r} d \cos\theta) \times \frac{\sin(k_0 \sin\theta \sin\phi W/2)}{k_0 \sin\theta \sin\phi W/2} \cos(k_0 L/2 \sin\theta \cos\phi);\ 0 \leq \theta \leq \pi/2. \tag{6.188}$$

$$E_\phi = \frac{jV_o k_0 W e^{-jk_0 r}}{\pi r} \sin\phi \cos\theta \cos(k_0 \sqrt{\varepsilon_r} d \cos\theta) \times \frac{\sin(k_0 \sin\theta \sin\phi W/2)}{k_0 \sin\theta \sin\phi W/2} \cos(k_0 L/2 \sin\theta \cos\phi); \quad 0 \leq \theta \leq \pi/2. \tag{6.189}$$

More accurate and complete modeling of various characteristics of a microstrip antenna often requires numerical methods (Pozar and Schawbert, 1995). Sophisticated designs, including techniques for achieving broad bandwidths, are also found in Pozar and Schawbert (1995).

6.7.6 Other Common Antenna Geometries

There are many possible antenna geometries in practical use today, each having some desirable properties suited for specific applications. This chapter has only discussed a few of the most basic radiating elements. The reader may be referred to antenna textbooks (Balanis, 1997; Kraus, 1950; Collin and Zucker, 1969; Jasik, 1961; Schelkunoff and Friis, 1952; Kraus and Fleisch, 1999) for a more elaborate set of practical antenna geometries. A few of the antenna geometries in common use are shown in Figure 6.18: (A) a **horn antenna**, (B) a **Yagi-Uda array**, and (C) a **spiral plate antenna**. A horn antenna is distinguished by its feeding from a input waveguide. The Yagi-Uda array is popularly used as a television antenna, having a high-gain radiation along the end-fire direction over a broad bandwidth. A much broader bandwidth of radiation can be achieved by a class of **frequency-independent** antennas, such as a spiral plate antenna. In principle, one needs an infinite-sized spiral structure for an ideal frequency-independent operation. However, a practical spiral antenna will have to be truncated at a finite spiral length. This would result in a finite, but large bandwidth. Other frequency-independent antennas include conical spiral and log-periodic structures.

Another common class of antennas make use of additional material structures, such as a focusing reflector or a dielectric lens structure, surrounding a basic source antenna to achieve focusing of the antenna radiation. This results in increasing the antenna gain. Although these structures are not really a part of the fundamental radiation mechanism, their designs are often critical for the overall performance of the total antenna system.

6.8 Antenna Array

An arbitrary configuration of an array of N identical antennas is shown in Figure 6.19. The center of the ith antenna is defined by a position vector $\bar{R}_i = \hat{x}x_i + \hat{y}y_i + \hat{z}z_i$, and the input current to the ith antenna is I_i. The electric field of the array in the far-field region can be expressed as the superposition of the individual contributions:

$$\bar{E}_i = I_i \frac{e^{-jk_0 r_i}}{r_i} \bar{e}_i(\theta, \phi),\ \bar{E} = \sum_{i=1}^{N} \bar{E}_i = \sum_{i=1}^{N} I_i \frac{e^{-jk_0 r_i}}{r_i} \bar{e}_i(\theta, \phi). \tag{6.190}$$

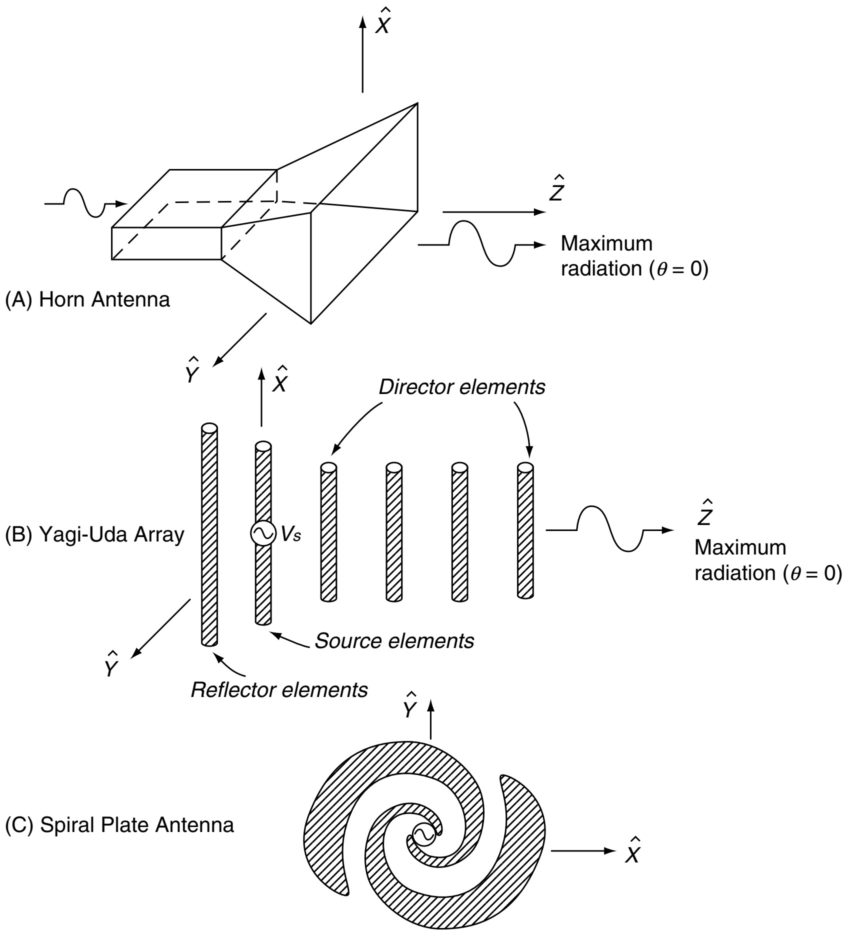

FIGURE 6.18 A Few Practical Antenna Geometries. (A) A waveguide horn antenna is excited from a waveguide input. (B) A Yagi-Uda array is commonly used in television receivers, having an end fire and high-gain beam. (c) A spiral plate antenna is shown here with broad band radiation along the broadside (z) direction.

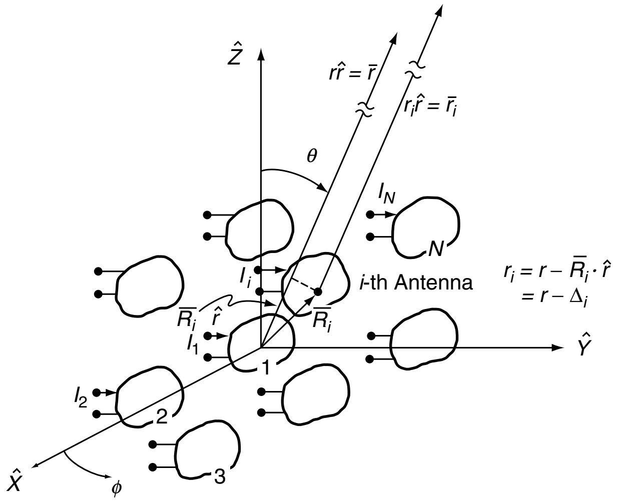

FIGURE 6.19 A General Configuration of an Array of N Identical Antennas. Each antenna is excited by a different input current I_i and placed at a different location $\bar{R}_i = x_i\hat{x} + y_i\hat{y} + z_i\hat{z}$.

$$\bar{r}_i = \bar{r} - \bar{R}_i = \hat{r}r_i, r - \bar{R}_i \cdot \hat{r} = r - \Delta_i. \tag{6.191}$$

in the far-field region, $r \gg \Delta_i$. Under this situation, the r_i in the denominator of equation 6.190 may be approximated as $r_i = r - \Delta_i \simeq r$. Such approximation, however, is not appropriate for the propagation factor in the numerator because of the oscillating nature of the propagation factor, which is sensitive to the small difference Δ_i between r_i and r.

$$\bar{E} = \sum_{i=1}^{N} I_i \frac{e^{-jk_0(r-\Delta_i)}}{r - \Delta_i}\bar{e}_i(\theta, \phi) \simeq \frac{e^{-jk_0 r}}{r}\sum_{i=1}^{N} I_i e^{jk_0\Delta_i}\bar{e}_i(\theta, \phi). \tag{6.192}$$

Often it may be assumed, with good approximation, that the transmit properties of each antenna are unaffected by the presence of the other elements. This assumption is valid when the **mutual-coupling effects** between the antennas have negligible effects on the radiation characteristics of the individual elements. Under this practical approximation, the total radiation from the array can be further simplified:

$$\bar{E} \simeq \bar{e}(\theta, \phi)\frac{e^{-jk_0 r}}{r}\sum_{i=1}^{N} I_i e^{jk_0\Delta_i};\ \bar{e}_i(\theta, \phi) = \bar{e}(\theta, \phi). \quad (6.193)$$

$$\bar{E} = (EF)\times(AF);\ EF = \bar{e}(\theta, \phi)\frac{e^{-jk_0 r}}{r},\ AF = \sum_{i=1}^{N} I_i e^{jk_0\Delta_i}. \quad (6.194)$$

The total radiation is thus separated into two independent factors. The element factor (EF) is the contribution due to the individual antenna elements, whereas the array factor (AF) may be seen as the effect due to the array configuration. Such factoring into EF and AF allows the study and design of the array to be used, independent of the specific antenna elements. When the antenna input currents are allowed to have different phases α_i as well as different amplitudes $|I_i|$, the AF may be expressed in the following compact form:

$$\begin{aligned} AF = \sum_{i=1}^{N} |I_i| e^{j\alpha_i} e^{jk_0\Delta_i} &= \sum_{i=1}^{N} |I_i| e^{j\psi_i};\ \psi_i = \alpha_i + k_0\Delta_i \\ &= \alpha_i + k_0(\hat{r}\cdot\bar{R}_i). \end{aligned} \quad (6.195)$$

6.8.1 One-Dimensional Array

As an example, consider an array of N antenna elements, equally spaced along the $\hat{y}$ axis, as shown in Figure 6.20. Also assume that each antenna is excited with the same amplitude, but phased in a linearly progressive manner. The array factor for this case can be expressed as follows:

$$I_i = |I_i| e^{j(i-1)\alpha} = I e^{j(i-1)\alpha}. \quad (6.196)$$

$$\bar{R}_i = \hat{y}(i-1)d,\ \Delta_i = \hat{r}\cdot\bar{R}_i = (i-1)d\sin\theta\sin\phi = (i-1)\Delta. \quad (6.197)$$

$$\begin{aligned} AF = I\sum_{i=1}^{N} e^{j\psi_i};\ \psi_i &= (i-1)\psi = (i-1)(\alpha + k_0\Delta) \\ &= (i-1)(\alpha + k_0 d\sin\theta\sin\phi). \end{aligned} \quad (6.198)$$

$\Delta_i = \bar{R}_i\,.\,\hat{r} = (i-1)\Delta = (i-1)d\sin\theta\sin\phi$

FIGURE 6.20 A One-Dimensional Array of N Antenna Elements. Elements are placed along the $\hat{y}$ axis, with interelement spacing d. The input currents are of equal magnitude I, but are progressively phased with interelement phase shift α.

$$|AF| = I\left|\sum_{i=1}^{N} e^{j(i-1)\psi}\right| = I\left|\frac{1 - e^{jN\psi}}{1 - e^{j\psi}}\right| = I\left|\frac{\sin\frac{N\psi}{2}}{\sin\frac{\psi}{2}}\right|. \quad (6.199)$$

It may be useful to normalize the array factor with respect its maximum value NI:

$$AF_n(\theta, \phi) = \frac{|AF(\theta, \phi)|}{|AF(\theta, \phi)|_{\max}} = \frac{\sin\frac{N\psi}{2}}{N\sin\frac{\psi}{2}};\ AF_n(\theta, \phi) \le 1. \quad (6.200)$$

Array Side Lobe Level

The peak value of the normalized array factor $AF_n(\theta, \phi)$ is unity, which occurs at $\psi = 0$ corresponding to the main direction of radiation. The next peak of AF_n occurs approximately at $N\psi/2 = 1.5\pi$, where $AF_n = \frac{1}{N\sin\frac{1.5\pi}{N}}$. This corresponds to the first side lobe level (SLL) of the array factor. For an array with large number of elements N, this level can be shown to be independent of N:

$$SLL = \frac{1}{N\sin\frac{1.5\pi}{N} \simeq \frac{1}{1.5\pi} \cong 13\text{dB}.} \quad (6.201)$$

Assuming that the element factor EF does not change significantly from the main beam to the side lobe of the array, the SLL of equation 6.201 is approximately equal to the SLL of the total radiation pattern. Remember that this SLL is derived for any large array ($N \to \infty$) while assuming that the amplitudes of excitation are uniform over the array. One can achieve a lower value of SLL, however, by using a nonuniform amplitude distribution.

Graphical Method of Sketching Array Factor

Notice that the array factor in equation 6.199 is represented as a function of $\psi = \alpha + k_0 d\sin\theta\sin\phi$. This should be fairly easy to sketch on the ψ plane. Ultimately one needs to sketch the array factor as a function of the space angles (θ, ϕ). This mapping may be done in a graphical manner, as demonstrated in Figure 6.21 for a four-element array. In Figure 6.21, the mapping from the ψ (upper sketch) to the θ plane (lower polar sketch) is demonstrated for the specific case of $\phi = \pi/2$ and $\alpha = \pi/2$ when $d = \lambda_0/2$. The reasoning for the method, as illustrated in this figure, should be self-explanatory and accordingly extended for other values of ϕ and α.

Notice that the array factor will be maximum ($= NI$) when ψ is zero or even multiples of π. This will determine the angle of the maximum radiation $\theta_{\max}$ for a given value of ϕ, or vice versa:

$$|AF(\theta, \phi)|_{\max} = I\left|\frac{\sin\frac{N\psi_{\max}}{2}}{\sin\frac{\psi_{\max}}{2}}\right| = NI, \quad (6.202)$$

$$\begin{aligned} &\psi_{\max} = \alpha + k_0 d\sin\theta_{\max}\sin\phi = 2n\pi, \\ &n = 0,\ \pm 1,\ \pm 2, \ldots \end{aligned} \quad (6.203)$$

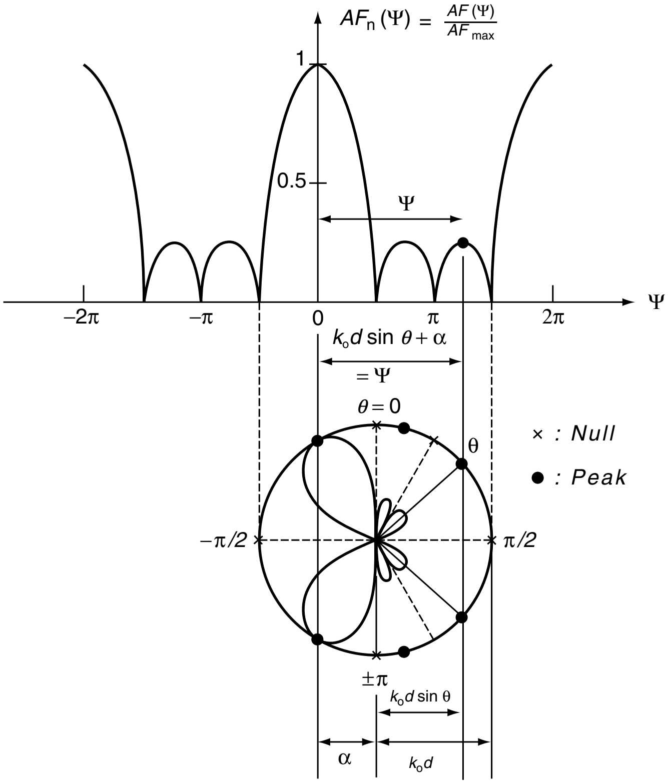

FIGURE 6.21 Graphical Method of Sketching the Array Factor of a Four-Element Array. Sketching is done as a function of θ in the polar form. (Top) Normalized array factor as a function of ψ, plotted in the rectangular coordinates. (Bottom) Mapping from Ψ to θ in polar coordinates, with $\phi = \pi/2$, where $\Psi = k_0 d \sin\theta \sin\phi + \alpha = k_0 d \sin\theta + \alpha$.

For example, if on the $\phi = \pi/2$ plane:

$$\psi_{\max} = \alpha + k_0 d \sin\theta_{\max} = 2n\pi, \quad n = 0, \ \pm 1, \ \pm 2, \ldots; \ \phi = \frac{\pi}{2}. \tag{6.204}$$

Grating Lobes

In general, depending on the spacing d, there can be more than one value of n for which one can find a solution for $\theta_{\max}$. The radiation lobe corresponding to $n = 0$ is called the **main lobe**, whereas all other lobes corresponding to all n other than $n = 0$ are called the **grating lobes** (borrowing the name from a similar situation in the study of periodic gratings). For the main-lobe radiation:

$$\theta_{\max} = \arcsin\frac{-\alpha}{k_0 d}; \ n = 0, \ \phi = \pi/2. \tag{6.205}$$

Accordingly, the value of $\theta_{\max}$ can be steered by controlling the interelement phasing α. However, it may be desirable to design d such that no grating lobe is allowed to exist for all possible values of α. As can be shown from equation 6.205, this is achieved if $k_0 d \leq \pi$, requiring the interelement spacing α to be less than half a wavelength.

6.8.2 Two-Dimensional Array

The one-dimensional array has the freedom of steering the main beam only in one plane: θ or ϕ. The concept may be extended to an array in two-dimensions, as shown in Figure 6.22, to allow beam steering both in θ and ϕ. As shown in this figure, consider an array of $(m \times n)$ elements placed on the x–y plane, with uniform amplitudes of excitation. The interelement spacing is d_x along the x axis and d_y along the y axis, which are in general different from each other. The interelement phasing is α_x and α_y, respectively, along the x and y axes. The interelement phasing can be independently controlled to allow steering in both θ and ϕ.

The derivation of the array factor for the two-dimensional array, as presented below, follows the same procedure used for a one-dimensional array. The same terminology is also used for equivalent parameters. Needed are double indexing of the elements along x and y as well as double summations for the total fields, instead of a single summation for a one-dimensional array:

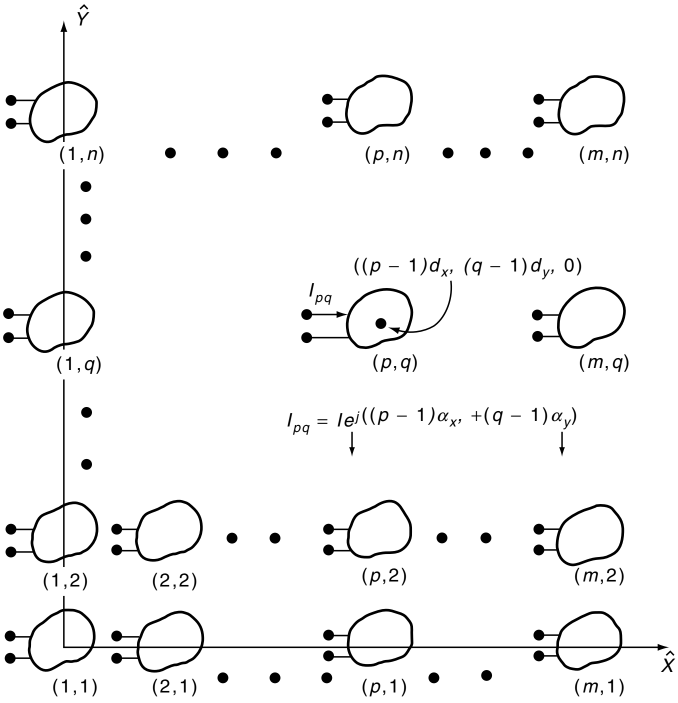

FIGURE 6.22 A Two-Dimensional Array of $m \times n$ Antennas. These antennas are placed on the $x-y$ plane. The interelement spacings are d_x and d_y, respectively, along the $\hat{x}$ and $\hat{y}$ directions. The input currents to the elements are assumed here to have the same magnitude ($= I$), with linearly progressing phases along the $\hat{x}$ and $\hat{y}$ directions.

$$I_{pq} = |I_{pq}| e^{j[(p-1)\alpha_x + (q-1)\alpha_y]} = I e^{j[(p-1)\alpha_x + (q-1)\alpha_y]}. \tag{6.206}$$

$$\bar{R}_{pq} = \hat{x}(p-1)d_x + \hat{y}(q-1)d_y. \tag{6.207}$$

$$\begin{aligned}\Delta_{pq} =& \hat{r} \cdot \bar{R}_{pq} = (p-1)d_x \sin\theta\cos\phi \\ &+ (q-1)d_y \sin\theta\sin\phi = (p-1)\Delta_x + (q-1)\Delta_y.\end{aligned} \tag{6.208}$$

$$\begin{aligned}AF = I \sum_{p=1}^{m} \sum_{q=1}^{n} e^{j\psi_{pq}} &= I \sum_{p=1}^{m} e^{j(p-1)\psi_x} \sum_{q=1}^{n} e^{j(q-1)\psi_y} \\ &= I(AF_x)(AF_y).\end{aligned} \tag{6.209}$$

$$\begin{aligned}\psi_{pq} &= (p-1)(\alpha_x + k_0\Delta_x) + (q-1)(\alpha_x + k_0\Delta_y) \\ &= (p-1)\psi_x + (q-1)\psi_y.\end{aligned} \tag{6.210}$$

$$|AF_x| = \left|\sum_{p=1}^{m} e^{j(p-1)\psi_x}\right| = \left|\frac{1 - e^{jm\psi_x}}{1 - e^{j\psi_x}}\right| = \left|\frac{\sin(m\psi_x/2)}{\sin(\psi_x/2)}\right|. \tag{6.211}$$

$$|AF_y| = \left|\sum_{q=1}^{n} e^{j(q-1)\psi_y}\right| = \left|\frac{1 - e^{jn\psi_y}}{1 - e^{j\psi_y}}\right| = \left|\frac{\sin(n\psi_y/2)}{\sin(\psi_y/2)}\right|. \tag{6.212}$$

$$|AF| = I|AF_x||AF_x| = I\left|\frac{\sin(m\psi_x/2)}{\sin(\psi_x/2)}\right|\left|\frac{\sin(n\psi_y/2)}{\sin(\psi_y/2)}\right|. \tag{6.213}$$

$$|AF(\theta, \phi)|_{\max} = I\left|\frac{\sin(m\psi_{x(\max)}/2)}{\sin(\psi_{x(\max)}/2)}\right|\left|\frac{\sin(n\psi_{y(\max)}/2)}{\sin(\psi_{y(\max)}/2)}\right| = mnI. \tag{6.214}$$

$$AF_n(\theta, \phi) = \frac{AF(\theta, \phi)}{|AF(\theta, \phi)|_{\max}} = \left(\frac{\sin(m\psi_x/2)}{m\sin(\psi_x/2)}\right)\left(\frac{\sin(n\psi_y/2)}{n\sin(\psi_y/2)}\right). \tag{6.215}$$

In general, it may be possible to have more than one value of $\psi_{x(\max)}$ and $\psi_{y(\max)}$ for which the array factor is maximum. All such values other than the dominant ones ($\psi_{x(\max)} = 0$, $\psi_{y(\max)} = 0$) correspond to the grating lobes of the array structure:

$$\begin{aligned}\psi_{x(\max)} &= 0,\ \pm 2\pi,\ \pm 4\pi \ldots;\ \psi_{y(\max)} \\ &= 0,\ \pm 2\pi,\ \pm 4\pi \ldots.\end{aligned} \tag{6.216}$$

As for a one-dimensional array, no grating lobe will occur when one designs with $d_x, d_y \leq \lambda_0/2$. For the dominant lobe of radiation, which is of particular practical interest, the equation is the following:

$$\begin{aligned}\alpha_x + k_0 d_x \sin\theta_{\max}\cos\phi_{\max} &= 0, \\ \alpha_y + k_0 d_y \sin\theta_{\max}\sin\phi_{\max} &= 0.\end{aligned} \tag{6.217}$$

$$\begin{aligned}\theta_{\max} &= \arcsin\left(\sqrt{\left(\frac{\alpha_x}{k_0 d_x}\right)^2 + \left(\frac{\alpha_y}{k_0 d_y}\right)^2}\right), \\ \phi_{\max} &= \arccos\left(\frac{-\alpha_x}{k_0 d_x \sin\theta_{\max}}\right).\end{aligned} \tag{6.218}$$

Accordingly, for given spacings d_x and d_y, the maximum directions $\theta_{\max}$ and $\phi_{\max}$ may be varied by controlling the interelement phasing α_x and α_y.

6.8.3 Mutual Coupling

As mentioned before, the analyses discussed earlier in this section are based on a critical assumption—there are negligible mutual interactions between the antenna elements. This allowed the key simplification of equation 6.193. In situations when this assumption is no longer valid, one needs to use the rigorous equation 6.192. In this rigorous formulation, $\bar{e}_i(\theta, \phi)$ is different from that of an isolated antenna. Instead, $\bar{e}_i(\theta, \phi)$ is the transmit vector when only the ith element is excited (other elements are open circuited with zero input currents), while all other elements are still physically present in their respective locations. In other words, $\bar{e}_i(\theta, \phi)$ is the superposition of the primary radiation from the ith antenna (when isolated), with secondary radiations from all the antenna elements passively excited through mutual coupling.

In addition to the radiated fields $\bar{e}_i(\theta, \phi)$, the voltages at the antenna inputs will also change due to the mutual coupling effects. An N-element array needs to be rigorously modeled as a N-port network using a $[Z]_{N\times N}$ impedance matrix:

$$[V] = [Z][I];\ V_i = \sum_{k=1}^{N} I_k Z_{ik},\ i = 1, N. \tag{6.219}$$

The input voltage of an antenna element operating in an array environment is dependent on the input currents of all other elements. The linearity constant relating V_i and I_k is called the mutual impedance Z_{ik}. When one excites only the ith element, with all other currents zero (but all other elements physically present) from equation 6.219, the result is $V_i = I_i Z_{ii}$. The Z_{ii} is called the self-impedance of the ith element, operating in the array environment. Note that the corresponding value, when the ith antenna is allowed to operate in an isolated manner, is $V_i = I_i Z_{\text{in}}$. The Z_{in} is, in general, different from Z_{ii}, and they would be equal to each other only in the limit of zero mutual coupling.

Technology, Zurich, Switzerland

7.1 General Concepts and Basic Definitions

Active and passive microwave devices and components are the essential building blocks of microwave circuits and systems that operate in the frequency range from 300 MHz to 300 GHz (corresponding to wavelengths of 1 m to 1 mm in free space). This chapter only presents passive components that are composed of lumped or distributed elements or a combination of both. At lower frequencies (e.g., 300 MHz–10 GHz), the emphasis is on lumped elements to keep circuit dimensions small. At higher frequencies, the quality of lumped elements deteriorates rapidly, and mostly distributed elements are employed. Microwave circuits are a combination of passive and active components, whereby the passive part easily makes up 75% or more of the circuit real estate area. Without passive components (e.g., filters, matching circuits, circulators, isolators resistors, etc.), active components (e.g., transistors, tubes) cannot be operated.

A **passive component** is a physical structure or circuit layout that performs one or multiple linear electronic functions without resorting to and consuming external biasing or controlling electric and/or magnetic sources. In other words, the circuit functionality of a passive component is self-contained and self-manifested without any consumable and external third-party intervention. In practice, a microwave signal passing through a passive component always experiences losses and dissipates power. A passive component may

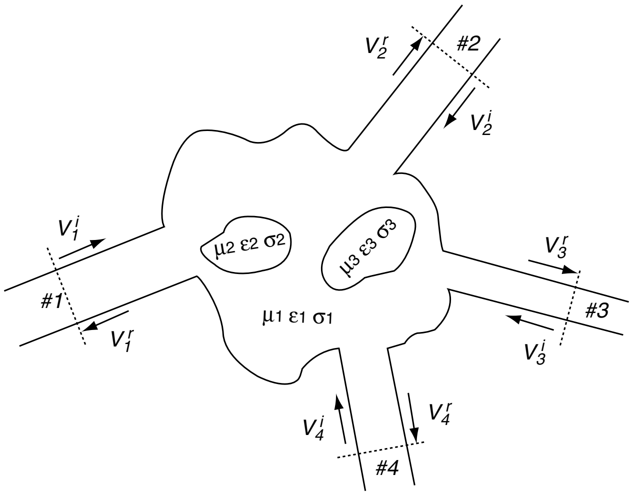

FIGURE 7.1 Graphic Description of a Generalized Four-Port Microwave Passive Component that may Involve Different Segmented Materials Within its Arbitrarily Shaped Circuit Domain.

be described as a closed-form network of one or multiple ports.

An arbitrarily shaped multiport (four ports in the following example) microwave passive component is depicted in Figure 7.1, in which the inbound (or incident) power is always equal to the outbound (or reflected) power plus the possible dissipated power in the circuit. In most practical applications, a microwave circuit is modeled by scattering or *S*-parameters that are defined through the incident and reflected measurable voltage (or alternatively current) waves V^i and V^r (or I^i and I^r) at particular planes of reference for a given mode of propagation, such as a transverse electric mode (TEM). Circuit properties considering multiple modes of operation (propagating or evanescent) are described with the generalized *S*-parameter matrix. The difference is that for only one mode of propagation, the voltages and *S*-parameters per port are single-valued, whereas for multimode propagation or evanescent modes, the voltages and *S*-parameters become vectors and submatrices, respectively. For single-mode propagation, the *S*-matrix of the four-port example in Figure 7.1 is given as a 4 × 4 matrix with complex elements as follows:

$$\begin{bmatrix} V_1^r \\ V_2^r \\ V_3^r \\ V_4^r \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} & S_{13} & S_{14} \\ S_{21} & S_{22} & S_{23} & S_{24} \\ S_{31} & S_{32} & S_{33} & S_{34} \\ S_{41} & S_{42} & S_{43} & S_{44} \end{bmatrix} \begin{bmatrix} V_1^i \\ V_2^i \\ V_3^i \\ V_4^i \end{bmatrix} \tag{7.1}$$

This matrix establishes a port-to-port signal flow relationship, such as transmission and reflection, at and between ports. The $S_{ii}(i = 1, 2, 3, 4)$ is referred to as the **reflection coefficient** (or Γ) at the corresponding ith port. This value is often expressed in decibels $[-20\log(S)]$ and is called the return loss. The S_{ii}(i, j = 1, 2, 3, 4 and i ≠ j) is defined as the transmission coefficient (or T) from the jth port (inbound) to the ith port (outbound) according to equation 7.1. This value expressed in decibels is defined as the insertion loss between two specific ports. One of the fundamental properties of the *S*-parameter matrix for a linear and lossless passive network is the unitary relationship:

$$[S][S]^{t^*} = I, \tag{7.2}$$

in which the superscripts t and * stand for transpose and conjugate complex, respectively. This equation is derived from the principle of energy conservation. The magnitude of *S*-parameters of a passive network is always equal to or smaller than one, depending on whether it is lossless or lossy. From the unitary condition, the correct relationship between the entries of the *S*-matrix can be established.

The *S*-parameters fully describe the electrical properties of a lumped or distributed microwave network. *S*-parameters can be converted to and from other network parameter representations such as Y, Z, and ABCD matrices (Collin, 1992). The ABCD (chain) matrix is popular in the analysis and design of microwave circuits when the voltage and current concepts can be applied. Smith chart techniques also provide a straightforward tool for most practical problems of design and analysis (Collin, 1992).

Microwave passive components may be composed of **lumped elements** (inductors, capacitors, and resistors) or **distributed elements** (transmission line sections and discontinuities) or both. The circuit is arranged in a particular configuration (topology) so that selected signal properties (amplitude, frequency, and phase) are processed or controlled in a desired manner. The lumped elements may also be regarded as a special class of transmission line structures whose geometrical size is always within a small fraction of the operating wavelength and thus, the embedded electromagnetic fields behave in a stationary manner. In that sense, all microwave passive components can be considered as transmission line structures consisting of certain transmission line discontinuities and connecting lines commensurate with wavelengths.

Judging from their circuit functionality, passive components can be classified into the following categories: **impedance matching/transformer, power dividing/combining, signal rerouting/coupling, frequency filter/resonator,** and **phase delay/shifter**. Among them, filters are a special and very important class of passive components because of their technical scope and design complexity. Hybrids and directional couplers are no less important but their realization spans a much smaller range than that of filters. Impedance matching or transformer networks are considered the most fundamental building blocks for nearly any microwave circuit. Possible realizations are strongly dependent on the circuit environment, and stand-alone components are not possible unless they are tunable. Ferrite components and some special material-related circuits (e.g., ferroelectrics) constitute another class of passive microwave components. They may be used to design tunable circuits by applying external magnetic or electric fields. Ideally, no external energy consumption takes place even in this case. Ferrite components have been widely used for isolators, phase shifters, and other nonreciprocal circuit functions like circulators and others.

In the design of a passive component, function-specific parameters, such as frequency bandwidth, insertion/return losses, input/output impedance levels, group/phase delays, and isolation and transient response, are usually the most important. Other parameters like temperature stability, vibration resistance, low passive intermodulation, or multipacting effects are secondary although, depending on the application, may have a direct influence on circuit design.

7.2 Basic Passive Elements and Circuits

The simplest form of a passive component is a section of transmission line bounded by certain impedance conditions, including short and open (electrically). The transmission line may be a **planar structure,** a **quasiplanar structure,** or a **nonplanar waveguide**. These three basic categories of transmission lines form the foundation for designing a microwave passive component.

Planar structures include strip line, microstrip, slot line, coplanar waveguide (CPW), and coplanar strip line (CPS) as well as other variants. Nonplanar structures usually refer to classical metallic waveguides, coaxial (coax) lines, and dielectric waveguides. Hybrid or quasiplanar structures are a combination of planar and nonplanar (waveguides) platforms such as slot lines suspended in the *E*-plane of a waveguide (finline) or strip lines suspended in the *H*-plane of a wave guide. From the manufacturing point of view, planar and hybrid structures offer easy integration of passive and active components. This is an advantage over classical waveguide or coax circuits for which integration of active and passive circuit parts is much more difficult and usually leads to much larger circuit layouts. Figure 7.2 shows a cross-sectional view of commonly used transmission lines that have already been discussed in Gupta *et al.* (1996) and Itoh (1987) with respect to their electrical and mechanical properties.

In the following sections, unless otherwise specified, we refer to the microstrip line or the rectangular waveguide as the basic building block for passive components. Important aspects of commonly used passive circuits are highlighted. Limited space does not permit to introduce such useful principles and theories like the even–odd mode decoupling scheme, Kuroda identities, and Richards's theorem (Pozar, 1998) that have been developed for modeling, designing, and synthesizing passive networks. For the relevant details, the reader is referred to the appropriate literature.

7.2.1 Transmission-Line Stubs

A **stub** is a typical one-port passive element in which one of the two ports of a transmission line is terminated by a certain reactive and/or resistive load denoted by Z_L or $Y_L(Y_L = 1/Z_L)$, as shown in Figure 7.3(A). A stub is an attachment to the main transmission line path, either at its end or somewhere along the line in parallel or in series. The input terminal of a stub (the part attached to the main transmission line), depending on its load condition and length, can appear as a capacitive or inductive impedance, as a series or parallel resonance circuit, or as purely inductive or purely capacitive. A transmission line stub is essentially an impedance transformer that must be mismatched at its end terminal to become effective or operative. Because of a wide range of input impedance possible, stubs are widely used as impedance transformers and matching networks, as tuning elements or dc-bias networks (a kind of low-pass filter), and as baluns or filters. The most commonly used load conditions of a stub are either a short load ($Z_L = 0$) or an open load ($Y_L = 0$). Their effect, however, is typically only narrow band. If broadband stubs are needed, so-called radial microstrip open-ended stubs (Figure 7.3), for example, are utilized. Other loads may be in the form of a lumped capacitor or a lumped inductor or a mixture of both. From transmission line theory (Collin, 1992), the input impedance Z_i of a stub can simply be formulated by:

$$Z_i = Z_0 \frac{Z_L + Z_0 \tanh\ \beta l}{Z_0 + Z_L \tanh\ \beta l}\bigg|_{\text{if } \beta=\alpha+j\beta}^{\text{lossy line}} = Z_0 \frac{Z_L + Z_0 \tan\beta l}{Z_0 + Z_L \tan\beta l}\bigg|_{\text{if } \beta=j\beta}^{\text{lossless line}}, \quad (7.2)$$

in which Z_L and Z_i are in general complex quantities. The Z_0 represents the characteristic impedance of the stub line or the main transmission line that, for a microstrip line, can be calculated at low frequency by knowing the line width, the substrate thickness, and the dielectric constant. Calculating Z_0 of a waveguide also requires knowledge of the frequency because waveguides are very dispersive (frequency dependent). Equation 7.2 clearly illustrates the important fact that impedance transformation on a transmission line is only possible if the line is mismatched ($Z_0 \neq Z_L$). Examples of short-circuited and open-ended transmission lines with an electrical length smaller than $\lambda/4$ are shown in Figure 7.4. Also shown is their possible realization in a microstrip circuit as well as the equivalent network.

7.2.2 Transmission Line Discontinuities

Passive circuits always consist of uniform sections of transmission lines interconnected by discontinuities (i.e., impedance steps). **Transmission-line discontinuities** can also appear as gaps, transmission line bends, waveguide apertures, and posts. The discussed short and open stubs may be regarded as part of the circuit discontinuities. Generally, discontinuities are

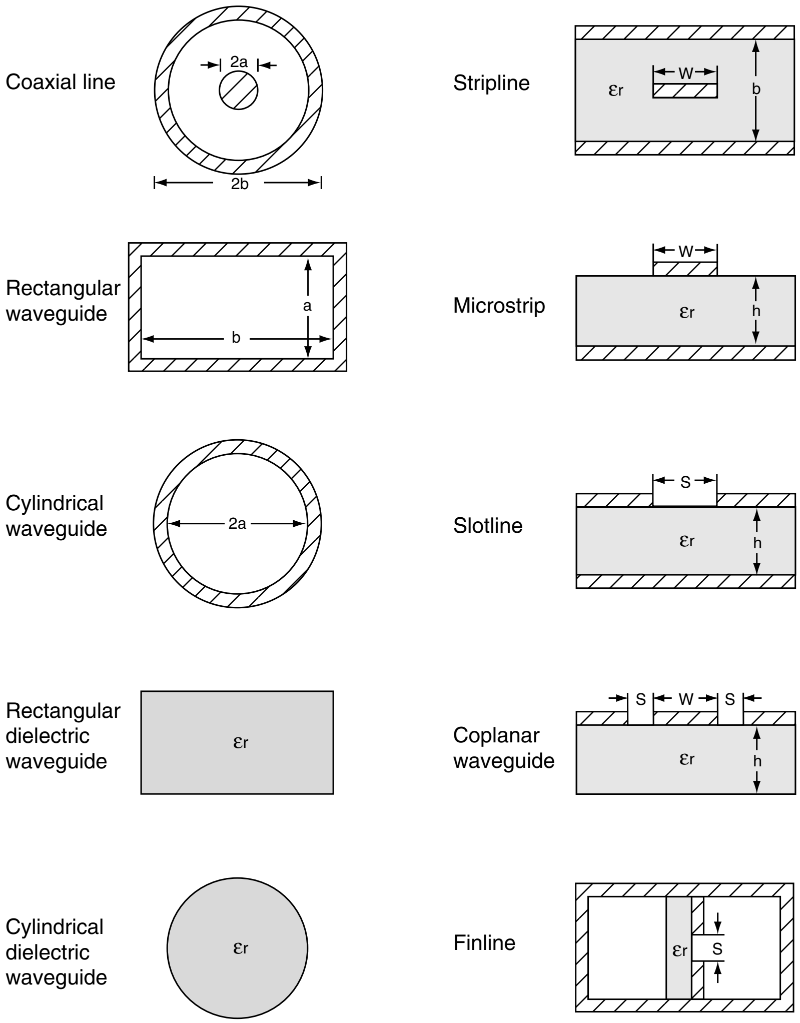

FIGURE 7.2 Cross-Sectional View of Commonly Used Planar and Nonplanar Transmission Lines that are Used in the Construction of Passive Microwave Components

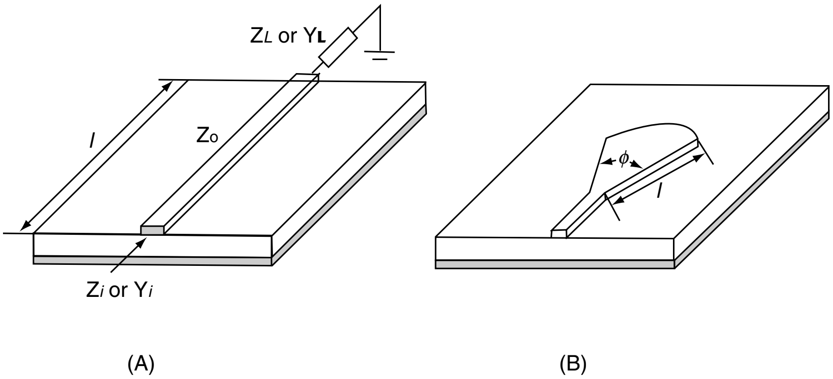

FIGURE 7.3 Examples of One-Port Microwave Passive Circuits. (A) Microstrip line loaded with reactive and/or resistive element; (B) Microstrip radial open-ended stub element.

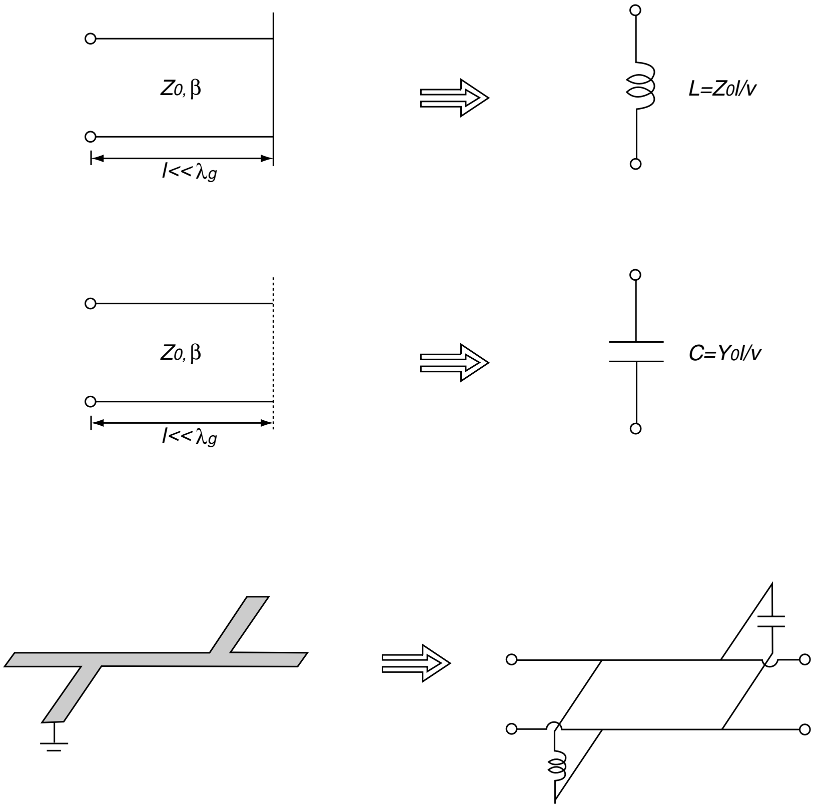

FIGURE 7.4 Short- and Open-Ended Transmission Line Elements Having Electrical Length Shorter than a Quarter-Wavelength and Their Equivalent Circuit Representations.

electrically small with respect to the wavelength. Lumped-element equivalent circuits can be developed to represent these discontinuities. A lumped-element representation of a transmission line discontinuity, such as bend or gap, is important in the design and analysis of passive microwave circuits and components. Values for the lumped elements can be obtained from either field theoretical computations, measurements, or empirical formulas.

Transmission-line discontinuities may be represented by a combination of lumped elements of circuit. Figure 7.5 presents a class of typical microstrip line discontinuities and its equivalent network parameters. Resistive elements may be included (series resistance and/or shunt conductance) to represent radiation and leakage as well as ohmic effects. Closed-form analytical formulas on the basis of quasistatic or simplified models are provided in Gupta (1996) and Itoh (1987). These useful tools allow approximate calculations of the lumped-element parameters for some commonly used discontinuities. Accurate parameter extractions using field theory-based full-wave techniques are preferred for higher frequency design. Figure 7.6 gives extracted lumped-element values from a self-calibrated method of moments (MoM) (Zhu and Wu, 1999) for asymmetrical microstrip gap and step discontinuities.

7.2.3 Lumped Circuit Elements

A **lumped element** or a **discrete circuit part** can normally be realized with a much smaller size than its distributed or transmission-line parameter counterpart. At lower microwave frequencies, a size reduction to $\lambda/10$ or less is possible. Therefore, lumped elements are used to miniaturize passive circuit components and also reduce losses as well as cost. Almost all of the low (usually megahertz to lower gigahertz range) radio frequency (RF) electronic components are in lumped-element form. At higher microwave frequencies and, in particular, at millimeter wavelengths, the loss of lumped elements becomes prohibitive for discrete circuit design and is therefore typically limited to special applications, such as in monolithic microwave integrated circuits (MMICS) (Robertson, 1995). In these applications, geometrical factors, dispersion, and, of course, losses must be taken into account. In addition, the variation of lumped-element values is often limited by structural topology, material, operating frequency, and manufacturing process.

Example topologies for the three basic lumped-element types (**inductor, capacitor,** and **resistor**) and their realization in layered planar geometry for higher frequency applications in MMIC and miniature hybrid microwave integrated circuit (MHMIC) technologies are shown in Figure 7.7. These elements

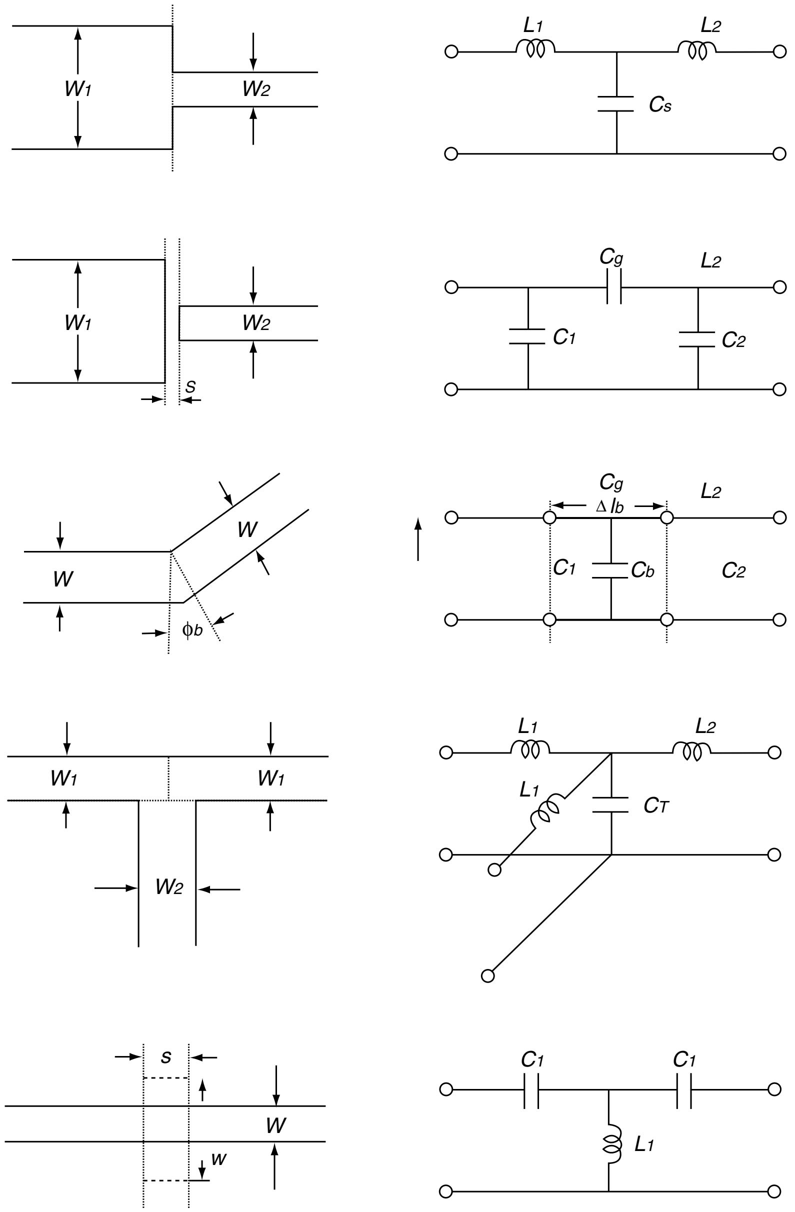

FIGURE 7.5 Physical Layout and Equivalent Circuit of Typical Transmission Line Discontinuities Used in the Design of Microwave Circuits

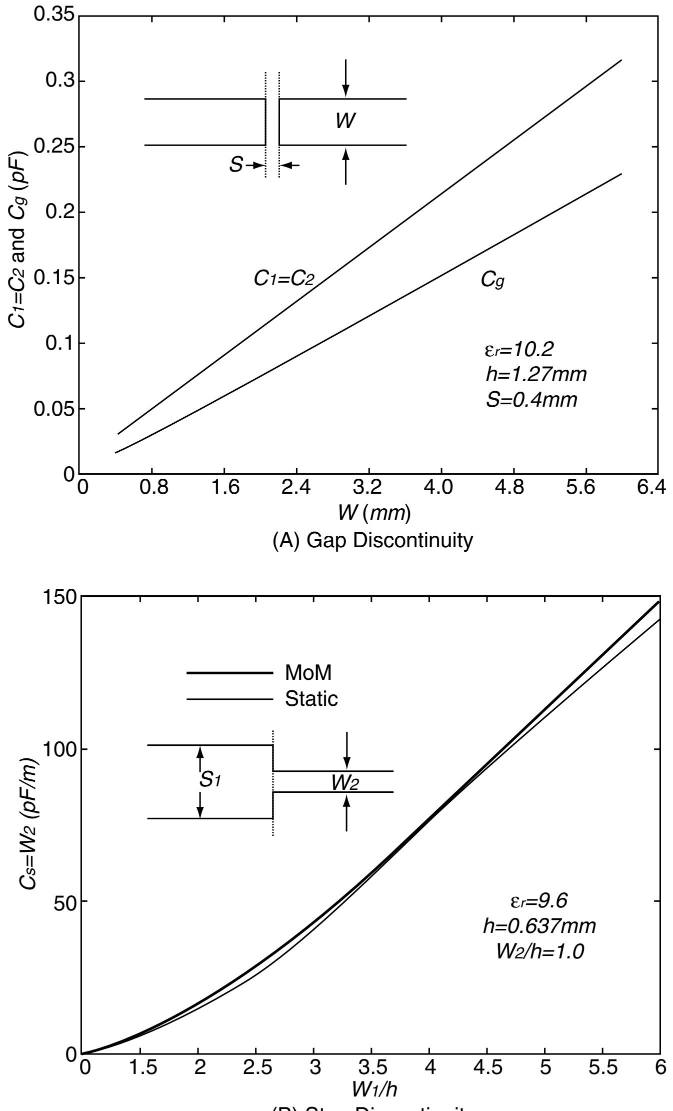
are commercially available in the form of surface-mountable chips for hybrid integration or in standard MMIC processes. For inductors and capacitors, the most important parameter is the quality (Q-) factor in addition to the characteristic value of the element. The Q-factor, which is used to measure the loss effects, depends on conductor and dielectric dissipation properties of the structure at a given frequency and can be calculated from the equivalent RGLC (resistance conductance inductance capacitance) model of the element.

A high-density current flowing over a transmission line with relatively narrow line width generates a strong magnetic field and thus creates the lumped inductance effect. Multiturn planar spiral inductors easily produce inductance values higher than 1 nH and are frequently used in MMIC design, either in the form of squared or circular topologies. Meander-line inductors may also be considered as a special class of spiral inductors, but they generate lower inductance values. The difficulty of the spiral layout is the electrical crossover from the center turn back to the outside circuit. This may be achieved by means of an air bridge or dielectrically spaced underpasses. If a silicon substrate is used, the resulting Q-factor is low, which is a major design concern for application at higher frequencies.

Two tightly spaced but physically insulated metallic plates or ends form a capacitor, in which a strong electric field is



(A) Gap Discontinuity

(B) Step Discontinuity

FIGURE 7.6 Extracted Equivalent Circuit Parameter Values of Asymmetrical Microstrip Gap and Step Discontinuity Formed on a Dielectric Substrate whose Thickness and Dielectric Constant Are Denoted by h and ε_r, Respectively.

induced once a voltage is applied between them. Such a capacitor is easily realizable in a multilayered platform. Two widely used structures are capacitors with overlay and interdigital topologies. The overlay capacitor is usually referred to as metal-insulator-metal (MIM) with insulators made of low-loss and temperature-stable thin-film materials, such as ceramic, silicon nitride, silicon dioxide, and polyimide. The interdigital capacitor consists of a number of interleaved microstrip fingers coupled together as indicated in Figure 7.7. Usually, the interdigital capacitor cannot be used to produce a capacitance value above 1 pF and tends to saturate at high frequency even with a large number of fingers, whereas the MIM technique can yield high capacitances. The tolerance of interdigital capacitors can be well controlled, and they are ideal for tuning, coupling, and matching element design where a small capacitance and a high precision are required. The Q-factors for the MIM and interdigital capacitors are mainly limited by insulator dielectric loss and ohmic effects of the fingers. Figure 7.8 illustrates some typical lumped element values for the interdigital capacitor (Zhu and Wu, 2000).

Resistors, such as the isolating resistor used in the design of Wilkinson's power dividers and combiners, are another fundamental building block for matching loads or special applications. Resistors can be made from deposited thin-film resistive layers or thin-metal films, whereby the film thickness is much less than its skin depth. Resistors can also be made from doped semiconductor layers (mesa resistors or implanted planar resistors). In either case, the layer or film thickness t is fixed, and the resistivity is conveniently quoted in terms of an ohms-per-square figure or simply square resistance $R_0 = (\sigma t)^{-1}$. As such, the film or layer resistance can be calculated by a simple formula:

$$R = R_0 \frac{l}{w}, \tag{7.3}$$

in which l/w is often called aspect ratio. The geometrical parameters l and w stand for the film length and width in view of the connecting pads of a resistor. The required tolerances and the expected power dissipation also determine the absolute size of a resistor. In addition, contact pads and grounding blocks may contribute to its parasitic effects (capacitance) that may be severe at high frequency. Other properties such as linearity and temperature coefficients are also critical for certain solid-state power device applications. In practice, $50 - \Omega$ resistors are the most important and popular standard reference for circuit design.

7.3 Impedance Transformers and Matching Networks

The purpose of an **impedance transformer** is to transform a given impedance to a specific value. An impedance **matching network** may consist of more than one impedance transformer. Its main goal is to match a given impedance to a prescribed value over a frequency range of interest to ensure maximum power transfer from a source to a load. Typical applications include returning loss optimization between an antenna and low-noise amplifier, achieving low-noise characteristics in active circuits, and providing conjugate complex matching in amplifier design. Electrical and/or mechanical impedance tuners are widely used in RF and microwave measurement setups, such as load-pull nonlinear characterization systems. Impedance transformers and matching networks are perhaps the most important and most widely used passive microwave circuit component.

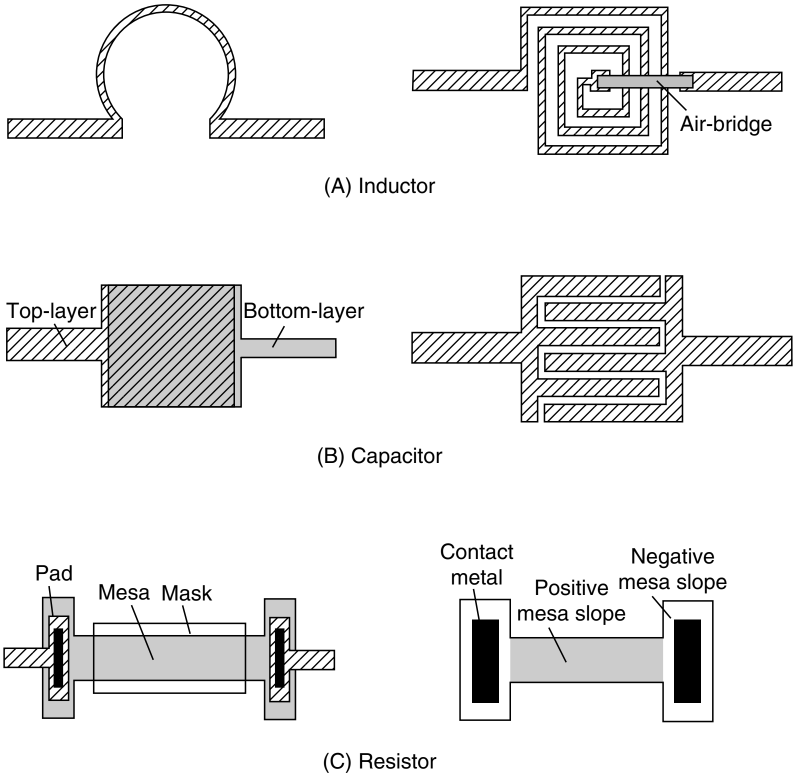


FIGURE 7.7 Three Basic Lumped Circuit Elements for Microwave IC Design: Inductor, Capacitor, and Resistor

In a practical design, the characteristic impedance of the transformer and matching network depends on the type of transmission line that dictates its achievable impedance range. Further, the type of transmission line used gives preference to either shunt (common voltage) or series (common current) branch connection. In a microstrip line, for example, stubs are best used in shunt–parallel connections.

Techniques based on the Smith chart are popular in the design of impedance transformers and matching networks, a basic block diagram of which is shown in Figure 7.9. Matching networks may be built from lumped or distributed elements or a combination of both. The quarter-wavelength section of a transmission line may be the easiest to realize. Classical shunt or series branch lines are widely used for more sophisticated matching networks. Commonly used topologies include single or multiple stubs and one or more quarter-wavelength sections. In addition, taped or nonuniform transmission line sections are also often found in broadband design.

7.3.1 Matching Sections and Stubs

Figure 7.10 shows a class of commonly used series cascaded sections and stubs for the design of impedance matching networks. A simple series connection of transmission lines may be used to match a complex load $Z_L(=R_L+jX_L)$ to a real resistance R, as shown in Figure 7.10(A). Note that this is a narrow-band matching scheme with very limited use because of a low degree of flexibility in the impedance choice and matchable area on the Smith chart. The two-section transformer as shown in Figure 7.10(B) can overcome this problem to some degree. Still, the useful bandwidth is relatively narrow for most practical applications.

The stubs attached to the main section of the transmission line provide a useful alternative if there is a requirement to reduce the circuit area. In addition, the use of stub impedance tuners gives an extra degree of freedom in the choice of matching strategies. This is because the lossless stub (open or short) represents just a pure reactance to the main line (see Subsection 7.2.1 for more details) and can effectively be used for canceling the load's imaginary part. In general, two stub tuners together with one line section are always enough to generate a complete matching condition for any complex load. The position, characteristic impedance, and line length of the stubs and the connecting lines are conveniently designed through the use of the Smith chart. Once again, the bandwidth remains inherently narrow because of the line length dependence of the impedance transformer or the matching network in question.

7.3.2 Quarter-Wavelength Transformers

An important class of impedance-matching networks is the **quarter-wavelength transformer;** these transformers are used

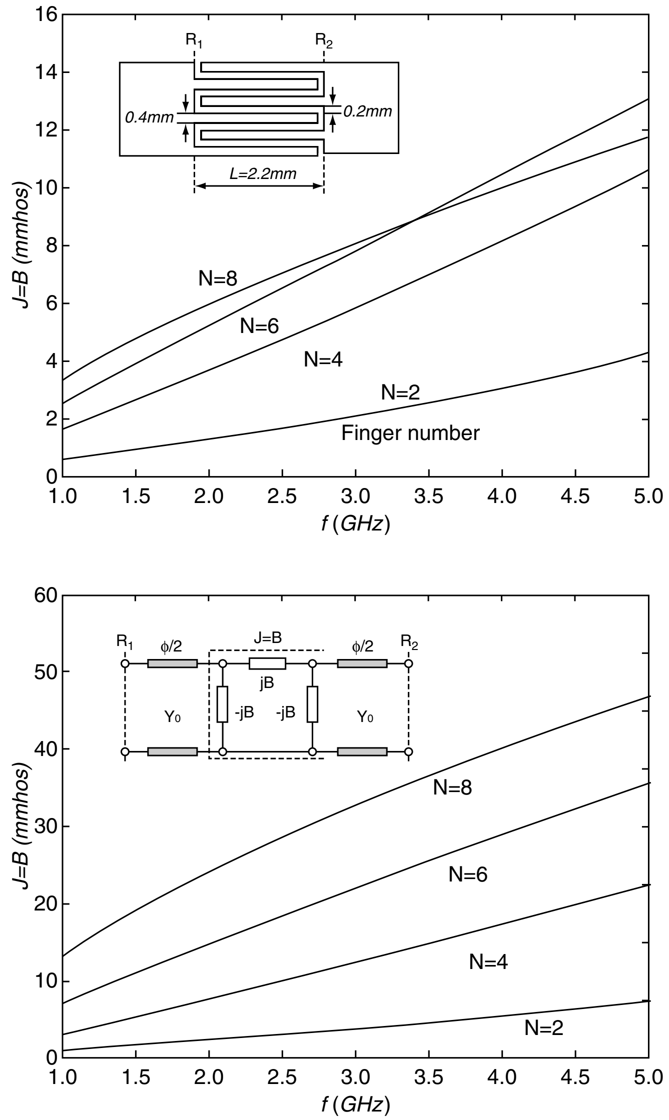

FIGURE 7.8 Typical Extracted Lumped Values of a Microstrip Interdigital Multifinger Capacitor

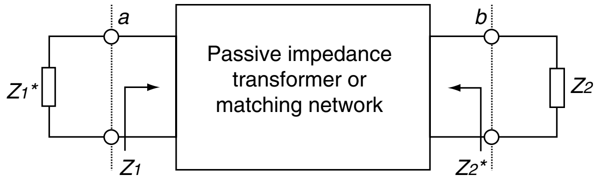

FIGURE 7.9 Schematic Description of a Two-Port Passive Impedance Transformer or Matching Network

to match a real-valued impedance load to another real-valued impedance at the input. If complex impedances are involved, the stub-tuning technique may be used to cancel out the transformer's imaginary part. Therefore, the quarter-wavelength transformer is widely used in practice in conjunction with impedance tuning stubs. For narrow band applications, a single section is adequate. Otherwise, multiple cascaded sections are required.

With reference to Figure 7.10(A), a quarter-wavelength section ($\beta l = \theta = \pi/2$) of a lossless network with the input impedance denoted by R gives the input impedance as follows (from equation 7.2):

$$Z_i = \frac{Z_0^2}{Z_L}. \tag{7.4}$$

The load impedance Z_L is matched to R if $Z_i = R$ and $Z_0 = \sqrt{RZ_L}$. Obviously, the prescribed quarter-wavelength condition yields a narrow band operation, which is also further limited by the impedance ratio of R/Z_0 and Z_0/Z_L.

A multisection impedance matching network is described in Figure 7.11, in which the sections may be equal or not equal to quarter-wavelengths. Broadband matching condition can be achieved with adequate design schemes, such as Chebyshev synthesis techniques. The matching bandwidth can be enlarged if the number of sections increases. Of course, in most practical cases, the limit is given by the maximum circuit area and loss considerations.

7.3.3 Tapered and Nonuniform Impedance Transformers

The nonuniform impedance transformer uses transmission lines with gradually varying line geometry. The **tapered impedance transformer** is a special case of nonuniform lines, and its impedance changes smoothly and monotonically in the propagation direction of the wave. This change of impedance is either linear or exponential or follows rules derived from Chebyshev or other designs. The synthesis of a tapered-line transformer is usually made at its lowest frequency of interest over the predesignated bandwidth because the derivative of the reflection coefficient decreases rapidly with frequency. The **nonuniform line** may be used not only for a broadband impedance transformer but also for other purposes, such as the realization of low-pass and stop-band filtering functions. Figure 7.12 presents two typical layout examples of a tapered impedance transformer and a nonuniform transmission line transformer.

7.3.4 Coupled-Line Transformers

In the design of coupling and filtering elements, impedance transformation may also be required because of the potential difference in impedance between the source at the input and load at the output. Such transformers not only match the input to the output, but, they function at the same time as building blocks for the couplers and the filters. Quarter-wavelength coupled lines with various terminal conditions are among the most popular structures, as shown in Figure 7.13 **Coupled-line**

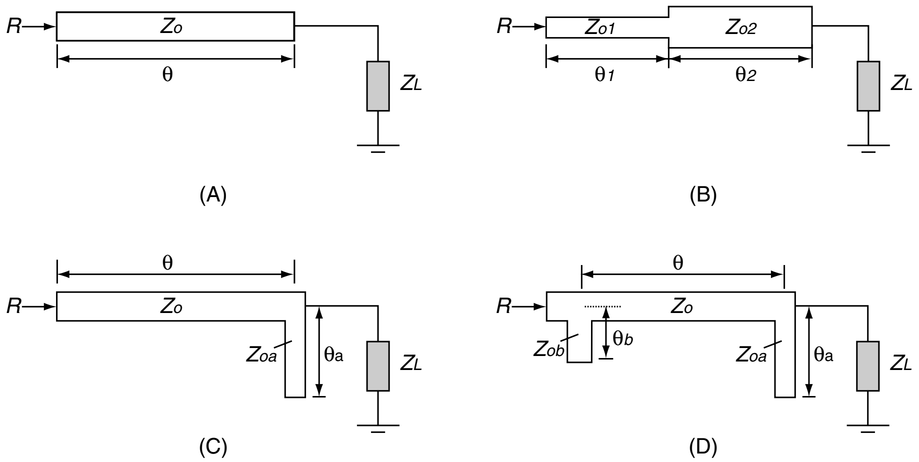

FIGURE 7.10 A Class of Series Cascaded Sections and Stubs for Design of Impedance Matching Network

FIGURE 7.13 Two Representative Quarter-Wavelength Coupled-Line Sections for Impedance Transformation and Matching Purposes

elements have no direct electrical contact, and this is why they are frequently used as dc bias blocks for active devices. Symmetrical coupling structures are most often used as coupled-line impedance transformers, but asymmetrical designs may offer more design freedom, for example, in enhancing the impedance transformation ratio. Usually, the coupled-line schemes may provide an impedance ratio up to 10, depending on the geometry and the substrate used in the design. For symmetrical structures, even- and odd-mode parameters are widely used for the analysis and synthesis of impedance transformers.

7.3.5 Lumped-Element Transformers

Transmission-line-based impedance transformation is made possible through distributed effects, which may also be realized by using lumped-element-based networks in terms of capacitors and inductors. Capacitors and inductors connected in *L*-/π-shaped configurations are widely used as impedance-matching networks. There are eight possible arrangements of the LC network topology, as shown in Figure 7.14. They are popular in the design of miniaturized ICs, such as monolithic (MMIC) and high-density hybrid circuits (MHMIC) as well as low-frequency ICs.

The ratio of impedance transformation depends on the value of the inductor and capacitor used in the network. It is

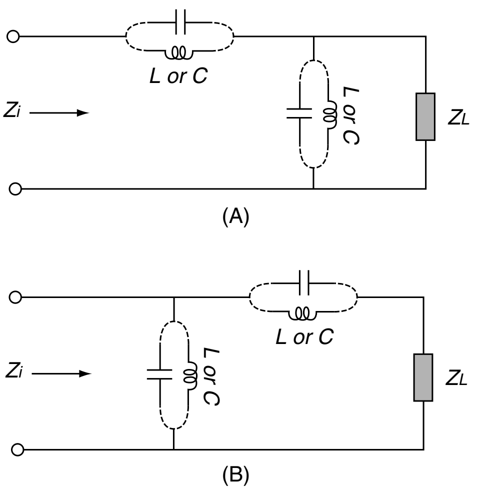

FIGURE 7.14 Generalized Lumped-Element Network Transformers with Various L-C Combinations

also possible to design broadband impedance matching networks by cascading lumped-element circuits. The design and synthesis of such lumped-element circuits can easily be made through the Smith chart by normalizing LC values with respect to an impedance of reference (normally the impedance of external connection lines).

7.3.6 Balun Transformers

This is a special class of microwave passive components that converts the fundamental guided mode from balanced to unbalanced or vice versa. This is why it is called **balun** (**bal**ance-to-**un**balance). In this case, the characteristic impedance may also be transformed in this line-to-line modal conversion. Usually, a balun structure deals with two different types of transmission line geometry that are used as input and output of the circuit.

Although the early version of a balun was proposed for coaxial lines and other nonplanar structures, **planar baluns** have received much attention and may be realized by two-sided and uniplanar MIC technologies. Generally, the baluns may be divided into two categories (Trifunovic and Jokanovic, 1994); **Marchand baluns** (band-pass networks) and **double-*Y* baluns** (all-pass networks, ideally), as shown in Figure 7.15. This figure presents three basic transformations: microstrip-slot line, CPW-slot line, and finite-ground CPW–CPS line.

The input and output lines are orthogonally crossed over in the Marchand baluns, and two ports are electrically terminated with either a short or open end that transforms either open or short effects at the junction through two quarter-wavelength line transformers. The modal conversion is thus achieved over the junction together with a potential line-to-line impedance transformation. Generally, the Marchand baluns are simple in geometry but have a narrow operating bandwidth (filter behavior). On the other hand, the double-*Y* baluns may be used for broadband design. They are based on a six-port double-*Y* junction that consists of three balanced and three unbalanced lines placed alternatively around the center of the junction. The input and output lines are usually aligned along the same axes, and the other four branch lines are short- or open-circuited and perform in-phase and out-of-phase signal dividing/combining procedures. This is very similar to the well-known low-frequency electrical bridge transformer.

7.4 Hybrids, Couplers, and Power Dividers/Combiners

Hybrids and **couplers** (directional couplers) are important components in microwave and millimeter-wave systems for rerouting or redistribution of the signal (Cohn and Levy, 1984). They are widely used in high-frequency signal measurements, amplitude, phase and frequency discriminators, balanced amplifiers, balanced mixers, feeding networks of antennas, and many other applications. In principle, a hybrid or a coupler may simply be described as a reciprocal multiport (usually four-port) network as shown in Figure 7.16. Hybrids are special classes of directional couplers that use commensurate line sections or junctions to connect ports or arms. Branch-line couplers, hybrid-rings (rat-race), and magic-tees are the most widely used designs of the hybrids. Their performance depends critically on the transmission line properties. Couplers rated at a 3-dB power splitting ratio are also often called hybrids. The designation of hybrid is not consistently used in the literature. In the following paragraphs, a hybrid describes a directional coupler consisting of several line sections that are physically connected to each other via junctions. Hybrids may be derived from all types of couplers, and they may be classified as 90° (quadratic) hybrids or 180° hybrids, depending on their circuit properties and application features.

Other types of couplers are based on distributed electromagnetic coupling between lines. In such cases, the mechanism of line-to-line coupling is important. 1-to-*N* way **dividers** or *N*-to-l way **combiners** present a class of alternative structures to directional couplers or hybrids for achieving equal or nonequal power dividing/combining functions. They are widely used in the design of multicell power amplifiers and feeding networks of antenna arrays. Among them, the **Wilkinson power divider/combiner** is the most prominent.

The four ports of a hybrid or a coupler are labeled as **input, direct, coupled,** and **isolated.** Suppose that P_1 is the power fed into port *l*, while P_2, P_3, and P_4 denote the power available at the other corresponding ports. Then, four important parameters that describe the electrical performance of this passive circuit are defined as follows:

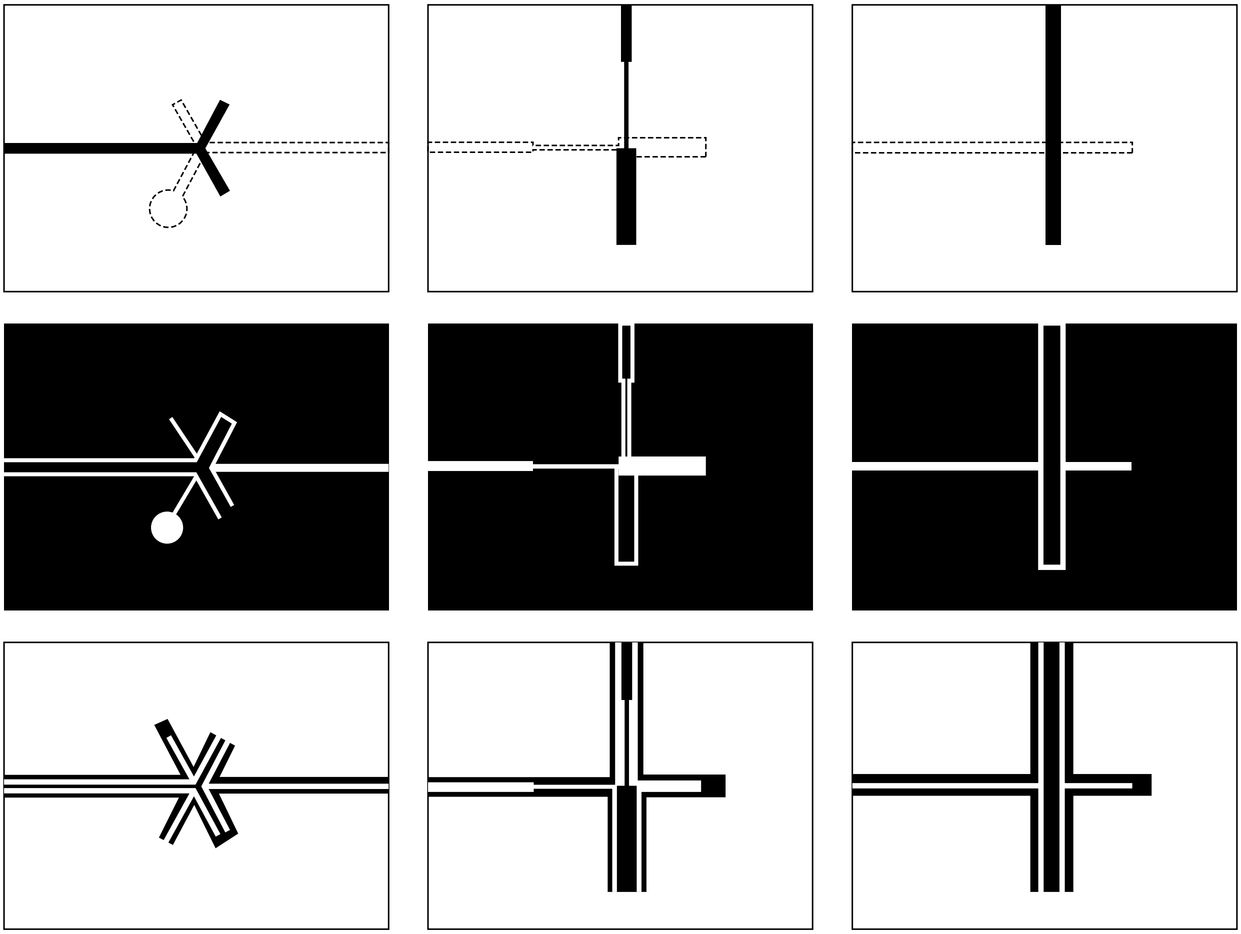

FIGURE 7.15 Three Basic Planar Marchand and Double-Y Balun Transformers: Microstrip-Slot Line, CPW-Slot Line, and Finite-Ground CPW-CPS Line

- **Coupling factor** $= C_{\text{dB}} = 10\log(P_1/P_3) = -20\log S_{31}$. (7.5)
- **Isolation** $= I_{\text{dB}} = 10\log(P_1/P_4) = -20\log S_{41}$. (7.6)
- **Directivity** is sometimes also used to characterize the isolation properties of a hybrid or directional coupler, which is defined as $D_{\text{dB}} = 10\log(P_3/P_4) = -20\log S_{43} = I_{\text{dB}} - C_{\text{dB}}$. In addition, the transmitted power at port 2 can be calculated through $T_{\text{dB}} = 10\log(P_1/P_2) = -20\log(S_{21})$.

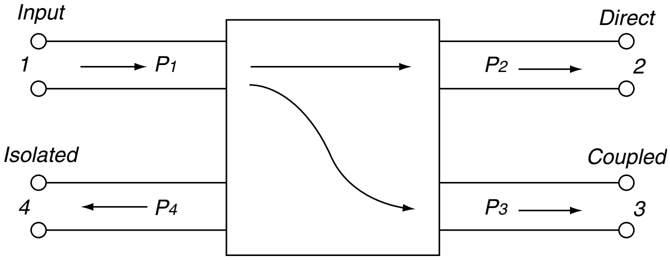

FIGURE 7.16 Reciprocal four-port representation of a microwave hybrid or directional coupler.

- **Input VSWR** (voltage standing wave ratio) is usually used to define the matching condition at port 1 because the other ports are matched to the corresponding external loads.
- **Bandwidth** refers to the operating bandwidth of a hybrid or directional coupler when its coupling factor, isolation, and input VSWR all satisfy the prescribed specifications. Generally, the single-section coupler (typically on the order of 10% for a branch-line hybrid) does not provide sufficient bandwidth. Bandwidth limitations, however, can easily be overcome by multisection designs that combine a number of single-section coupling cells.

7.4.1 Quadrature 90° Hybrids (Branch-Line Couplers)

The structure of a **quadrature 90° hybrid** has two series quarter-wavelength sections that are connected by two shunt quarter-wavelength sections, as shown in Figure 7.17 for a microstrip realization. In most practical cases, the equal power dividing (3-dB) structure is most popular. For a lossless hybrid,

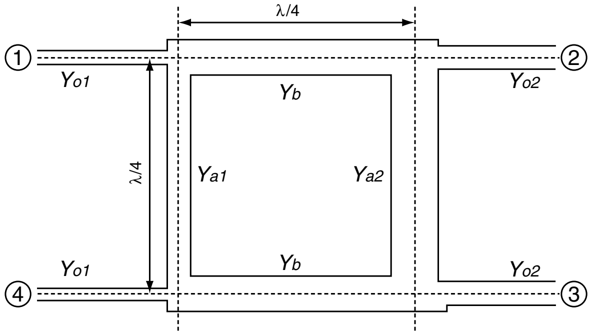

FIGURE 7.17 Physical Layout of a Microstrip Quadrature 90° Hybrid Branch-Line Coupler

the input signal at port 1 is divided into two parts. Some of the power is combined at port 4 but out of phase by 180°. Thus, if the signal amplitude is equal (depending on adequate choice of branch-line admittance Y_{a1}, Y_{a2}, and Y_b between both ports), no signal appears at port 4, the signals at ports 2 and 3 may be equal (3-dB) but out of phase by 90°. In practice, the isolated port 4 is terminated with a matched load. The power-dividing ratio at ports 2 and 3 also depends on an appropriate choice of the branch-line admittances. The direct and the coupling port (2 and 3) may be connected to admittance Y_{02} that is different from Y_{01} of the input port, which suggests that this type of hybrid has impedance transformation properties.

Table 7.1 presents a list of closed-form design equations for this type of hybrid, which are derived from transmission line theory such as the even–odd mode decoupling technique. As an example, it shows a specific selection of branch-line admittances for the design of a 3-dB hybrid with various input-to-output impedance transformations. Figure 7.18 gives a schematic view of an N-section cascaded branch-line coupler with $N+1$ branches. The aim of this arrangement is to enlarge the 10% limiting bandwidth of a single-section hybrid to more than one octave.

7.4.2 The 180° Hybrid Rings (Rat-Race Couplers)

Hybrid rings also nicknamed as **rat-race couplers,** are made of an annular line of one-and-half wavelengths, (1.5λ) in circumference with four arms connected at appropriate

TABLE 7.1 3dB 90° Hybrid Design Data ($C_{dB} = 3\ dB$)

$R = \dfrac{Y_{o1}}{Y_{o2}}$	1	0.75	0.5	1/3
$\lvert V\rvert = \sqrt{\dfrac{R}{\log^{-1}(C_{dB}/10)}}$	$1/\sqrt{2}$	0.614	0.5	$1/\sqrt{6}$
$\dfrac{Y_b}{Y_{o1}} = \dfrac{1}{\sqrt{R-\lvert V\rvert^2}}$	$\sqrt{2}$	1.61	2	$\sqrt{6}$

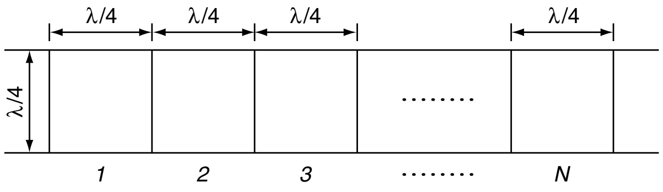

FIGURE 7.18 Schematic View of an N-Section Cascaded Hybrid Branch-Line Coupler with N + 1 Branches

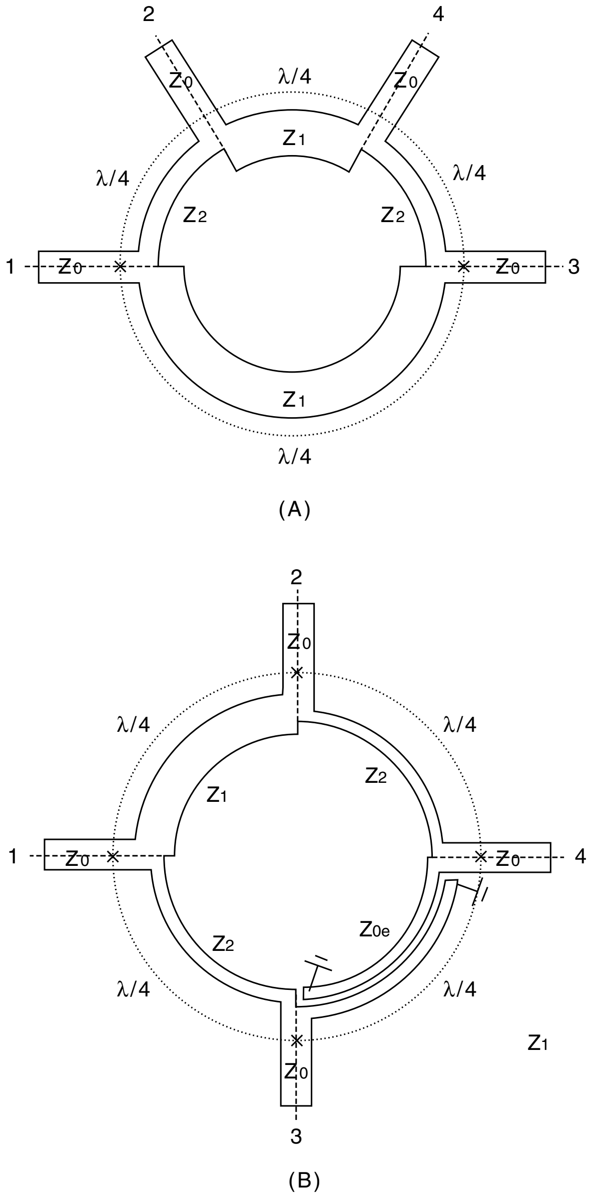

FIGURE 7.19 Two Structure Representations of 180° Hybrid Microstrip Ring Rat-Race Coupler

positions along the annular ring as shown in Figure 7.19(A). The electrical characteristics of hybrid rings are quite similar to those of the 90° branch-line hybrids except that the output ports 2 and 3 have a phase difference of 180° instead of 90°. With reference to Figure 7.19, the design of a 3-dB coupler requires $Z_1 = Z_2 = \sqrt{2}Z_0$. Generally, the rat-race hybrid has a broader bandwidth than its branch-line counterpart, but it is also limited by resonance of the ring or the commensurate line sections.

A substantial increase in bandwidth for this type of coupler is made possible by replacing the 3λ/4-section of the original ring geometry by a shorted λ/4 parallel coupled-line section as shown in Figure 7.19(B). In this case, the ring is reduced to one wavelength, and its bandwidth can be increased by roughly one octave. The effective bandwidth of ring-based hybrids can be further extended by using a generalized design theory developed by Wang and Wu (1999) that requires a small modification of the impedance ratio of the ring with respect to the externally connected branch lines. In addition, innovative structures can be found in the literature for the design of a 3-dB coupler on the basis of some bandwidth-broadening and size-reduced schemes, such as microstrip disc or waveguide cavity geometry.

7.4.3 Magic Tees (Matched Hybrid Tees)

A **matched hybrid tee** (also called a **magic tee** or **T** consists of a combined *E*- and *H*-plane waveguide *T*-junction, as shown in Figure 7.20. A magic tee is a 3-dB hybrid with directional coupling properties quite similar to the above-discussed 180° hybrid rate-race ring. The most critical issue in the design of a magic tee is a broadband matching post or rod located in the center of the waveguide junction. The magic tee is a popular component for low-loss and/or high-power circuit applications.

Referring to Figure 7.20, if a fundamental TE_{10} wave is incident at port 4, the electric field shows even symmetry at the mid-plane and, hence, no power is directed into port 3 because the electric field is in the opposite direction and cancels out. The coplanar arms 1 and 2 receive equal powers that appear in phase at both ports if the arm lengths are equal.

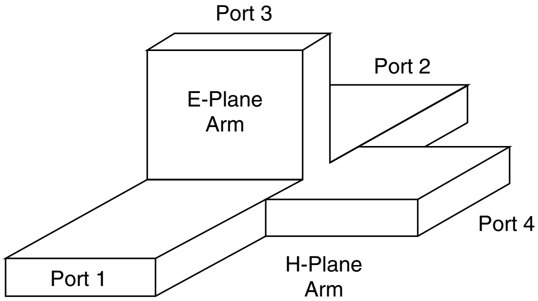

FIGURE 7.20 Waveguide Hybrid Tee Structure or Magic T

When a TE_{10} wave becomes incident at port 3, its electric field is parallel to the broadwall of arm 4 in which it is below cutoff. Hence, no power is directed into that arm. Arms 1 and 2, however, receive once again equal powers that are 180° out of phase in this case (provided both arms are of equal length). If ports 3 and 4 are both matched, the amplitude of all four phasors is the same. Provided all arms are of equal length, the signals add at port 1 and cancel at port 2. Arms 3 and 4 are decoupled. The magic tee is described by the following symmetrical *S*-matrix:

$$[S] = \frac{1}{\sqrt{2}} \begin{bmatrix} 0 & 0 & 1 & 1 \\ 0 & 0 & -1 & 1 \\ 1 & -1 & 0 & 0 \\ 1 & 1 & 0 & 0 \end{bmatrix} \tag{7.7}$$

The magic tees may also be realized through planar approaches similar to the balun design. In practice, a planar magic tee is made of a hybrid strip/slot geometry, where slot and strip are usually located on opposite sides of a dielectric substrate.

7.4.4 Parallel-Line Coupler

The **parallel-line coupler** is a well-known class of directional couplers. When two parallel TEM lines are brought in close proximity of each other, electrical and magnetic field coupling takes place, and a certain portion of the signal of one line is coupled onto the other. With an appropriate choice of coupling length, broadband directional couplers can be built; a typical example is described in Figure 7.21. Symmetrical geometries are most often used even though nonsymmetry of the coupled lines can be considered as well. Geometrical symmetry of the coupled lines leads to a simplification of design models, and even–odd mode analysis can be applied. Otherwise, a modified $C - \pi$ model (Tripathi, 1975) must be employed to decouple the two-line system.

The parallel-line coupler is not restricted to TEM-mode structures although its earliest versions were made from coaxial- or strip-coupled lines, which support pure TEM-modes. The microstrip parallel-line coupler supports quasi-TEM-mode propagation, whereas non-TEM mode couplers may be in the form of a dielectric waveguide, a rectangular waveguide, and slot lines that are known to be dispersive. Design equations, obtained from even–odd mode analysis,

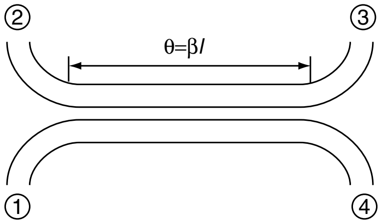

FIGURE 7.21 Typical Sketch of Parallel-Line Directional Coupler.

can be summarized as follows (with quarter-wavelength coupling sections):

$$Z_0^2 = Z_{0e}Z_{0o}. \tag{7.8}$$

$$C = \frac{Z_{0_e} - Z_{0_o}}{Z_{0_e} + Z_{0_o}} = -20\log\left|\frac{Z_{0_e} - Z_{0_o}}{Z_{0_e} + Z_{0_o}}\right|\text{dB}. \tag{7.9}$$

The characteristic impedances for the even- and odd-modes of the coupled line system can be easily found from a given external line impedance Z_0 and a specified coupling coefficient C required for the coupler design. In the TEM mode case, the even- and odd-mode velocities are always equal and given by:

$$\begin{cases} Z_{0_e} = Z_0\sqrt{\dfrac{1+C}{1-C}}. \\ Z_{0_o} = Z_0\sqrt{\dfrac{1-C}{1+C}}. \end{cases} \tag{7.10}$$

As indicated in Figure 7.21, this type of coupler presents a backward coupling property because the coupled energy is directed at port 2 instead of port 3 as it is in the branch-line hybrid that is a forward coupler. For microstrip quasi-TEM mode couplers and non-TEM mode structures, the above design equations are no longer valid. As a general rule, equal even- and odd-mode phase velocities are required for achieving the best directivity performance, which may be difficult to achieve in quasi- and non-TEM mode coupled lines unless a compensation technique is applied.

The type of coupler shown in Figure 7.21 is best suited for weak couplings (e.g., 10$^-$ or 20$^-$dB couplers for microwave instrumentations and measurements). Tight coupling requires the lines to be very close together, which may not be realizable because of fabrication tolerances.

Some practical solutions have been developed to remedy these shortcomings of the parallel-line coupler. Figure 7.22 shows a class of commonly used parallel-line couplers including edge, broadside, and interdigital multiconductor couplings. The **De Ronde coupler** may be regarded as a special type of coupler that uses both sides of a substrate (Hoffmann, 1987) employing a combination of coupled microstrip and slot lines to ease the tight coupling problem. On the other hand, the interdigital **Lange coupler** is most noteworthy since it combines the features of both a 90° hybrid and a parallel-line coupler. It usually uses λ/4 coupled microstrip-line sections for a 3-dB design. The Lange coupler has the advantage of small size, relatively large coupled line spacing, and wide bandwidth.

Ultrabroadband components can be designed with long or multisectioned inhomogeneous and nonuniform tapered coupled lines as described by the example of Figure 7.22(E). In the case of a continuously and gradually tapered line coupler, its operating bandwidth can be easily extended by several octaves. The design is usually made for the upper frequency range in the bandwidth of the coupler.

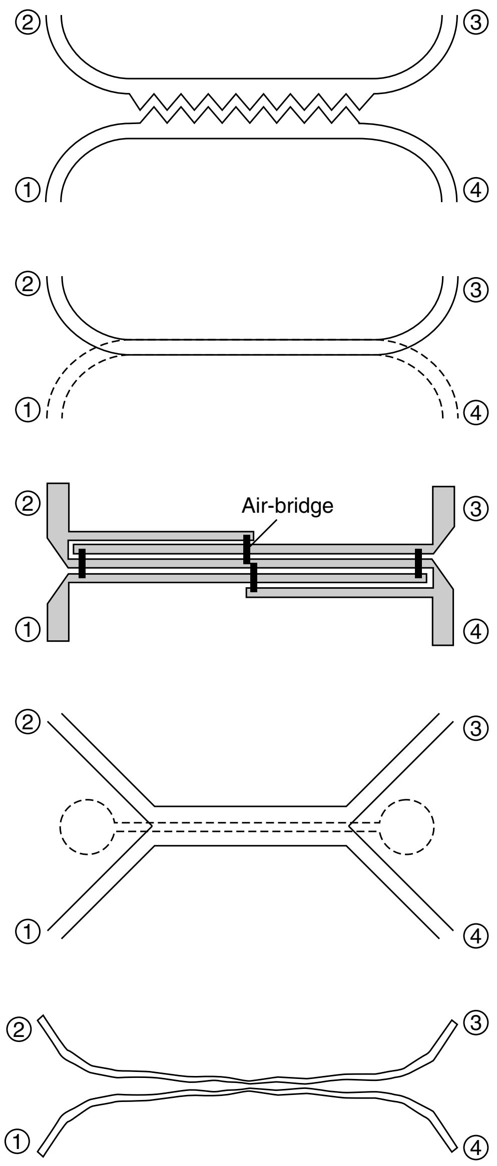

FIGURE 7.22 Various Physical Realizations of Parallel-Line Directional Coupler

7.4.5 Hole- and Aperture-Based Waveguide Couplers

Some waveguide couplers are made of a series of **coupling holes** or some well-placed short slots in the common broad or sidewall of two parallel waveguide sections (shown in Figure 7.23). This design principle is also applicable to multilayered planar structures. In this case, **coupling slots** or **apertures** are etched into the common ground plane(s). Hybrid planar/nonplanar design approaches can also be used for the coupling from planar lines to nonplanar lines or vice versa.

Figure 7.23 presents four well-known couplers: (a) **Bethe-hole coupler** (b) **Moreno cross-guide coupler** (c) **Schwinger reversed-phase coupler** and (d) **Riblet short-slot coupler**.

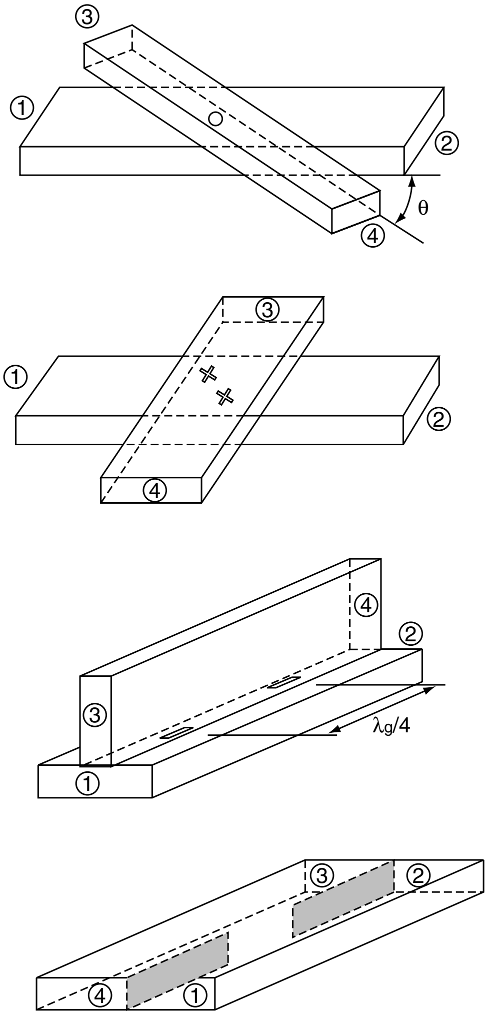

FIGURE 7.23 Typical Hole- and Aperture-Based Waveguide Couplers

The Bethe-hole coupler consists of two stacked waveguides with small-hole dipole coupling on the common broad wall or sidewall of the guides, the cross-guide coupler consists of two joint waveguides that are coupled through the crossed slots on the broadside of the guides. The cross-guide coupler has an added-up forward coupling due to a backward cancellation of the two excited waves generated by the crossed slots. The short-slot coupler couples electromagnetic energy of the TE_{10} (even) and TE_{20} (odd) modes along the common cross section of the two guides. This coupler design is actually derived from the parallel-line principle but results in forward coupling instead of backward coupling. This difference is caused by the different nature of the mode coupling.

7.4.6 Wilkinson Power Dividers/Combiners

The original three-port **Wilkinson strip-like** (microstrip and strip line) **divider/combiner** offers a one-to-two equal power dividing or two-to-one equal power combining function over a broad bandwidth. Two Wilkinson dividers are shown in Figure 7.24. This type of divider can be designed to give an arbitrary ratio of power division at the outputs. It is a well-known fact that a lossless reciprocal passive three-port junction cannot be matched at all ports simultaneously. In the Wilkinson power divider/combiner, a resistor is introduced to bridge the two output ports for improving their isolation, which is usually called "resistor of isolation." The resistor is placed λ/4 away from the junction and can be considered as the fourth port.

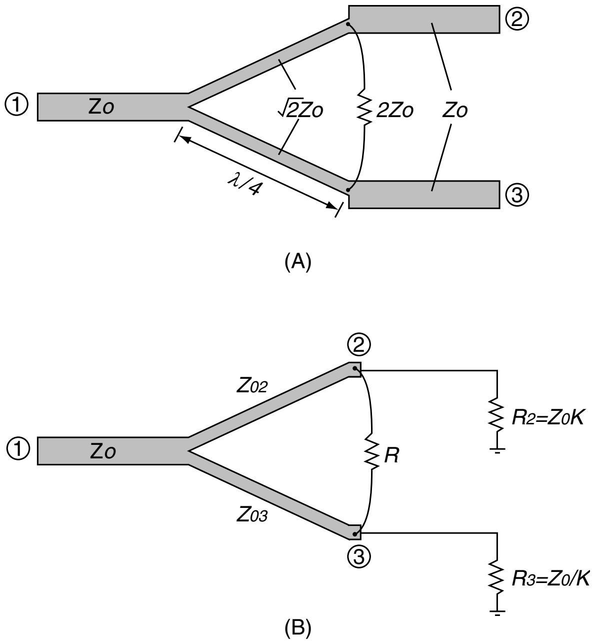

FIGURE 7.24 Wilkinson Microstrip Line Power Divider and Combiner with Equal (A) and Unequal (B) Power Dividing and Combining Schemes

The requirements for power dividing on the component design may be quite different from power combining even though the same component may posses both functions. This is because only a single input signal is concerned in the divider while two signals are simultaneously injected at the parallel-ports of the combiner, and these signals are not necessarily equal in magnitude and in phase. This may cause a serious problem of power or signal unbalance in the combiner junction. The added resistor, however, ensures that the two output/input ports are electrically isolated.

The two splitting branch lines of the strip-line equal-power Wilkinson divider/combiner have the characteristic impedances of $\sqrt{2}Z_0$, which is obtained from the input-matching requirement (characteristic impedance $= Z_0$ of the three external ports is assumed). The resistor of isolation is $2Z_0$. A Wilkinson divider may offer a bandwidth of about one octave, which can be further improved by using a cascaded multi-section topology.

Wilkinson dividers can also be made with unequal power splits $K^2 = P_3/P_2$, as shown in Figure 7.24(B). The design parameters are then obtained as follows:

$$R = Z_0\left(K + \frac{1}{K}\right). \qquad (7.11)$$

$$Z_{02} = Z_0 K\sqrt{\left(K + \frac{1}{K}\right)}. \qquad (7.12)$$

$$Z_{03} = \frac{Z_0}{K}\sqrt{\left(K + \frac{1}{K}\right)}. \qquad (7.13)$$

Generalized N-way Wilkinson power divider/combiner can be easily constructed in a similar manner. The only problem is that it requires crossover-bridged resistors if $N > 2$, which makes realization difficult in planar form (Maurin and Wu, 1996). In some cases, the design of Wilkinson power divider or combiner may not need a resistor of isolation. This is particularly the case with binary (corporate) power dividers or combiners for antenna feeding networks and may require a symmetrical and balanced topology. The bandwidth in this application, however, is relatively narrow.

7.4.7 Non-Wilkinson Power Dividers/Combiners

Although the Wilkinson structure is probably the most popular choice in the design of a power divider/combiner, other solutions may be useful alternatives when certain design requirements such as phase, power level, bandwidth, operating frequency, combining efficiency, and compactness may not be satisfied with the Wilkinson structure. These alternatives may be classed as **resonant** and **nonresonant** structures and are detailed in Chang (1989). In general, the nonresonant type is more useful, providing broader operating bandwidth. Among them, the corporate (binary-tree type) network may use hybrids, directional couplers, and Wilkinson topology that depend on the required phase relationship of the inputs and the outputs. The N-way network may use spatial or quasi-optical techniques or radial lines and generalized Wilkinson topology. Innovative dividing/combining approaches, have also been developed, such as multihole planar patch dividers/combiners (Kobeissi and Wu, 1999).

7.5 Resonators and Cavities

Resonators are fundamental building blocks for microwave filters, diplexers, frequency discriminators, and tuners. Resonators are used for frequency stabilization in oscillators or as control or tuning elements for amplifiers. A resonator is generally a structure that confines electromagnetic energy either inside a block of dielectric material, inside a section of metallic waveguide enclosure (Figure 7.25), or between the open or shorted ends of a piece of planar transmission line (i.e., microstrip, Figure 7.27). A combination of these may also be used as a resonator. The electrical and magnetic energies stored in the resonator determine its equivalent inductance and capacitance. Any energy dissipation in the resonator due to ohmic, dielectric, or radiation losses can be expressed by an equivalent resistance or a conductance, which directly determines the quality factor (Q-factor) of the resonator. The three electrical parameters RLC constitute a complete equivalent circuit network for characterizing a resonator in terms of bandwidth, center frequency, and Q-factor.

(B) Aperture-Coupled Microstrip Patch Resonator

(C) Coaxial-Line Excited Waveguide Resonator

FIGURE 7.25 Different Mechanisms of Excitation on the Basis of a Transmission Line for Dielectric, Planar Patch, and Waveguide Resonators

Resonant cavities are an important class of resonators that refer to almost completely closed metallic enclosures that have openings only for input and/or output coupling of electromagnetic energy. Cavity resonators are usually in the form of empty or dielectric-filled rectangular or circular waveguide bodies as well as coaxial line sections. The **Fabry-Perot cavity** is a special case of a quasioptical resonator. The resonance takes place between two face-to-face mirrors while other boundaries are open space. Therefore, it is sometimes called **open or quasioptical resonator** and is useful at very high frequency.

A resonator has an infinite number of resonant modes that satisfy the boundary conditions inside the cavity (eigenvalues of the cavity). Each mode corresponds to a resonant frequency that is characteristic for the cavity dimensions. At resonance, the electric W_e and magnetic W_m energies are equal, and the lowest resonant frequency is characterized by the fundamental (or dominant) mode. Regardless of its geometry or shape, a resonator can usually be modeled by either a series or parallel RLC lumped-element equivalent circuit, and the choice of an equivalent circuit may also depend on a resonant mode in question.

The resonant frequency can be found by:

$$\omega_0 = \frac{1}{\sqrt{L_0 C_0}}. \tag{7.14}$$

The quality factor Q, which is a measure of the resonator loss, is defined as:

$$Q = \omega \frac{\text{average energy stored}}{\text{energy dissipation/second}} = \omega \frac{W_e + W_m}{P_{\text{loss}}}. \tag{7.15}$$

A lossless resonator yields an infinite Q. If the resonator is completely isolated from external loading or coupling, the resulting Q is called the unloaded Q_u. Otherwise, the term **loaded Q_L** is used to account for external loading effects. Q_L is always lower than Q_u as long as the external coupling or load is passive. External loading effects are also extracted by a term called **external Q_e** that can be defined in the same way as equation 7.15, except that in this case the loss P_{loss} is due to the energy transferred to the external circuitry. The loaded Q_L can be expressed as:

$$\frac{1}{Q_L} = \frac{1}{Q_u} + \frac{1}{Q_e}. \tag{7.16}$$

In practice, the unloaded Q(or Q_u) value is closely related to the half-power or 3-dB fractional bandwidth (BW) of the resonator by.

$$Q = \frac{1}{BW_{3\text{dB}}}. \tag{7.17}$$

Because the resonator is always coupled to an external circuity, the coupling scheme is another important aspect in the design of a resonant circuit. Usually, a gap or an aperture is used as the coupling structure. The choice of an adequate coupling mechanism depends on the type of mode one wants to excite as well as the coupling strength required. To measure the coupling or energy transfer between a resonator and the external circuitry, a coupling coefficient κ is defined as:

$$\kappa = \frac{Q}{Q_e}. \tag{7.18}$$

Three types of coupling can be observed:

- $\kappa < 1$ if the feed line is overcoupled to the resonator.
- $\kappa = 1$ if the feed line is critically coupled to the resonator.
- $\kappa > 1$ if the feed line is undercoupled to the resonator.

Critical coupling occurs when the resonator is matched to the feed line. In most filter designs, this is the desired case.

Microwave resonators can be classified into three basic categories: **metallic cavities**, **planar resonators,** and **dielectric resonators**. In addition, open resonators of the Fabry-Perot type and other quasioptical geometries are gaining interest in millimeter-wave applications.

7.5.1 Metallic Cavity Resonators

A **cavity resonator** can be regarded as a section of metallic waveguide including coaxial lines that is usually short-circuited at both ends, thus forming a closed box or cavity. Electric and magnetic fields are confined in the structure, and currents flowing on the interior's imperfect conducting walls cause power dissipation. Electrical and/or magnetic coupling to this type of resonator can be made through a small aperture or a small loop or probe.

Resonant frequencies and mode profiles can be obtained through the solution of Maxwell's satisfying the metallic boundary conditions. The current distribution over the surface of the cavity depends on the profile of magnetic fields that are in turn determined by a particular mode. Generally, the existence of a mode also depends on the excitation mechanism, such as the shape of aperture or probe. Consequently, the power dissipation is expected to be different from mode to mode, leading to different Q values. In practice, the selection of an adequate resonant mode is of critical importance for high-Q operation.

Figure 7.26 illustrates three basic types of cavity resonators: a **rectangular cavity** of height b, width a, and length d; a **cylindrical cavity** of length d with radius a; and a **coaxial line cavity** of length d with an inner and outer radius denoted by a and b. The coaxial cavity resonator operators in the TEM mode, which is much easier to control than other (waveguide) modes. For simplicity, the coaxial line cavity will not be discussed because its information can be found widely in the literature.

For the rectangular cavity resonator, the resonant frequency of the TE$_{mnl}$ or TM$_{mnl}$ modes is given by:

$$f_r^{mnl} = \frac{c}{2}\sqrt{\left(\frac{m}{a}\right)^2 + \left(\frac{n}{b}\right)^2 + \left(\frac{l}{d}\right)^2}, \tag{7.19}$$

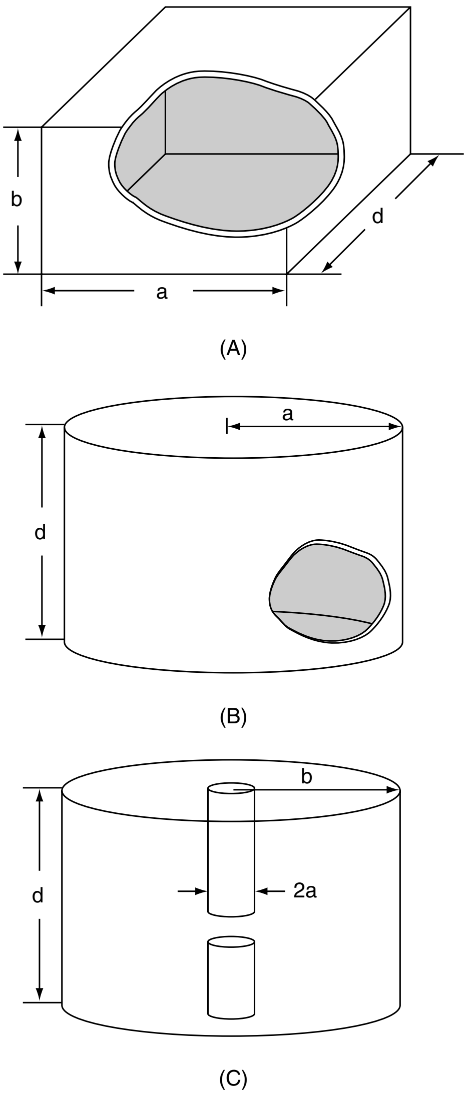

FIGURE 7.26 Representative Waveguide and Coaxial Line Cavity Resonators

in which c is the speed of light. The mode subscript *mnl* refers to the number of half-sinusoidal variations in the standing-wave pattern (resonance) along the x, y, and z directions, respectively. If $b < a < d$ is valid, the cavity will support the dominant mode TE_{101}, which has the lowest resonant frequency. The unloaded Q value of this mode can range from 5,000 to 15,000 depending on the cavity surface and the metal conductivity. Obviously, the smoother the surface is, the lower the losses. The dominant TM resonant mode is TM_{110}.

The cylindrical cavity resonator is a closed section of circular waveguide similar to its rectangular waveguide counterpart. The resonant frequency of the TE_{mnl} or TM_{mnl} modes is given by:

$$f_r^{mnl} = \frac{c}{2}\sqrt{\left(\frac{p_{nm}^{TE.TM}}{a\pi}\right)^2 + \left(\frac{l}{d}\right)^2}. \qquad (7.20)$$

The integer number $l = 0, 1, 2, 3$ refers to the number of half-guided-wavelengths that fit into a longitudinal section of a waveguide. The values of p can be obtained from the zeros of the Bessel functions and their derivatives for TM and TE modes, respectively. In view of the resonant frequency, the dominant mode is TM_{010} for $d/a < 2$, while the TE_{111} mode becomes dominant for $d/a > 2$.

Of all the modes, the TE_{011} is perhaps the most interesting for practical applications because it has only a circumferential current in both the cylindrical wall and the end metallic plates. This means that the end plate is free to be moved to adjust the length d for frequency tuning purpose, which hardly affects the unloaded Q. The maximum Q can be obtained with $d/a = 2$, and a range of 20,000 to 60,000 is possible. This value is significantly higher than the achievable Q values of other modes even though the TE_{011} is not the dominant mode. This is why this mode is used in the design of precision frequency meters that function on the basis of a circular cavity resonator with a movable length of the cavity.

To control the coupling mechanisms in connection with the above cavity resonators, in particular for input/output coupling, can become quite involved, especially if modes other than the wanted one can resonate in the cavity as well. The design of an appropriate coupling topology is also important in view of achieving the highest Q possible for the wanted mode. Two modes are sometimes possible to resonate at the same resonant frequency. These are so-called **degenerated modes** which can be used quite favorably as dual-mode filters, for example, in very narrowband applications. The advantage is that with only one physical cavity, two electrical resonators can be realized.

7.5.2 Planar Resonators

Planar resonators may conveniently be classified as **transmission line resonators** and **patch resonators**. Figure 7.27 shows three typical planar transmission line resonators. Their line length is always commensurate with wavelength. Figure 7.28 illustrates two examples of patch resonators. The transmission line resonators consist of sections of line having the physical length equal to a certain fraction of the guided-wave wavelength. A closed ring geometry where the electrical length equals an integer multiple of the wavelength also acts as a resonator. For open-ended planar resonators, the fringing field effects at the open end introduce an effective lengthening of the line and, thus, lower the resonant frequency. This effect must be taken into account in the calculation. Hence, resonant modes of such resonators may be considered to have approximately a one-dimensional dependency. This is quite different for the resonance condition of a patch resonator, which depends on both length and width of the patch (two-dimensional problem).

The electric energy is predominately confined in the dielectric substrate under the strip, while the magnetic energy

FIGURE 7.27 Gap-Excited Typical Microstrip Line Resonators

extends into both the substrate and air regions around the line or patch. Simple lossy transmission line theory can be used to calculate the resonant frequencies and Q values of the transmission line resonators. Their unloaded Q values are evaluated by:

$$Q = \frac{\beta}{2\alpha}\frac{v_p}{v_g}, \tag{7.21}$$

in which α and β are the attenuation and phase constants of the resonator line, and v_p and v_g are the phase and group velocities, respectively (Konishi, 1991). As for the TEM-mode transmission line resonators, the condition of $v_p = v_g$ is always valid. The resonant characteristics of an arbitrarily shaped planar patch resonator can be obtained by applying a field modeling technique (two-dimensional problem). For a regularly shaped resonator, such as the circular disk or radial resonator shown in Figure 7.28(A), the resonant frequencies can be approximately calculated by simple closed-form formulas. TM_{nm0} modes are dominant in those structures where the subscripts n and m indicate the number of half-wave variations of the fields along two (planar) orthogonal directions of the coordinate, respectively. The subscript 0 stands for no variation of fields in the vertical direction of substrate.

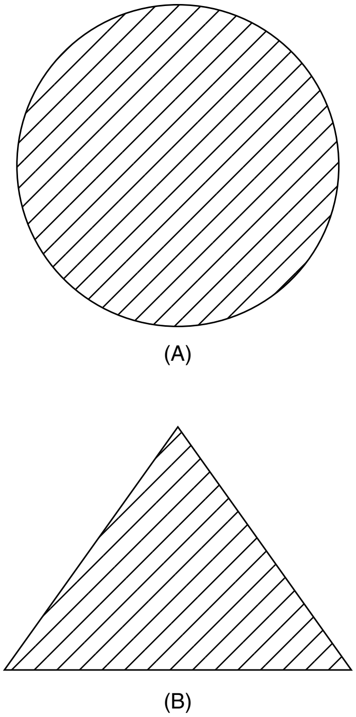

FIGURE 7.28 Layout View of Circular and Triangular Microstrip Patch Resonators.

Generally speaking, the unloaded Q of the planar resonators is basically determined by the conductor loss if the dielectric substrate has a loss tangent $\tan\boldsymbol{\delta}$ small than 10^{-3}. Practical values of Q are in the range of 100 to 500. A patch resonator usually has a slightly higher Q than its transmission line counterpart. On the other hand, the Q value of a patch resonator also depends on its operating mode because ohmic losses are different from mode to mode. Planar resonators find wide-ranging applications in particular in the lower microwave regime. Coupling between planar resonators is easily accomplished by a capacitive gap. The resulting loaded Q_L value is usually low and may range from 10 to 100. Patch resonators are good candidates for antenna design.

A planar resonator may also be constructed by lumped elements such as parallel or series LC networks, which are popular choices in MMICs. This is in particular adequate for some active circuit designs, such as voltage-controlled oscillators (VCO).

7.5.3 Dielectric Resonators

A **dielectric resonator** (DR) is a small piece (disc, cube, or rectangle) of ceramic or other low-loss dielectric material with a high relative dielectric constant ε_r, normally in the range of

10 to 100. The reflections at the dielectric–air interface confine the electromagnetic fields mainly inside the dielectric region and its immediate vicinity. The operating principle of a dielectric resonator is quite similar to that of rectangular or cylindrical cavity resonators. Calculation of the resonant frequencies is, however, more involved because of the inhomogeneous medium in which the electromagnetic wave resonates.

Dielectric resonators can serve two basic functions. One is to keep the electromagnetic energy away from any metallic boundary and thus increase the *Q* factor significantly, provided the dielectric is of low loss (specialized ceramic). The other function is to reduce the resonator size by approximately $1/\sqrt{\varepsilon_r}$. Specially designed ceramic materials offer excellent temperature stability and high *Q* value. Typical values for *Q* are in the range of 1,000 to 60,000. In a practical realization, a dielectric resonator is either enclosed in a metallic cavity (placed sufficiently away from the housing) or, for lower *Q* applications, metallized at its surface. A dielectric resonator can also be used as a drop-in resonator in a planar circuit (surface-mounted on a metallic surface) or even sandwiched between two parallel metallic plates. The latter application prevents to some degree radiation loss and unwanted interference with other circuits.

Figure 7.29 presents four different uses of the dielectric resonator, including two applications for millimeter-wave circuit applications (for a nonradiative dielectric waveguide [NRD] resonator and for a planar dielectric resonator (Ishikawa *et al.*, 1996). A **cylindrical dielectric resonator** as shown in Figure 7.29(A) is probably the most commonly used structure in which the low-permittivity dielectric substrate may be used to keep the resonator in place. In this resonator structure, the dominant resonant modes are usually the $\text{HE}_{11\delta}$ and $\text{TE}_{01\delta}$ modes, respectively. The subscript δ denotes the number of resonating waves in the longitudinal direction of the resonator. The lowest number is $\delta = 1$. A complete field solution for the resonance properties of cylindrical resonators can be obtained through field modeling and matching the boundary conditions at the air–dielectric interfaces.

Figure 7.30 shows some field profiles of the principal modes for the cylindrical dielectric resonator suspended between two metallic plates and surrounded by air. In this figure, two classes of hybrid modes are illustrated: the HE_{nm} and EH_{nm} modes. The former describes a mode in which the H_l component of the mode is dominant, whereas in the latter case, it is the E_z component. Figure 7.31 depicts three practical techniques commonly used to achieve magnetic coupling between a microstrip line and a $\text{TE}_{01\delta}$ mode dielectric resonator.

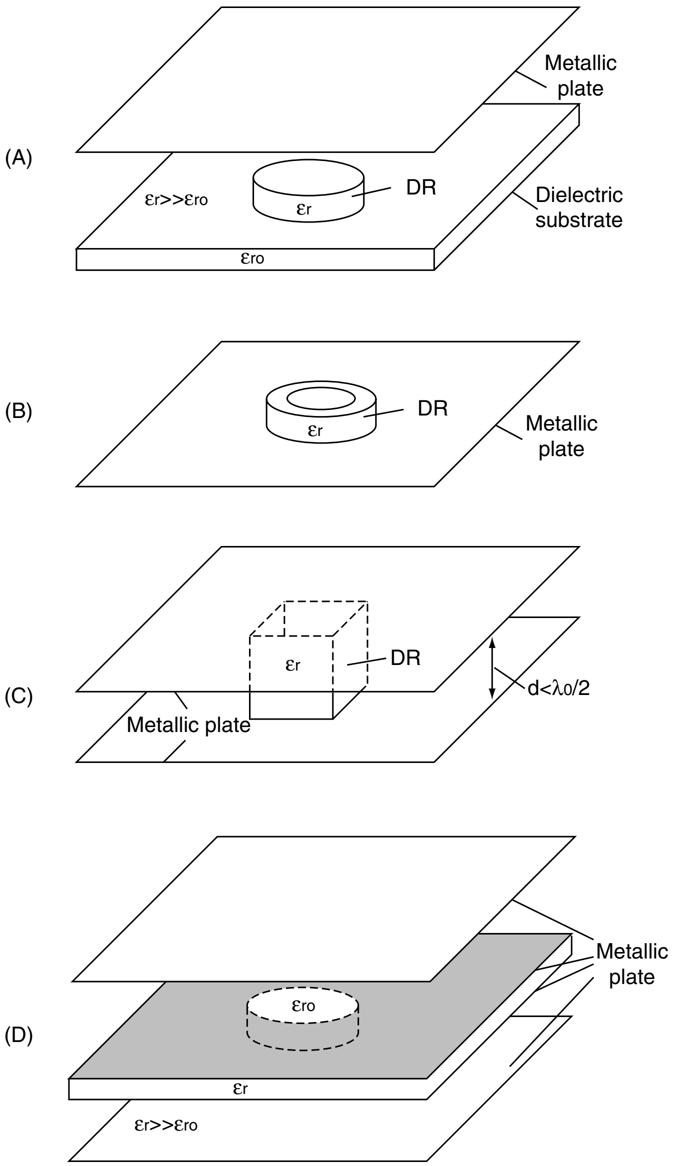

FIGURE 7.29 Four Different Dielectric Resonators (DR): (A) Surface-Mounted DR; (B) Image DR; (C) Non-Radiative Dielectric (NRD) resonator; and (D) Planar DR

In general, applications of dielectric resonators are limited to lower frequencies only since the loss of tangents at millimeter-wave frequencies may become prohibitive. Furthermore, size reductions at millimeter wavelengths may be too great to be practical. An exception may be the **whispering-gallery** (WG) **mode dielectric resonator** that can be generated in a hollow dielectric cylinder as shown in Figure 7.29(B). This resonator exhibits a large number of azimuthal field variation around the hollow cylinder, which is quite similar to the higher order resonances of a microstrip ring resonator. The WG resonator is essentially "oversized" for millimeter wavelengths and thus enables the designer to use larger structures.

In case of an **NRD-guide resonator,** the dielectric block may be in the form of a rectangle made of a relatively low permittivity and low-cost dielectric material. Thus, size is not a problem. The intrinsic nonradiating condition of the NRD-guide will give rise to a high *Q* value of the resonator since the fields are well confined inside the dielectric region and pose no leakage problem. The NRD-guide resonator is also a promising

solution for millimeter-wave circuits. Figure 7.29(D) shows a planar dielectric resonator that is compatible with a conventional lithographic fabrication process for planar circuits. The resonance takes place around the circular aperture area of the dielectric substrate while the remaining dielectric surfaces are metallized. This structure offers a very good Q value at millimeter-wave frequencies while it is compatible with coplanar waveguide or slot lines realized on the same substrate.

7.6 Filter Circuits

Filters may be constructed by active and passive elements, and they are indispensable in almost all microwave electronics and communication systems that need to control, channelize, or combine signals. A passive filter may be designed by either lumped LC or distributed resonators (planar, dielectric resonators, or metallic cavities) or both and arranged in a cascaded transfer network.

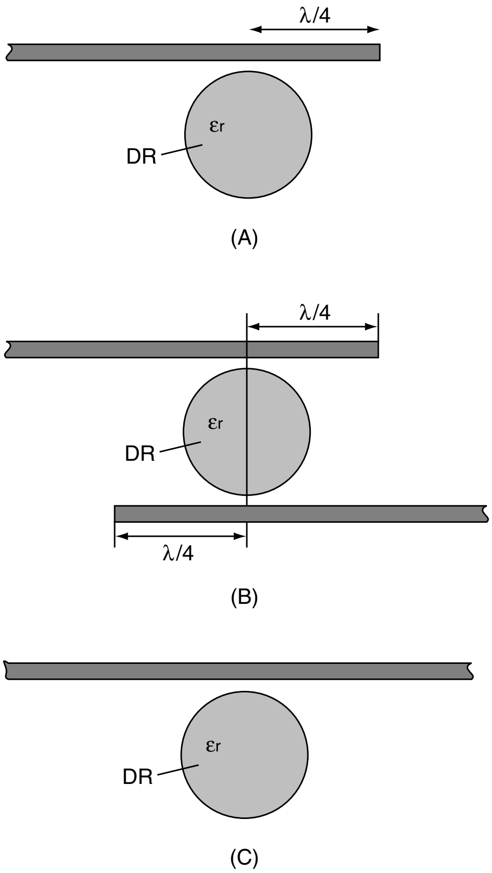

FIGURE 7.31 Basic Coupling Schemes Between $TE_{01\delta}$ Dielectric Resonator and Microstrip Line: (A) Reflection Type, (B) Transmission Type, and (C) Reaction Type

A passive filter is usually regarded as a two-port linear network that allows a signal to pass over desired frequency range(s) with minimum possible attenuation, whereas undesired frequency bands are attenuated as much as possible in the given constraints. In the design of a filter, the most important specifications are related to bandwidth, insertion loss, stopband attenuation or out-of-band rejection, spurious response, return loss, input/output impedance levels, VSWR, group delay, topological size, temperature range, power handling capability, and transient response. In practice, a selected group of those specifications is most dominant and determines the design approach.

A filter is usually synthesized and designed through some well-established network theories for a given frequency response or a designated frequency-related network transfer function. A reciprocal two-port filter network is schematically

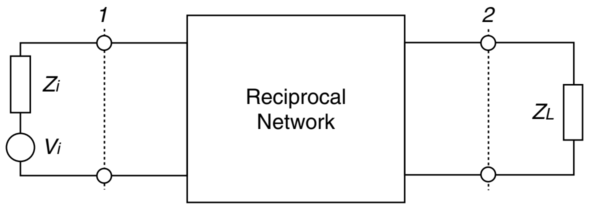

FIGURE 7.32 Schematic Reciprocal Two-Port Filtering Network

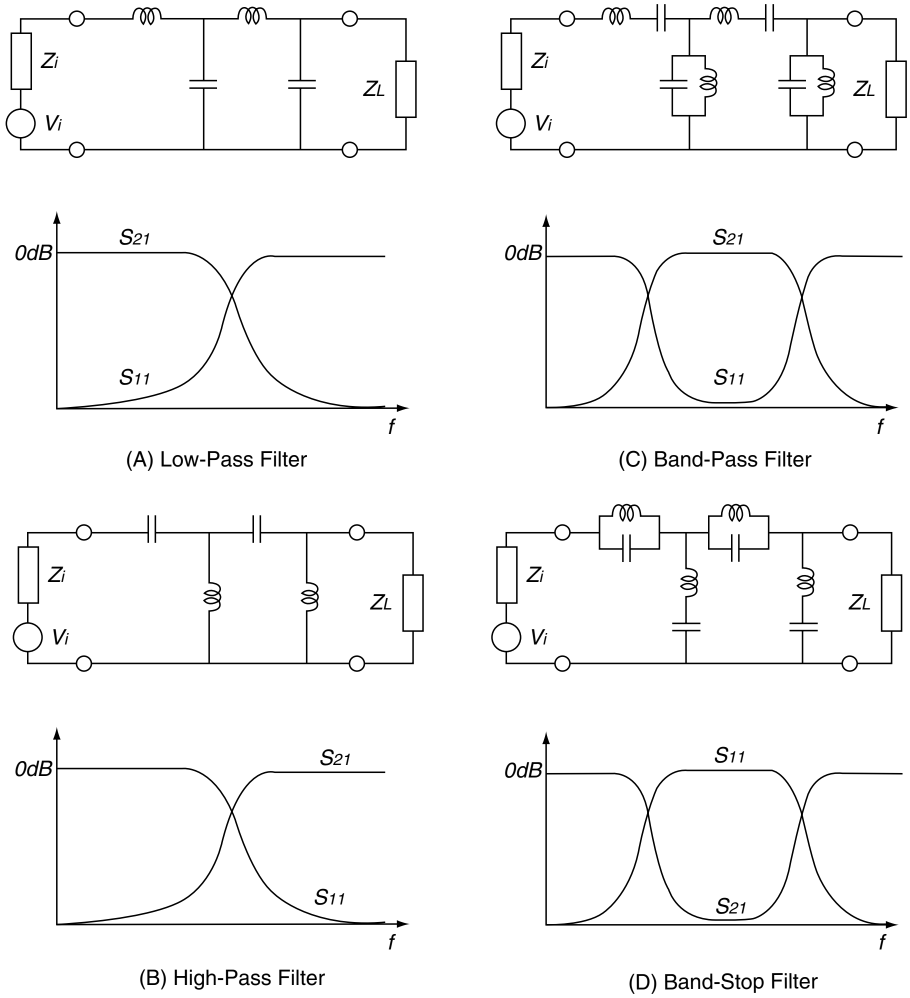
described in Figure 7.32. Note that the source and load terminal conditions are part of the design parameters and are included in the network synthesis. In this case, two-port *S*-parameters can effectively be used to characterize a filter in terms of S_{11} and S_{21} for its return and insertion losses, respectively. In a low-loss filtering system, magnitudes of both *S*-parameters are directly related to each other, thus allowing to derive one if the other is known. Phase characteristics of a filter are important for certain practical applications, such as phase and frequency modulation schemes. The group delay is also usually used to measure how long it takes for the signal to pass through the filter (in seconds). The group delay is also usually frequency dependent (dispersion). In addition, temperature sensitivity may be a delicate issue of design considerations, in particular for narrow band applications in all areas (e.g., commercial, military, and satellite).

There are four basic types of filters classified according to the frequency response: **low-pass**, **band-pass**, **band-stop or stopband** (also called band rejection or notch), and **high-pass** filters. They are illustrated in Figure 7.33. An ideally lossless filter has zero transmission loss and infinite out-of-band rejection as well as abrupt band response. Practically, a filter always presents a loss-related degradation of performance, and it also exhibits unwanted spurious responses beyond a certain limit of the frequency range of interest.

Filter design is usually based on a prototype network for which the transfer function can be described mathematically. The transfer function is usually given in the form of a



(A) Low-Pass Filter

(C) Band-Pass Filter

(B) High-Pass Filter

(D) Band-Stop Filter

FIGURE 7.33 Simplified Equivalent Circuit Representation and Typical Frequency Response of Four Basic Filters

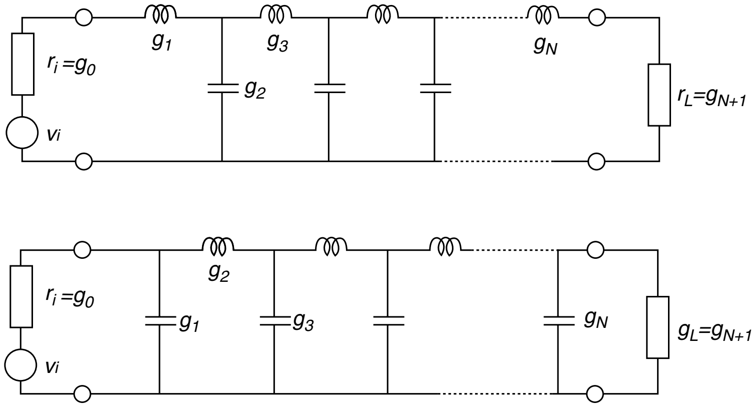


FIGURE 7.34 Two Possible Prototype Low-Pass Filter Networks

frequency-dependent polynomial or other mathematical functions. In general, the design of a filter requires three steps, starting with the network synthesis of a low-pass LC prototype (using normalized frequency, normalized bandwidth, and specified slope selectivity) as shown in Figure 7.34. The insertion–loss method and the image–parameter method are most frequently used to calculate network parameters of the prototype transfer function. Then, the prototype network and parameters are transformed or frequency-scaled to the actual frequency specifications. Finally, the synthesized network is physically designed and produced by either lumped LC elements, commensurate line planar microstrip, waveguide sections, or other building blocks. Special techniques to transform LC parameters into corresponding line dimensions or waveguide geometries have been developed. Most of them are based on the well-established impedance and admittance inverters technique (so-called *K*- and *J*-inverters) (Mattaei *et al.* 1980). In practice, postfabrication tuning elements or other similar corrective measures are required to account for interelement coupling, inaccurate material parameters, mechanical tolerances, and parasitic effects.

Most **microwave filters** are designed as either **maximally flat** (Butterworth), **equal-ripple** (Chebyshev), or **elliptic function response** (Figure 7.35). Other types of transfer functions are possible and depend on specific design requirements. The degree of the low-pass prototype function (the order of the

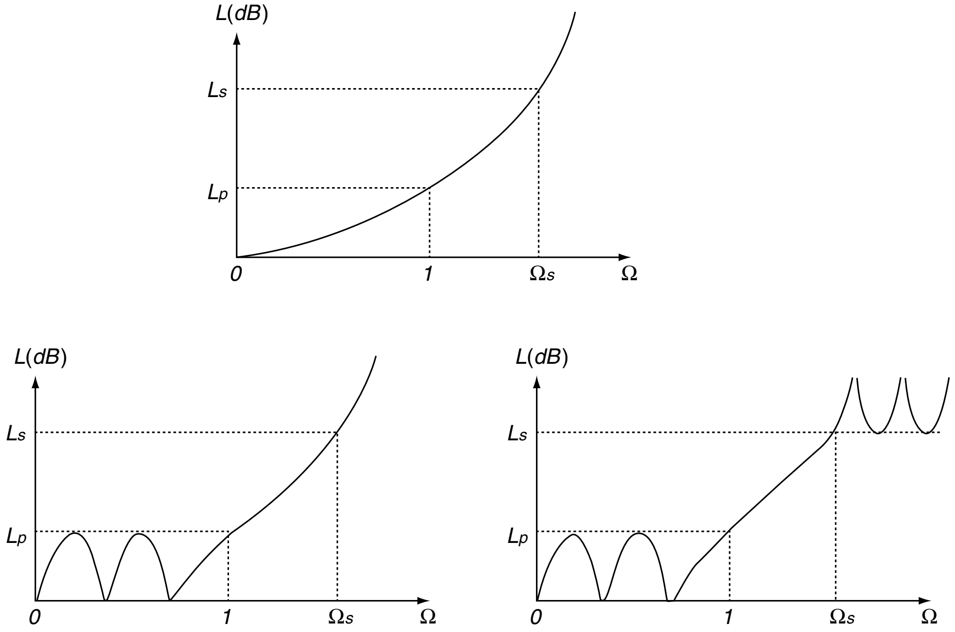

FIGURE 7.35 Three Popular Frequency Responses or Transfer Functions of the Prototype Filters Selected in the Design: Maximally Flat (Butterworth), Equal-Ripple (Chebyshev), and Elliptic Function

polynomial) corresponds to the number of reactive LC elements required to obtain the desired response. This is called the **order of the filter**. In the case of band-pass and stopband filter designs, the order is also related to the number of poles or zeros of the frequency response (resonance-related effects). A practical filter design usually requires an order ranging from 2 to 10.

A filter may be realized in any one of the following technologies: **metallic waveguides** (including coaxial lines), **dielectric waveguides,** and **planar transmission lines**. Planar filters are small in size, lightweight, and low in cost but have usually a low *Q* value compared to waveguide and dielectric resonator filters. In practice, high-quality band-pass and stopband filters that require high *O* resonators are made of waveguide and/or dielectric resonators. For narrow band realization (less than 1.5%) with low insertion loss as well as broadband application, extremely low-loss resonators are needed. Broadband applications (greater than 15%) with high slope-selectivity are possible. Generally, the broader the bandwidth is, the higher the order of the filter. Moreover, the higher the required slope-selectivity is, the higher the order of the filter. Single-mode resonators arranged as direct coupled (Chebyshev or Butterworth) or crosscoupled filters with elliptic transfer function response are possible. Dual-mode or multimode resonators allow the realization of more than one electrically equivalent resonator in a single physical cavity. These filters are attractive for space applications due to their small size and lightweight features.

7.6.1 Low-Pass Filters

The equivalent circuit of a typical **low-pass filter** consists of a cascade of series inductances and parallel capacitors. It is usually realized with TEM or quasi-TEM mode transmission lines like strip line, microstrip line, coaxial line, and coplanar waveguide because they have no cutoff frequency. The equivalent LC circuit elements can be designed with short line sections of high and low impedances (stepped impedance), respectively. In some cases, LC lumped elements like spiral inductors and MIM capacitors are used to realize a filter on an MMIC chip or a high-density hybrid integrated circuit. Although using LC lumped elements reduces the size of the passive filter structure, the *Q* value, insertion loss, and slope selectivity may deteriorate significantly.

Figure 7.36 illustrates examples of low-pass filters that can be made out of strip line, microstrip line, and coaxial line sections. The simplest example of a low-pass filter may be a dc-biasing block filter used to isolate the RF from the dc source, for example, in a microwave amplifier circuit. The operating bandwidth of a low-pass filter can range widely depending on its lowest cutoff frequency point. Note that a waveguide filter can also be designed as pseudo low-pass filter in a waveguide band, but below the waveguide cutoff frequency, no signal propagation will take place.

7.6.2 Band-Pass Filters

A **band-pass filter** may also be called a **band-select filter** as it selects a specific frequency range to pass a signal unattenuated. This type of filter is the most frequently used. Band-pass filters may be built from all common transmission line media, ranging from waveguide to microstrip line. A basic feature of the geometry of a band-pass filter is that it may consist of resonators coupled along the transmission path of signal, and its number of poles is related to the number of resonant modes of the filter.

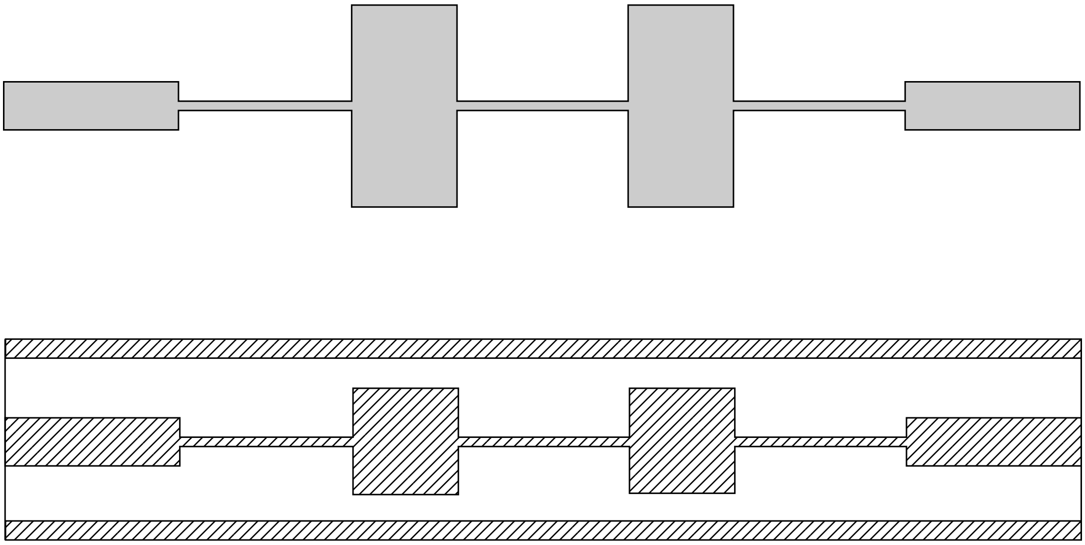

FIGURE 7.36 Examples of Low-Pass Filter Made of Microstrip, Stripline, or Coaxial Line Sections

Planar resonators are known to suffer from high ohmic losses, in particular at high frequency, which excludes them from the construction of high-performance, narrow band filters. Usually, they are limited to the lower microwave domain (up to 15 GHz) and only if insertion loss and slope-selectivity is not a major concern. Some Q-enhanced planar filters are possible in conjunction with strip line and suspended microstrip structures (up to 30 GHz). In the higher microwave domain and well into the millimeter wave region, waveguide filters are most commonly used. With the emergence of commercial broadband systems in the millimeter-wave range, quasiplanar filters have made a comeback. Coaxial line and dielectric resonator filters are most frequently used in the lower microwave range if high Q values or small size are needed. In addition, low-loss and lightweight dielectric filters are constructed for millimeter-wave applications.

One of the most difficult problems for band-pass filters (especially for narrow-band types) is the need for postfabrication tuning. Fabrication tolerances and material uncertainties as well as inaccurate design techniques may all contribute to the need for tuning. Field theory-based design techniques may alleviate this problem to some degree.

Most frequently used configurations for planar band-pass filters are **direct-coupled, parallel-coupled, interdigital, comb-line, hairpin-line, dual-mode ring,** and **square-patch resonators,** some of which are shown in Figure 7.37. Direct-coupled resonator filters are of excessive length that can be reduced by using a parallel-coupled geometry. The parallel coupling can be made stronger to achieve a larger bandwidth. The interdigital combline, and hairpin-line have side-to-side inter-resonator coupling schemes, and filters can be made compact if spurious responses are suppressed. In addition,

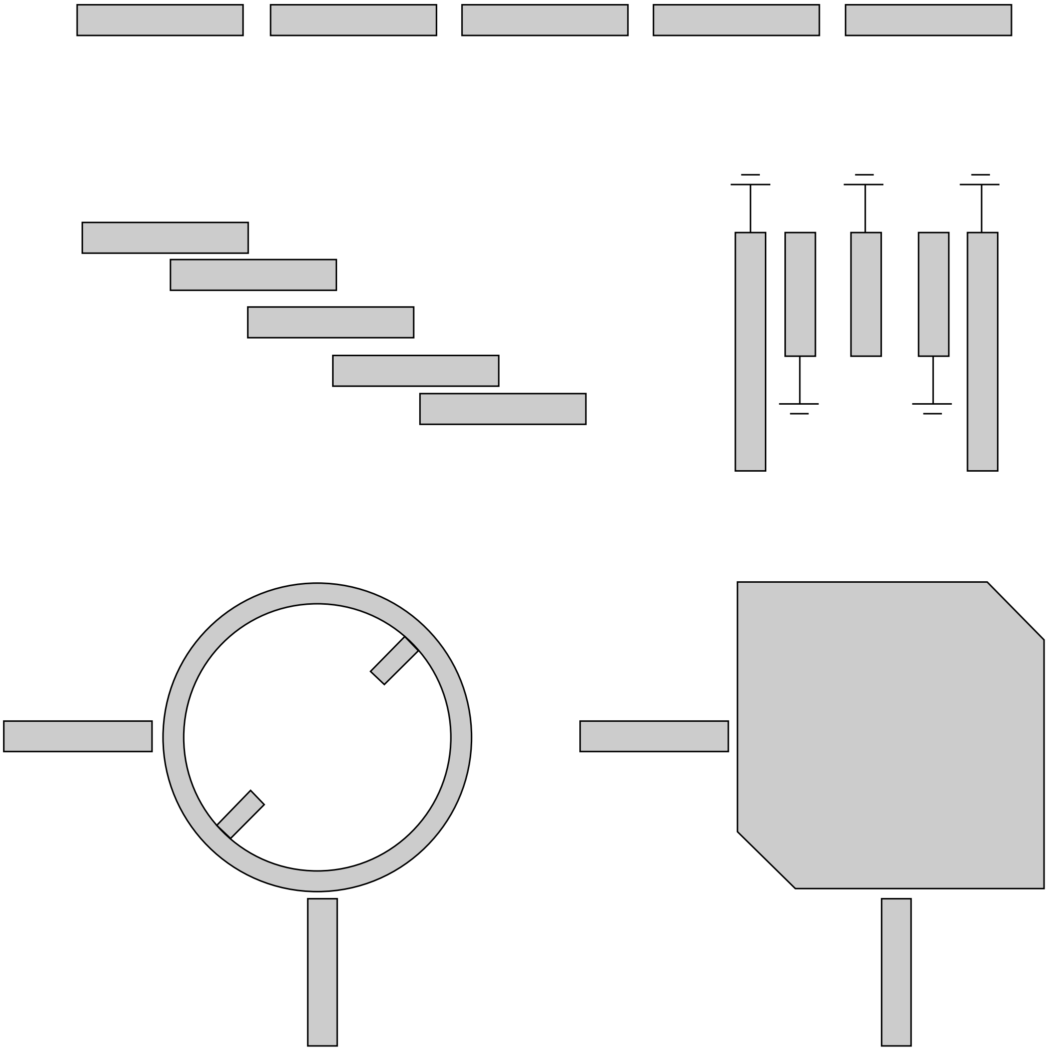

FIGURE 7.37 Some Popular Configurations of Planar Transmission-Line Band-Pass Filter Including Dual-Mode Filters

they are good candidates for narrow band designs. The dual-mode ring and square-patch resonators can simultaneously induce two resonant modes that are orthogonal in space and are excited by the two orthogonally arranged input and output lines. The coupling between the two modes is accomplished by a topological perturbation that takes place along the symmetrical axes with respect to the input and output lines.

Figure 7.38 presents a number of nonplanar band-pass filters, including waveguide, dielectric, and coaxial line filters. Various waveguide filters have been developed over the frequency range from 1 GHz to more than 100 GHz. They are in the form of cascaded rectangular or circular cavities in which low-loss resonant modes are excited. Waveguide filters may be categorized as **stub type, *E*- or *H*-plane type, dual-mode type,** or **filters with corrugated geometry**. Most of the resonator sections are coupled through evanescent mode waveguide sections. Among them are *E*-plane filters that are most suitable for mass-fabrication. In contrast, popular dual-mode and crosscoupled filters are very special designs requiring very particular knowledge in design and tuning.

E-plane filters are usually referred to as **finline** and metal insert filters that consist of ladder-shaped inserts in the *E*-plane of metallic waveguide (Vahldriek, 1989). The inserts can either be made from pure metal or they consist of a ladder-shaped metal pattern etched on a thin supporting low-permittivity substrate. The latter structure is called a quasiplanar filter.

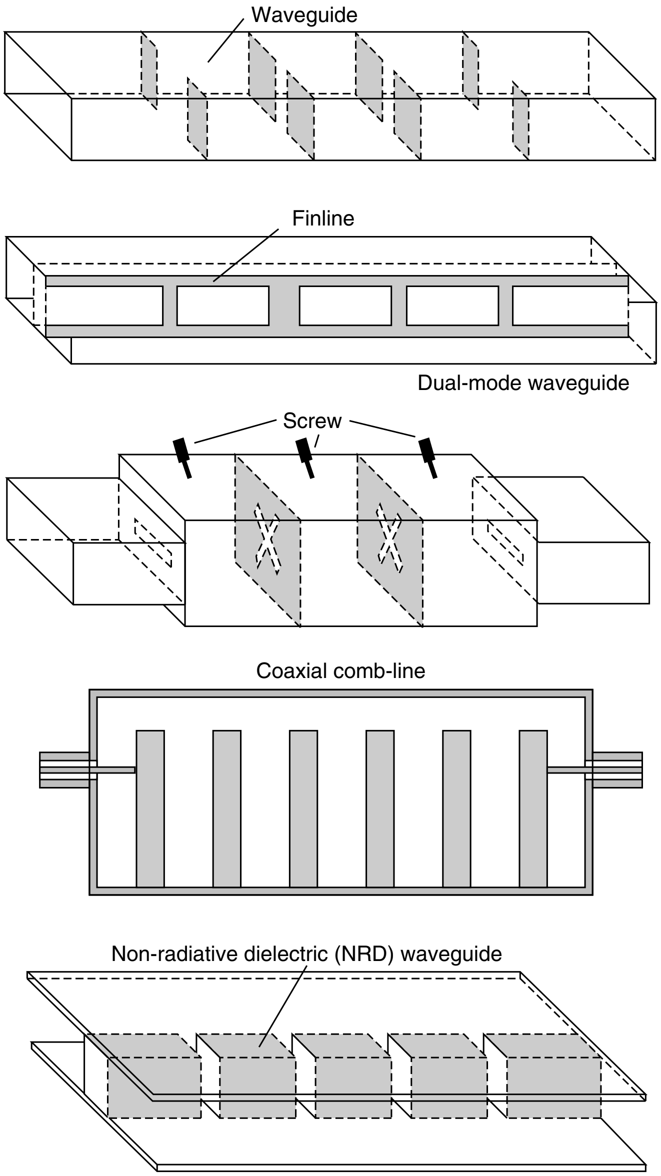

FIGURE 7.38 Selected Design Choices of Band-Pass Filter with Nonplanar Metallic Waveguide, Finline, Coaxial Line, and Dielectric Waveguide

The filter function is mostly determined by the ladder-shaped pattern. The pure metal insert structure is used if insertion loss is of paramount importance. The quasiplanar structure is used when the following components are printed on the same substrate, allowing high integration density.

Dual-mode filters (canonical symmetric design), as described in Figure 7.38, are based on square or circular waveguide cavities that support two orthogonals in a single cavity (Zaki *et al.*, 1987). Thus, the filter structure can be miniaturized, and elliptic function and linear phase performance can also be obtained. Dual-mode filters can be based on low-loss high-permittivity square or cylindrical dielectric blocks. The idea is to maintain the electromagnetic field inside the dielectric material and away from the lossy metallic wall to improve the *Q* factor. These design approaches are found in very narrow band applications (less than 0.1%) at low frequencies (Less than 3 GHz). Even smaller bandwidth is only obtainable with superconductor filters. Depending on how much the dielectric fills the metal cavity, the size reduction effect sets in.

Coax filters are found as combline and interdigital filters and are mainly used in the lower microwave domain. Interdigital filters are based on side-to-side coupled $\lambda/4$ resonators, whereas the combline filters (Figure 7.38) consist of coupled resonators that are loaded with lumped capacitors at the open ends to reduce the lengths of the resonators and thus help to shrink the complete filter volume. Dielectric waveguide filters use high *Q* dielectric resonator building blocks, and the input and output lines are usually in the form of waveguide or coaxial lines. The dielectric resonators are canonical with high dielectric constants, and they are coupled with each other through irises or adjacent air interfaces. Generally, the dielectric band-pass filters can be used over the frequency range from 300 MHz to 100 GHz. For high-frequency applications, NRD waveguide filters (Figure 7.38) gain interests because of the extremely low-loss and low dielectric constant materials that can be used in the design.

7.6.3 Band-Stop Filters

The band-stop class of filters is designed to reject signals over the selected bandwidth and pass all other frequencies. Therefore, these filters are also called band rejection filters. They can be used, for example, to reject only the harmonics generated by a nonlinear circuit or to cancel out interferences at selected frequencies. The basic strategy of *band-stop* filter design is to place resonators in parallel with the main transmission line. When these resonators are in resonance, they short-circuit the signal at that particular frequency. At other frequencies, they do not load the main transmission line and are therefore invisible to the signal.

Figure 7.39 describes two typical *band-stop* filters. One of them is a **waveguide stub filter** with stubs attached to the broad wall of the main line. A signal will be rejected if its operating frequency falls into the resonant frequency range of the stubs. The other example is a simple **microstrip line** coupled with a series of dielectric resonators that observe the similar operating mechanism. On the other hand, a periodic structure is used that exhibits alternated pass and stopbands. The stopband is called **bandgap** in quantum physics and optics for periodic patterned structures or simply bandgap structures.

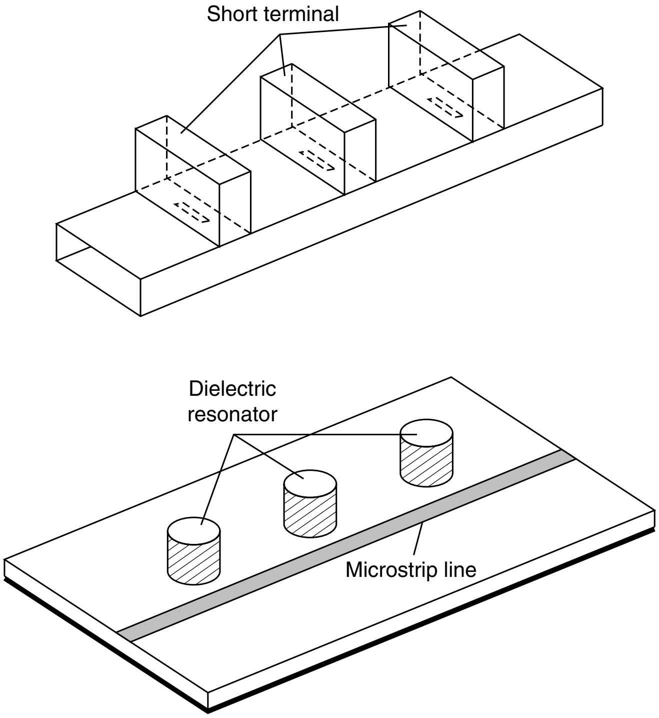

FIGURE 7.39 Two Typical Waveguide and Planar Line/DR Stopband Filters

7.6.4 High-Pass Filters

High-pass filters are complementary to low-pass filters. From an equivalent network point of view, the design of a high-pass network is quite straightforward as it is sufficient to interchange the topological position of inductors and capacitors of the low-pass filter. Thus, high-pass filters consist of a series capacitor elements with joint shunt inductors. As a matter of fact, a metallic waveguide itself is a natural high-pass filter because the signal is completely rejected below the cutoff frequency of the guide. Figure 7.40 shows two representative examples of stopband filters made of planar elements and waveguide sections, respectively.

7.6.5 Multiplexers

Multiplexers (Rhodes and Levy, 1979) are important components for channel combination or separation in multichannel communication systems. They are usually part of the antenna feed systems in front-end modules. Generally, there are four

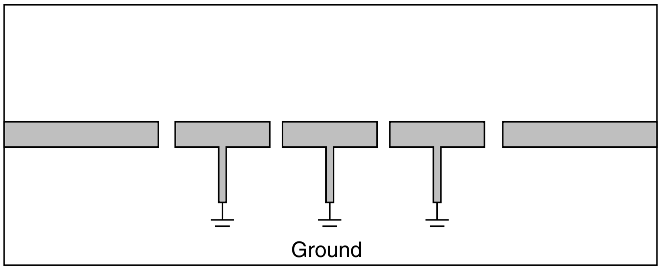

FIGURE 7.40 Representative Microstrip Line High-Pass Filter

different multiplexing methods: (1) the **circulator/filter chain** (2) the **directional filter technique**, (3) the **manifold multiplexing approaches**, and (4) the **branching filter concepts**. Each of them has its particular merits and applications (Uher *et al.*, 1993).

The **diplexer** (Menzel *et al.*, 1997) is a special case of a multiplexer. Its purpose is to separate two channels, the receiving channel and the transmit channel by means of two band-pass filters whose paths are terminated on the same antenna. The diplexer is a low-loss alternative to a circulator-based solution. In the design of the band-pass filters, the slope-selectivity between both filters must be sufficient to ensure a certain level of isolation between the transmit and the receiving paths. This isolation is necessary to protect the input of the receiver from the output power of the transmitter. The isolation bandwidth between the transmitting and the receiving bandwidths is known as guard band. Figure 7.41 illustrates two possible diplexer arrangements based on waveguide and planar circuit technology, respectively.

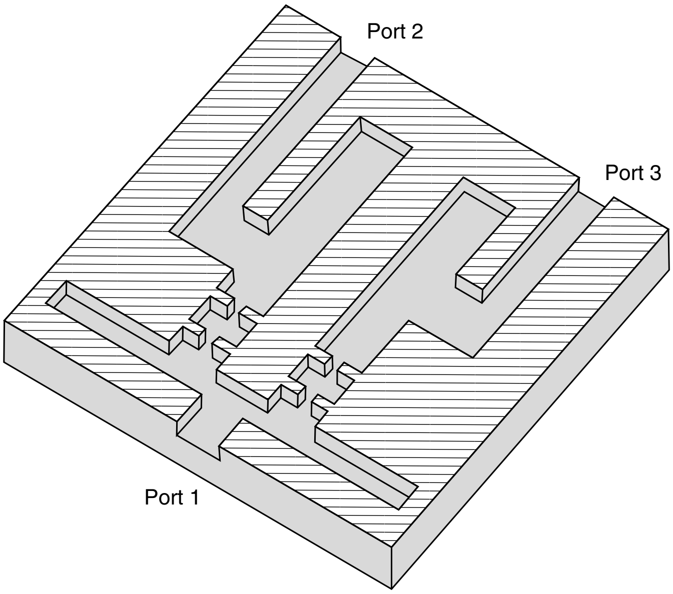

FIGURE 7.41 Transparent Half-Plane View of a Metallic Waveguide Diplexer

7.7 Ferrite Components

This discussion has only presented reciprocal passive components, and they were realized with isotropic materials (air or any other dielectric). Nonreciprocal components, dealt with in the following, show different properties in different propagation directions of the wave (electrically and/or magnetically). They are realized with anisotropic materials, such as ferrimagnetic and ferromagnetic compounds, that are generically termed as **ferrites**. Ferrites are widely used in the design of microwave passive components to control the amplitude (e.g., attenuators, limiters), the phase (e.g., phase shifters), frequency (e.g., YIG or yttrium iron garnet), the transmission paths (e.g., circulators, isolators, switches), and frequency bandwidth (e.g., filters) of microwave signals. Ferrites possess low-loss and high-anisotropy properties for microwave applications.

Ferrite materials are generally categorized as garnets, spinels, and hexagonal ferrites. The latter are composed of iron oxides (a kind of ceramics) and many other elements. The magnetic anisotropy of a ferrite is controlled by applying an external static (dc) magnetic field. This field aligns the inherent magnetic dipoles in the material to produce a net (nonzero) magnetic dipole moment, which causes the magnetic dipoles to precess at a frequency controlled by the strength of the bias field. The ideally lossless macroscopic description of the anisotropic properties of ferrites can be described by a Hermitian permeability tensor as follows:

$$[\mu] = \mu_0 \begin{bmatrix} \mu & j\kappa & 0 \\ -j\kappa & \mu & 0 \\ 0 & 0 & 1 \end{bmatrix}. \quad (\vec{z}\text{-biased with } \vec{H}_0 = \vec{z}H_0) \quad (7.21)$$

Similar forms of the permeability tensor can be derived for the x- and y-oriented static magnetic fields. In equation 7.21, the dependency of the applied external magnetic field strength H_0 and the material parameters are involved in the matrix elements μ and κ (Chang, 1989).

The nonreciprocal behavior of ferrite microwave components is basically described by two different scalar permeabilities for oppositely rotating microwave magnetic fields that are perpendicular to the static magnetic field. Thus, a microwave signal will propagate through a ferrite differently in different directions. The propagation characteristics are controlled by the strength of the applied magnetic field, which is also related to the power handling capability. Once the biasing field exceeds a threshold value, the transmission loss increases rapidly. The dielectric properties of ferrite materials are described by the relative permittivity and the loss tangent $\tan\delta = \varepsilon''/\varepsilon'$, with ε' being the real part of the dielectric constant and ε'' being the imaginary part. High-quality commercial ferrites have values of the loss tangent lower than 0.001 for microwave applications.

In the following paragraphs, a number of widely used ferrite components are presented, including isolators, phase shifters, and circulators.

7.7.1 Isolators

The **isolator** is a two-port device with a very low insertion loss (e.g., less than 0.5 dB) in one direction (forward) and very high insertion loss (e.g., greater than 20 dB) in the other (reverse) direction. The forward and reverse transmission losses depend on the choice of ferrite materials and design topology as well as operating frequency. Isolators are used to provide protection from high-power reflection and to stabilize signal sources or power sensitive devices from frequency shifts caused by variations in load impedance. Isolators are also important devices for eliminating unwanted interactions between components. An ideal isolator is shown in Figure 7.42 with matched ports and lossless transmission from port 1 to port 2. The corresponding *S*-matrix is as follows:

$$[S] = \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix}. \tag{7.22}$$

Basically, there are four types of ferrites isolators: **terminated circulators, Faraday rotation isolators, resonance isolators,** and **field displacement isolators**. They may be designed with different transmission line media, such as waveguide or microstrip. Important design specifications are forward and reverse insertion loss, frequency bandwidth, and power handling capability. The ratio of reverse (isolation) to forward insertion loss may also be used and is called the **figure of merit**.

The most commonly used isolators are related to the resonance and the field displacement principle and will be discussed here.

Resonance Isolators

Resonance isolators make direct use of the ferrimagnetic resonance phenomenon to achieve the nonreciprocal operation. A circularly polarized wave rotating in the same direction as the precessing magnetic dipoles is known to have a strong interaction with the material, while its opposite counterpart has a weaker interaction. Thus, the attenuation (absorption) of the strong interacting wave is very large near the gyromagnetic resonance of the ferrite, while it is very small for the wave propagation in the other direction. This resonance effect is used to construct the resonance isolators, which usually consist of a ferrite slab or strip mounted at a certain position along a transmission line.

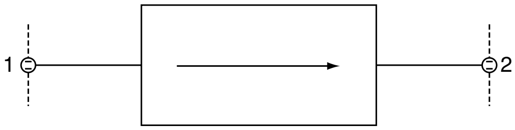

FIGURE 7.42 Network Representation of an Ideal Isolator

In principle, resonance isolators can be designed for any transmission line in which circularly polarized electromagnetic waves exist. Most often, isolators are realized in rectangular waveguides. Figure 7.43 shows two typical waveguide isolators in the *E*-plane and *H*-plane. The *E*-plane geometry has the advantages of requiring a lower biasing field to drive the isolator, while its *H*-plane counterpart is normally used for high-power applications because of easy heat dissipation.

Field Displacement Isolators

The **field displacement isolators** are based on the fact that field profiles of forward and reverse waves can be quite different in transmission lines, such as waveguides, when loaded with a biased ferrite. Such a distinct nonreciprocal behavior can be used to construct field displacement isolators. As shown in Figure 7.44 for a TE_{10} waveguide field displacement isolator, the largest electric field of the reverse wave is located at the ferrite slab where the electric field of the forward wave has a negligible level. If a thin resistive sheet is introduced in this position, the forward wave will be essentially unaffected while the reverse wave will be greatly attenuated. This is the operating principle of the field displacement isolators.

The field displacement isolators show excellent performance with reverse isolation better than 30 dB and forward insertion loss lower than 0.3 dB. Compared to the resonance isolators, they require a much smaller bias field because they operate below resonance. In addition to the waveguide geometry, other forms of the field displacement isolators have been developed, which include strip line and finline types.

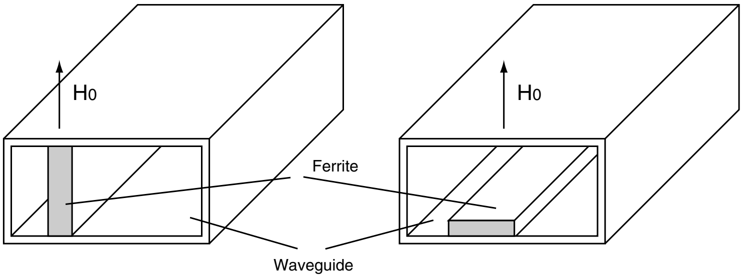

FIGURE 7.43 Two Typical Waveguide Isolators Loaded with Ferrite Slab

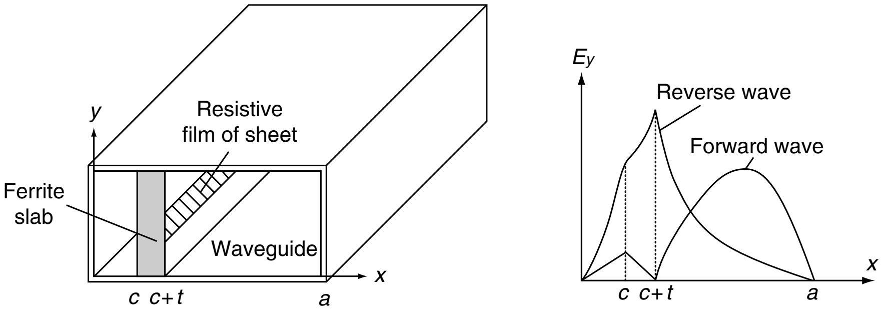

FIGURE 7.44 Geometrical View and Operating Principle of a Field Displacement Waveguide Isolator

7.7.2 Phase Shifters

Ferrite phase shifters are usually two-port devices that provide a variable phase shift of the transmission path by changing the bias field of the ferrite. There are many types that are characterized by their microwave performances, their switching characteristics, and their control characteristics. These include waveguides and planar circuits, transverse and longitudinal biasing, latching and continuous phase variation, and reciprocal and nonreciprocal operations. Special devices are also developed with the ferrite phase shifters, such as gyrators that have a 180° differential phase shift in the forward direction but no phase shift in the reverse direction.

One example of a ferrite phase shifter is a **nonreciprocal waveguide latching phase shifter** whose geometry is described in Figure 7.45. It consists of twin-toroids symmetrically located in the waveguide with bias wires passing through their centers, and the two toroids are separated by a dielectric spacer. If β_+ designates the propagation constant in one direction when a positive bias field saturates the ferrite, then β_- denotes the propagation constant for a negative bias field. The maximum amount of variable phase shift per unit length is the difference of $\beta_+ - \beta_-$. This differential phase shift may be achieved over a very broad bandwidth with good switching speed and phase accuracy.

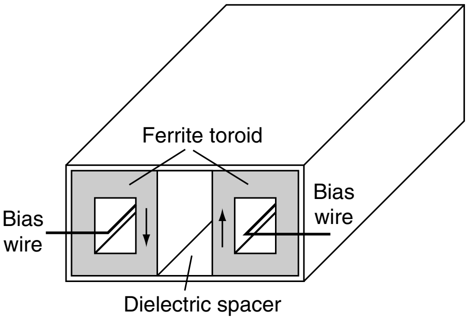

FIGURE 7.45 Topological Sketch of a Ferrite-Based Waveguide Phase Shifter

7.7.3 Circulators

Circulators find wide applications in microwave systems particularly in separating transmitter and receiver paths of a microwave front-end. Circulators are three-port devices that can ideally be lossless and simultaneously matched at all ports because of their nonreciprocity. An ideal circulator has the following *S*-matrix form:

$$[S] = \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}. \tag{7.23}$$

Equation 7.23 indicates that signal flow can occur from ports 1 to 2, 2 to 3, and 3 to 1, but flow cannot occur in the reverse direction. The opposite path may be obtained by changing the polarity of the ferrite bias field. In practice, permanent magnets are used to generate the bias field. A circulator may also be used as an isolator by terminating one of its ports with a matched load. Design and performance specifications include required insertion loss, isolation, power handling capability, and bandwidth.

There are three different types of circulators: **Y-junction circulators, differential phase-shift circulators,** and **Faraday rotation circulators**. The most popular configurations are the junction circulators that can be constructed in waveguide or strip line and microstrip, for example.

Figure 7.46 presents typical geometries of strip line and waveguide *H*-plane junction circulators. In the strip line junction geometry, two ferrite disks are stacked between the two ground planes and the center metallic disk, forming a resonant cavity. Three external strip lines are symmetrically connected to the periphery of the center disk at 120° intervals and form three ports of the circulators. The static magnetic field is applied normal to the ground planes. In the waveguide junction, a cylindrical ferrite or other shaped ferrite is placed in a usually ridged or stepped *Y*-junction. This ridge or step form is also used to provide impedance match to the three external waveguide ports.

In the absence of a magnetic bias field for the strip line circulator, the resonant cavity supports two contrarotating

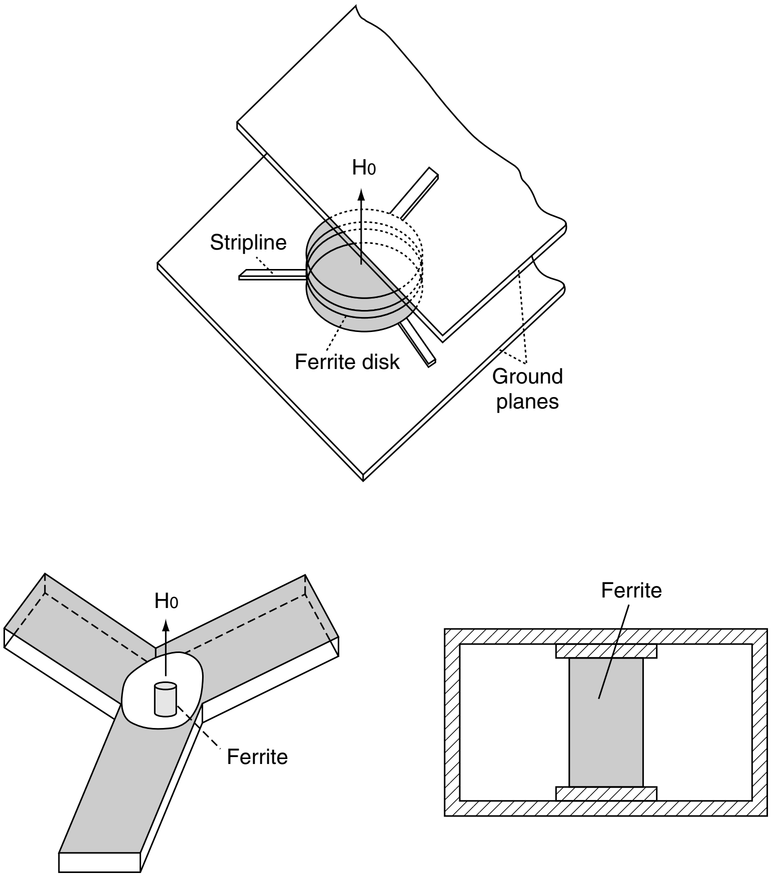

FIGURE 7.46 Three-Port Stripline and Waveguide Circulators with the Ferrite Film or Post-Loaded Within the Junction of Structure

modes that are degenerated (have the same resonant frequency). Application of a bias field will remove this mode degeneracy with two resonant modes having slightly different resonant frequencies, which are referred to as **mode splitting**. The operating frequency of the circulator can then be chosen between the two resonant frequencies so that the superposition of those two modes add at the output port and cancel out at the isolated port. A similar operating principle is also applied to the waveguide *Y*-junction circulator.

7.8 Other Passive Components

In this section, several classes of passive components are briefly described that are related to special materials and special techniques for designing and realizing certain classes of passive microwave components (as described in previous sections). Without getting into details, these components include **acoustic microwave devices, microwave ferroelectric devices, micromachined components,** and **superconducting components**. No doubt, new and innovative passive components are emerging, owing to the advancement of new materials (e.g., low-loss RF ferroelectrics), new processing techniques (e.g., nanotechnologies), and new design schemes (e.g., multilayers).

7.8.1 Acoustic Microwave Devices

The class of passive components that is usually constructed on piezoelectric crystals or similar materials is called **acoustic microwave devices**. These devices allow the conversion of electromagnetic and mechanical energies within the bulk or surface structure. The most popular microwave devices based on this technology are generally known as surface acoustic wave (SAW) devices. Because the velocity of ultrasonic waves in crystals is in the order of 10^5 times lower than that of electromagnetic waves, the microwave SAW circuits can be made extremely compact. Usually, the SAW components are loss-limited at higher frequency by characteristics of the transducers, and they are used for microwave frequency up to several gigahertz ($\sim 2\,\text{GHz}$). Higher frequency applications are still subject of ongoing research. Well-known passive SAW devices include filters, delay lines, and resonators. Technical details on the microwave SAW devices and useful references can be found in Chang (1989), Konishi (1991), and Webster (1999).

7.8.2 Microwave Ferroelectric Devices

Analog to the ferrite materials, the **ferroelectric materials** (a kind of ceramics) provide a variable dielectric constant ranging from a dozen to several thousands by applying an electric field or voltage over the ferroelectric substrate. This controllable dielectric constant allows the design of electrically tunable devices. In addition, attractive properties of ferroelectric materials, such as barium strontium titanate ($Ba_{l-x}Sr_xTiO_3$), are able to provide reciprocal and broadband operations. Fundamental design considerations are related to the tunability with biasing voltage levels and transmission losses to be as low as possible. The design of the geometry of such circuits is very involved to reduce the potential bias voltage and to have an appreciable tunability of the dielectric constant or other electrical properties. Ferroelectric thin films are compatible with integrated circuits. Usually, a high-quality ferroelectric substrate has a negligible current leakage over the biasing direction and thus has virtually no power consumption. This is why some ferroelectric components are considered passive.

Passive components based on ferroelectric materials include **phase shifters**, **delay lines**, **tunable filters**, **resonators**, and many others. Useful references are given in (Webster, 1999).

7.8.3 Micromachined Components

The micromachining process was developed in the study of the micro-electro-mechanical system (MEMS) in the 1960s for the miniaturization of mechanical machines for sensors and other applications. It can be used to fabricate a number of high-quality microwave components with the existing silicon (Si) or GaAs-based process. The Si-based micromachined components are attractive because they are relatively low cost. There are two basic micromachining techniques: **bulky** and **surface micromachining**. In certain microwave designs, nearly lossless SiO_2 or Si_3N_4-based membranes with low dielectric constant are used. Micromachined passive components offer attractive performance, namely ultrabroadband nonuniform line couplers, high-quality filters, and ultra-rapid MEMS switches. Further details can be found in De Los Santos (1999) and Nguyen *et al.* (1999).

7.8.4 Superconducting Components

The **superconducting class** of passive components is fabricated by using both low- and high-temperature superconductors, such as NbN and YBCO materials, that are able to reduce the conductor loss to a negligible level. Therefore, extremely high Q superconductive planar transmission lines and waveguides can be used to design various loss- and noise-sensible passive microwave components that include filters, diplexers, low-loss antenna feeders, delay lines, and phase shifters. In particular, the extremely narrow band-pass filters and very long time delay lines can be realized, for which the ordinary planar lines are not amenable in practice. Generally, the superconducting technologies are expensive, and they are widely studied for planar passive components that require special dielectric substrates in support of superconducting thin films, such as MgO and $LaAlO_3$.

Superconducting passive components (Shen, 1994) can be used in space-and military-oriented systems. Limited commercial applications are also being exploited in competition with other enabling technologies.

Computational Electromagnetics: The Method of Moments

Jian-Ming Jin and
Weng Cho Chew
*Center for Computational Electromagnetics,
Department of Electrical and Computer Engineering,
University of Illinois at Urbana-Champaign,
Urbana, Illinois, USA*

8.1 Introduction

Due to the rapidly increasing capability of computers, computational electromagnetics has become a very important analysis tool in electromagnetics. This is partly due to the predictive power of Maxwell's theory as proven over the years—**Maxwell's theory** can predict the design performances or experimental outcomes if Maxwell's equations are solved correctly. Moreover, Maxwell's theory, which governs the basic principles behind the manipulation of electricity, is also extremely pertinent in many electrical engineering and scientific technologies. Examples of these technologies are radar, remote sensing, geoelectromagnetics, bioelectromagnetics, antennas, wireless communication, optics, and high-frequency circuits. Furthermore, Maxwell's theory is valid over a broad range of frequencies spanning static to optics and over a large dynamic range of length scales, from subatomic to intergalactic. In view of this, there is always a quest to solve Maxwell's equations accurately from first principles using numerical methods so that increasingly complex structures can be handled.

After the establishment of Maxwell's theory in 1873, the early electromagnetics analyses were associated with such simple shapes as spheres, cylinders, and planes. As the scientific and engineering demand for sophistication rose, solutions to more complex geometries were needed. As a result, approximate techniques were developed to solve Maxwell's equations. One can view circuit theory as a reduced form of Maxwell's theory in the low-frequency limit where approximate analyses of many complex geometries have been obtained with astounding success. At the other end of the spectrum, high-frequency ray theory, diffraction theory, and perturbation theory were developed to provide approximate solutions to Maxwell's equations. Recently, with the advent of computer technology, numerical methods were developed in the 1960s to allow more versatility and accuracy in the solution methods.

The **method of moments**, also known as the **moment method**, is one of the numerical methods developed to rise up to the challenge of solving increasingly complex problems in electromagnetics. It transforms the governing equation of a boundary-value problem into a matrix equation to enable its solution on a digital computer. Although the basic mathematical concepts of the moment method were in existence during early 20th century, true interest in it did not arise until the mid-1960s, with the publication of pioneering work by Mei and Van Bladel (1963), Andreasen (1964), Oshiro (1965), and Richmond (1968). The unified formulation of the method was presented by Harrington in his seminal book in 1968. Since then, the method has been further developed and applied to a variety of important electromagnetic problems. It has become one of the dominant methods in computational electromagnetics. It is not our intent here to present a complete history and list of references on the method. The reader is referred to Miller (1992) for a 35-page bibliography of the journal articles from 1960 to 1990. This book also presents a selection of key articles for the analytical formulation, numerical implementation, and practical application of the method. Other books on the topic include the ones by Mittra (1973), Hansen (1990), Wang (1991), and Peterson *et al.* (1997).

8.2 Basic Principle

The solutions to Maxwell's equations can be sought directly by solving related differential equations. Alternatively, they can be obtained by solving an integral equation derived from Maxwell's equations. For example, in the electrostatic case, an integral equation can be derived using the **Green's function approach**. A Green's function is a point source response and, in this case, is the potential produced by a point charge. As an example, in the capacitance problem, where one is interested in finding the total capacitance of a piece of metal, one can formulate an integral equation to solve for the charge in the metal. Using the Green's function approach, one can write, by the principle of linear superposition, the total potential due to the charges on the surface of a metallic conductor as:

$$\phi(\boldsymbol{r}) = \int_S G(\boldsymbol{r}, \boldsymbol{r}')\sigma(\boldsymbol{r}')dS', \tag{8.1}$$

where $\sigma(\boldsymbol{r}')$ is the surface charge density on the metallic surface, $G(\boldsymbol{r}, \boldsymbol{r}')$ is the Green's function or the point source response, S is the surface of the metallic object, and $\phi(\boldsymbol{r})$ is the potential generated by the surface charge. On the metallic surface S, $\phi(\boldsymbol{r})$ must be a constant. As a consequence, one has:

$$\Phi = \int_S G(\boldsymbol{r}, \boldsymbol{r}')\sigma(\boldsymbol{r}')dS' \quad \boldsymbol{r} \in S. \tag{8.2}$$

Equation 8.2 is an integral equation where Φ is a known constant, $G(\boldsymbol{r}, \boldsymbol{r}')$ is a known function, and $\sigma(\boldsymbol{r}')$ is the unknown surface charge density on the metal surface. The integral equation can be solved for the unknown $\sigma(r')$.

Equation 8.2 typifies an integral equation in electromagnetics. Integral equations can also be derived for dielectric and metallic bodies for electrostatics and electrodynamics. These integral equations are generally solved using the moment method. Notice that the function $\sigma(\boldsymbol{r}')$ in equation 8.2 has infinite degrees of freedom. Such infinite degrees of freedom cannot be handled by a computer. We say that $\sigma(\boldsymbol{r}')$ is a function representing a vector in an infinite dimensional space. To make equation 8.2 solvable by a computer, we approximate its solution in a finite dimension subspace using the moment method.

To illustrate this procedure, we choose a set of functions called basis functions that can be used to approximate $\sigma(\boldsymbol{r}')$. For example, we let:

$$\sigma(\boldsymbol{r}') = \sum_{n=1}^{N} c_n \upsilon_n(\boldsymbol{r}'), \tag{8.3}$$

where $\upsilon_n(\boldsymbol{r}')$ are the basis functions that can be used to approximate $\sigma(\boldsymbol{r}')$ and c_n are the unknown coefficients yet to be determined. In this manner, we have given $\sigma(\boldsymbol{r}')$ only N degrees of freedom. Substituting equation 8.3 into equation 8.2, we have:

$$\sum_{n=1}^{N} c_n \int_S G(\boldsymbol{r}, \boldsymbol{r}')\upsilon_n(\boldsymbol{r}')dS' = \Phi \quad \boldsymbol{r} \in S. \tag{8.4}$$

However, equation 8.4 still does not allow us to solve for c_n—we have to convert equation 8.4 into a matrix equation. To this end, we choose a set of functions $w_1(\boldsymbol{r}), w_2(\boldsymbol{r}), \ldots, w_N(\boldsymbol{r})$ and multiply equation 8.4 by these functions individually. We then integrate to obtain:

$$\begin{aligned} &\sum_{n=1}^{N} c_n \int_S w_m(\boldsymbol{r}) \int_S (\boldsymbol{r}, \boldsymbol{r}')\upsilon_n(\boldsymbol{r}')dS'dS \\ &\quad = \int_S w_m(\boldsymbol{r})\Phi dS \quad m = 1, 2, \ldots, N. \end{aligned} \tag{8.5}$$

Notice that the double integrals above produce a number A_{mn} that depends only on m and n, and the integral on the right-hand side produces a number b_m that depends only on the index m. Consequently, equation 8.5 becomes:

$$\sum_{n=1}^{N} A_{mn}c_n = b_m \quad m = 1, 2, \ldots, N. \tag{8.6}$$

The 8.6 matrix equation from which we can solve for c_n in turn can be used in equation 8.3 to provide an approximate solution $\sigma(\boldsymbol{r}')$.

In a more abstract level, the moment method can be presented as follows. All integral equations can be expressed as:

$$\mathcal{L}\phi = f, \tag{8.7}$$

where $\mathcal{L}$ represents an integral operator, ϕ is the unknown to be sought, and f is a known driving term for the integral equation. We pick a finite basis set to approximate the solution:

$$\phi = \sum_{n=1}^{N} c_n\phi_n, \tag{8.8}$$

to arrive at:

$$\sum_{n=1}^{N} c_n\mathcal{L}\phi_n = f. \tag{8.9}$$

As mentioned, ϕ_n are called **basis** or **expansion functions**. We next convert the above equation into a matrix equation by testing the above with w_m, $m = 1, 2, \ldots, N$, and integrate over the solution domain. This corresponds to equation 8.5 and can be abstractly written as:

$$\sum_{n=1}^{N} c_n \langle w_m, \mathcal{L}\phi_n \rangle = \langle w_m, f \rangle \quad m = 1, 2, \ldots, N, \tag{8.10}$$

where $\langle w_m, f \rangle$ is an abbreviation for an integration; in particular, it is the following:

$$\langle w_m, f \rangle = \int_S w_m(\boldsymbol{r}) f(\boldsymbol{r}) dS, \tag{8.11}$$

in the electrostatic example. The functions w_m are usually referred to as **testing** or **weighting functions**. Equation 8.10 can be written as a matrix equation:

$$[A]\{c\} = \{b\}, \tag{8.12}$$

where $[A]$ is called the **system matrix** whose elements are given by:

$$A_{mn} = \langle w_m, \mathcal{L}\phi_n \rangle, \tag{8.13}$$

and $\{b\}$ and $\{c\}$ are called the **source** and **unknown** vectors, respectively, with the elements of $\{b\}$ given by:

$$b_m = \langle w_m, f \rangle. \tag{8.14}$$

The solution procedure described above is called the **method of moments** because equation 8.10 is equivalent to taking the moments of equation 8.9. It is also known as the **weighted residual method** because equation 8.10 can be interpreted as setting the weighted residual of equation 8.9 to zero. The solution procedure works for both differential and integral operators. In fact, it is a widely used procedure to formulate the well-known finite element method (Jin, 1993). In the computational electromagnetics community, the name of the moment method is reserved for the case when $\mathcal{L}$ is an integral operator involving a Green's function.

It is clear that there are four basic steps for solving an electromagnetic boundary-value problem using the moment method:

- To formulate the problem in terms of an integral equation
- To represent the unknown quantity using a set of basis functions
- To convert the integral equation into a matrix equation using a set of testing functions
- To solve the matrix equation and calculate the desired quantities

These steps are discussed in more detail in the following sections.

8.3 Integral Equations

This section presents some fundamental integral equations in two and three dimensions that are found in most electromagnetic problems.

8.3.1 Scalar Equations

Consider the problem of a **scalar wave** produced by a source $f(\rho)$ in the presence of an arbitrarily shaped object immersed in an infinite medium, as illustrated in Figure 8.1. Assume that both the source and the object have no variation along the z-axis; thus, we only have to consider a plane perpendicular to the z-axis. Exterior to the object, the wave function $\phi(\boldsymbol{\rho})$ satisfies the inhomogeneous Helmholtz equation:

$$\nabla^2\phi(\boldsymbol{\rho}) + k^2\phi(\rho) = -f(\boldsymbol{\rho}) \quad \boldsymbol{\rho} \in \Omega_\infty, \tag{8.15}$$

where k is the wavenumber and Ω_∞ denotes the exterior region. The wave function should also satisfy the radiation condition:

$$\sqrt{\rho}\left[\frac{\partial\phi(\boldsymbol{\rho})}{\partial\rho} + jk\phi(\boldsymbol{\rho})\right] = 0 \quad \rho \to \infty, \tag{8.16}$$

which simply indicates that the wave propagates outward into infinity without reflection.

Using Green's identity (Tai, 1994; Poggio and Miller, 1973; Morita *et al.*, 1990), we can derive an integral representation for the wave function everywhere:

$$\phi^{\text{inc}}(\boldsymbol{\rho}) + \int_{\Gamma_o}\left[\phi(\boldsymbol{\rho}')\frac{\partial G_0(\boldsymbol{\rho}, \boldsymbol{\rho}')}{\partial n'} - G_0(\boldsymbol{\rho}, \boldsymbol{\rho}')\frac{\partial\phi(\boldsymbol{\rho}')}{\partial n'}\right] d\Gamma' = \begin{cases} \phi(\boldsymbol{\rho}) & \boldsymbol{\rho} \in \Omega_\infty \\ 0 & \boldsymbol{\rho} \in \Omega_o, \end{cases} \tag{8.17}$$

where $\phi^{\text{inc}}(\boldsymbol{\rho})$ denotes the incident wave generated by the source $f(\boldsymbol{\rho})$ in the absence of the object and where G_0 is called the free space **Green's function** given by:

$$G_0(\boldsymbol{\rho}, \boldsymbol{\rho}') = \frac{1}{4j} H_0^{(2)}(k|\boldsymbol{\rho} - \boldsymbol{\rho}'|), \tag{8.18}$$

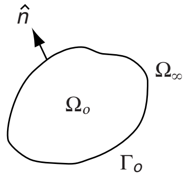

FIGURE 8.1 A Two-Dimensional Object Ω_o Having a Boundary Γ_o Immersed in an Infinite Medium Ω_∞

in which $H_0^{(2)}$ denotes the zero-order Hankel function of the second kind.

Equation 8.17 provides the foundation to establish an integral equation for ϕ and $\partial\phi/\partial n$ on the surface of the object. We now consider four cases.

Impenetrable with a Hard Surface

If the object is impenetrable with a hard surface where ϕ satisfies the boundary condition:

$$\phi(\boldsymbol{\rho}) = 0 \quad \boldsymbol{\rho} \in \Gamma_o, \tag{8.19}$$

equation 8.17 becomes:

$$\phi^{\text{inc}}(\boldsymbol{\rho}) - \int_{\Gamma_o} G_0(\boldsymbol{\rho}, \boldsymbol{\rho}') \frac{\partial\phi(\boldsymbol{\rho}')}{\partial n'} d\Gamma' = \begin{cases} \phi(\boldsymbol{\rho}) & \boldsymbol{\rho} \in \Omega_\infty. \\ 0 & \boldsymbol{\rho} \in \Omega_o. \end{cases} \tag{8.20}$$

Applying this equation on Γ_o, we obtain:

$$\int_{\Gamma_0} G_0(\boldsymbol{\rho}, \boldsymbol{\rho}') \frac{\partial\phi(\boldsymbol{\rho}')}{\partial n'} d\Gamma' = \phi^{\text{inc}}(\boldsymbol{\rho}) \quad \boldsymbol{\rho} \in \Gamma_o, \tag{8.21}$$

which is the integral equation for $\partial\phi/\partial n$ on Γ_o.

Impenetrable with a Soft Surface

If the object is impenetrable with a soft surface where ϕ satisfies the boundary condition:

$$\frac{\partial\phi(\boldsymbol{\rho})}{\partial n} = 0 \quad \boldsymbol{\rho} \in \Gamma_o, \tag{8.22}$$

equation 8.17 becomes:

$$\phi^{\text{inc}}(\boldsymbol{\rho}) + \int_{\Gamma_o} \phi(\boldsymbol{\rho}') \frac{\partial G_0(\boldsymbol{\rho}, \boldsymbol{\rho}')}{\partial n'} d\Gamma' = \begin{cases} \phi(\boldsymbol{\rho}) & \boldsymbol{\rho} \in \Omega_\infty. \\ 0 & \boldsymbol{\rho} \in \Omega_o. \end{cases} \tag{8.23}$$

Applying this equation on Γ_o, we obtain:

$$\frac{1}{2}\phi(\boldsymbol{\rho}) - \fint_{\Gamma_o} \phi(\boldsymbol{\rho}') \frac{\partial G_0(\boldsymbol{\rho}, \boldsymbol{\rho}')}{\partial n'} d\Gamma' = \phi^{\text{inc}}(\boldsymbol{\rho}') \quad \boldsymbol{\rho} \in \Gamma_o, \tag{8.24}$$

where $\fint$ denotes the integral excluding the contribution from the singular point $\boldsymbol{\rho} = \boldsymbol{\rho}'$, which is known as the **principal value integral**. Equation 8.24 is the integral equation for ϕ on Γ_o.

Impenetrable with a Surface Satisfying Mixed Boundary

If the object is impenetrable with a surface where ϕ satisfies the mixed boundary condition:

$$\frac{\partial\phi(\boldsymbol{\rho})}{\partial n} + \gamma\phi(\boldsymbol{\rho}) = 0 \quad \boldsymbol{\rho} \in \Gamma_o, \tag{8.25}$$

Equation 8.17 becomes:

$$\begin{aligned} &\phi^{\text{inc}}(\boldsymbol{\rho}) - \int_{\Gamma_o} \phi(\boldsymbol{\rho}') \left[\gamma G_0(\boldsymbol{\rho}, \boldsymbol{\rho}') - \frac{\partial G_0(\boldsymbol{\rho}, \boldsymbol{\rho}')}{\partial n'}\right] d\Gamma' \\ &\qquad = \begin{cases} \phi(\boldsymbol{\rho}) & \boldsymbol{\rho} \in \Omega_\infty. \\ 0 & \boldsymbol{\rho} \in \Omega_o. \end{cases} \end{aligned} \tag{8.26}$$

Applying this equation on Γ_o, we obtain:

$$\begin{aligned} &\frac{1}{2}\phi(\boldsymbol{\rho}) - \fint_{\Gamma_o} \phi(\boldsymbol{\rho}') \left[\gamma G_0(\boldsymbol{\rho}, \boldsymbol{\rho}') + \frac{\partial G_0(\boldsymbol{\rho}, \boldsymbol{\rho}')}{\partial n'}\right] d\Gamma' \\ &\qquad = \phi^{\text{inc}}(\boldsymbol{\rho}) \quad \boldsymbol{\rho} \in \Gamma_o, \end{aligned} \tag{8.27}$$

which is the integral equation for ϕ on Γ_o.

Penetrable and Homogeneous Object

If the object is penetrable and homogeneous, we apply equation 8.17 on Γ_o to obtain:

$$\begin{aligned} &\frac{1}{2}\phi(\boldsymbol{\rho}) - \fint_{\Gamma_o} \left[\phi(\boldsymbol{\rho}') \frac{\partial G_0(\boldsymbol{\rho}, \boldsymbol{\rho}')}{\partial n'} - G_0(\boldsymbol{\rho}, \boldsymbol{\rho}') \frac{\partial\phi(\boldsymbol{\rho}')}{\partial n'}\right] d\Gamma' \\ &\qquad = \phi^{\text{inc}}(\boldsymbol{\rho}) \quad \boldsymbol{\rho} \in \Gamma_o. \end{aligned} \tag{8.28}$$

To solve for ϕ and $\partial\phi/\partial n$ on Γ_o, we need another equation that can be derived by considering the interior of the object. This is given by:

$$\begin{aligned} &\frac{1}{2}\phi(\boldsymbol{\rho}) - \fint_{\Gamma_o} \left[\tilde{G}_0(\boldsymbol{\rho}, \boldsymbol{\rho}') \frac{\partial\phi(\boldsymbol{\rho}')}{\partial n'} - \phi(\boldsymbol{\rho}') \frac{\partial \tilde{G}_0(\boldsymbol{\rho}, \boldsymbol{\rho}')}{\partial n'}\right] d\Gamma' \\ &\qquad = 0 \quad \boldsymbol{\rho} \in \Gamma_o, \end{aligned} \tag{8.29}$$

where:

$$\tilde{G}_0(\boldsymbol{\rho}, \boldsymbol{\rho}') = \frac{1}{4j} H_0^{(2)}(\tilde{k}|\boldsymbol{\rho} - \boldsymbol{\rho}'|). \tag{8.30}$$

The $\tilde{k}$ in equation 8.30 is the wave number inside the object. Equation 8.29 can be used together with equation 8.28 for a numerical solution of ϕ and $\partial\phi/\partial n$ on Γ_o.

For an inhomogeneous object, we can follow the basic approach outlined above to derive a so-called **volume-surface integral equation** (Jin *et al.*, 1988), which contains an integral over Ω_o in addition to the integral over Γ_o. As a result, the unknown function is distributed over Ω_o and Γ_o.

8.3.2 Vector Equations

Consider the problem of electromagnetic fields ($\boldsymbol{E}$, $\boldsymbol{H}$) produced by an electric current source of density $\boldsymbol{J}_i$ in the presence of an arbitrarily shaped object in an infinite homogeneous space, as illustrated in Figure 8.2. The $\boldsymbol{E}$ and $\boldsymbol{H}$ satisfy the **vector wave equations**:

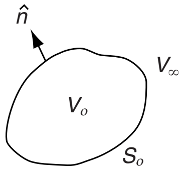

FIGURE 8.2 A Three-Dimensional Object V_o Bounded by Surface S_o in an Infinite Space V_∞

$$\nabla \times \nabla \times \boldsymbol{E}(\boldsymbol{r}) - k^2\boldsymbol{E}(\boldsymbol{r}) = -j\omega\mu\boldsymbol{J}_i(\boldsymbol{r}) \quad \boldsymbol{r} \in V_\infty. \tag{8.31}$$

$$\nabla \times \nabla \times \boldsymbol{H}(\boldsymbol{r}) - k^2\boldsymbol{H}(\boldsymbol{r}) = \nabla \times \boldsymbol{J}_i(\boldsymbol{r}) \quad \boldsymbol{r} \in V_\infty. \tag{8.32}$$

In these equations, V_∞ denotes the exterior region.

Using Green's identity (Tai, 1994; Poggio and Miller, 1973; Morita, *et al.*, 1990), we can derive the following integral representations:

$$\boldsymbol{E}^{\text{inc}}(\boldsymbol{r}) - \int_{S_o} [(\hat{n}' \cdot \boldsymbol{E})\nabla G_0 + (\hat{n}' \times \boldsymbol{E}) \times \nabla G_0 + j\omega\mu(\hat{n}' \times \boldsymbol{H})G_0]dS'.$$
$$= \begin{cases} \boldsymbol{E}(\boldsymbol{r}) & \boldsymbol{r} \in V_\infty. \\ 0 & \boldsymbol{r} \in V_o. \end{cases} \tag{8.33}$$

$$\mathbf{H}^{\text{inc}}(\boldsymbol{r}) - \int_{S_o} [(\hat{n}' \cdot \boldsymbol{H})\nabla G_0 + (\hat{n}' \times \boldsymbol{H}) \times \nabla G_0 - j\omega\varepsilon(\hat{n}' \times \boldsymbol{E})G_0]dS'.$$
$$= \begin{cases} \mathbf{H}(\mathbf{r}) & \boldsymbol{r} \in V_\infty. \\ 0 & \boldsymbol{r} \in V_o. \end{cases} \tag{8.34}$$

In these equations:

$$G_0(\boldsymbol{r}, \boldsymbol{r}') = \frac{e^{-jk|\boldsymbol{r}-\boldsymbol{r}'|}}{4\pi|\boldsymbol{r}-\boldsymbol{r}'|}, \tag{8.35}$$

and $\boldsymbol{E}^{\text{inc}}(\boldsymbol{r})$ and $\boldsymbol{H}^{\text{inc}}(\boldsymbol{r})$ represent the electric and magnetic fields produced by $\boldsymbol{J}_i$ in the infinite space without the object.

To write equations 8.33 and 8.34 in compact form, we define the operators:

$$\boldsymbol{L}(\boldsymbol{X}) = jk\int_{S_o}\left(\boldsymbol{X}G_0 + \frac{1}{k^2}\nabla' \cdot \boldsymbol{X}\nabla G_0\right)dS'. \tag{8.36}$$

$$\boldsymbol{K}(\boldsymbol{X}) = \int_{S_o} \boldsymbol{X} \times \nabla G_0 dS'. \tag{8.37}$$

We also introduce the equivalent surface currents:

$$\bar{\boldsymbol{J}}_s = \hat{n} \times \bar{\boldsymbol{H}} = \sqrt{\frac{\mu}{\varepsilon}}\hat{n} \times \boldsymbol{H}, \quad \boldsymbol{M}_s = \boldsymbol{E} \times \hat{n}. \tag{8.38}$$

As a result, equations 8.33 and 8.34 can be written as:

$$\boldsymbol{E}^{\text{inc}}(\boldsymbol{r}) - \boldsymbol{L}(\bar{\boldsymbol{J}}_s) + \boldsymbol{K}(\boldsymbol{M}_s) = \begin{cases} \boldsymbol{E}(\boldsymbol{r}) & \boldsymbol{r} \in V_\infty. \\ 0 & \boldsymbol{r} \in V_o. \end{cases} \tag{8.39}$$

$$\bar{\boldsymbol{H}}^{\text{inc}}(\boldsymbol{r}) - \boldsymbol{K}(\bar{\boldsymbol{J}}_s) - \boldsymbol{L}(\boldsymbol{M}_s) = \begin{cases} \bar{\boldsymbol{H}}(\boldsymbol{r}) & \boldsymbol{r} \in V_\infty. \\ 0 & \boldsymbol{r} \in V_o. \end{cases} \tag{8.40}$$

Equations 8.39 and 8.40 provide the foundation to derive integral equations for $\boldsymbol{J}_s$ and $\boldsymbol{M}_s$. Taking the cross product of these with $\hat{n}$ and letting $\boldsymbol{r}$ approach S_o, we have:

$$\frac{1}{2}\boldsymbol{M}_s(\boldsymbol{r}) - \hat{n} \times \boldsymbol{L}(\bar{\boldsymbol{J}}_s) + \hat{n} \times \tilde{\boldsymbol{K}}(\boldsymbol{M}_s) = -\hat{n} \times \boldsymbol{E}^{\text{inc}}(\boldsymbol{r}) \quad \boldsymbol{r} \in S_o. \tag{8.41}$$

$$\frac{1}{2}\bar{\boldsymbol{J}}_s(\boldsymbol{r}) + \hat{n} \times \tilde{\boldsymbol{K}}(\bar{\boldsymbol{J}}_s) + \hat{n} \times \boldsymbol{L}(\boldsymbol{M}_s) = \hat{n} \times \bar{\boldsymbol{H}}^{\text{inc}}(\boldsymbol{r}) \quad \boldsymbol{r} \in S_o. \tag{8.42}$$

The $\tilde{\boldsymbol{K}}$ is the same integral as the one in equation 8.37, except that the singular point $\boldsymbol{r} = \boldsymbol{r}'$ is now removed by using a principal value integral. Equation 4.41 is known as the **electric field integral equation** (EFIE) and equation 8.42 is called the **magnetic field integral equation** (MFIE).

If the object is a perfect electric conductor, $\boldsymbol{E}$ satisfies the boundary condition:

$$\hat{n} \times \boldsymbol{E} = 0 \quad \boldsymbol{r} \in S_o. \tag{8.43}$$

Hence, $\boldsymbol{M}_s = 0$ and equations 8.41 and 8.42 reduce to:

$$\hat{n} \times \boldsymbol{L}(\bar{\boldsymbol{J}}_s) = \hat{n} \times \boldsymbol{E}^{\text{inc}}(\boldsymbol{r}) \quad \boldsymbol{r} \in S_o. \tag{8.44}$$

$$\frac{1}{2}\bar{\boldsymbol{J}}_s(\boldsymbol{r}) + \hat{n} \times \tilde{\boldsymbol{K}}(\bar{\boldsymbol{J}}_s) = \hat{n} \times \bar{\boldsymbol{H}}^{\text{inc}}(\boldsymbol{r}) \quad \boldsymbol{r} \in S_o. \tag{8.45}$$

Any of these two equations can be used to solve for $\bar{\boldsymbol{J}}_s$. However, for a given S_o, $\boldsymbol{L}$ can be singular at certain frequencies when the exterior medium is lossless. Consequently, equation 8.44 may give an erroneous solution at these frequencies. This is known as the **problem of interior resonance**, and the singular frequencies correspond to the resonant frequencies of a cavity formed by filling the interior of S_o with the exterior medium. A similar problem occurs in equation 8.45 as well. To eliminate this problem, we can combine equations 8.44 and 8.45 to find:

$$\alpha n \times \hat{n} \times \boldsymbol{L}(\bar{\boldsymbol{J}}_s) + (1-\alpha)\left[\frac{1}{2}\bar{\boldsymbol{J}}_s(\boldsymbol{r}) + \hat{n} \times \tilde{\boldsymbol{K}}(\bar{\boldsymbol{J}}_s)\right]$$
$$= \alpha\hat{n} \times \hat{n} \times \boldsymbol{E}^{\text{inc}}(\boldsymbol{r}) + (1-\alpha)\hat{n} \times \bar{\boldsymbol{H}}^{\text{inc}}(\boldsymbol{r}) \quad \boldsymbol{r} \in S_o, \tag{8.46}$$

which is known as the **combined field integral equation** (CFIE) (Mautz and Harrington, 1978). This combination results in an integral operator corresponding to the corresponding operator for a cavity with a resistive wall whose resonant frequencies are complex. As a result, the operator cannot be singular for a real frequency. The combination parameter α is usually chosen between zero and one.

If the object is an impedance body, there exists a relation between $\bar{\boldsymbol{J}}_s$ and $\boldsymbol{M}_s$, which is known as the **impedance boundary condition**. Substituting this relation into either equation

8.41 or equation 8.42 yields an integral equation containing only one unknown function.

If the object is a homogeneous body, we can apply Green's theorem to the interior of the object to formulate another two equations: EFIE and MFIE. One of these two equations can be used with either equations 8.41 or 8.42 to form a complete system for the solution of $\bar{\boldsymbol{J}}_s$ and $\boldsymbol{M}_s$. Again, to overcome the problem of interior resonance, one can combine the EFIE and MFIE to form the CFIE for the interior field. This CFIE can then be used with the CFIE for the exterior field to form a complete system (Rao and Wilton, 1990). A better approach is, however, to add the EFIEs for the interior and exterior fields to form a new integral equation. This is then used with the integral equation obtained by adding the MFIEs for the interior and exterior fields. This formulation results from work by Poggio and Miller (1973), Chang and Harrington (1977), and Wu and Tsai (1977); the formulation is found to be free of interior resonances and yields accurate and stable solutions (Mautz and Harrington, 1979).

If the object is inhomogeneous, one can employ the volume equivalence principle to derive a volume integral equation (Livesay and Chen, 1974; Schaubert *et al*., 1984), which contains an integral over V_o, in contrast to the surface integral equations described previously. As a result, the unknown function is distributed over the entire V_o, and its numerical solution is very computationally intensive unless some special techniques with certain approximations are used (Borup and Gandhi, 1984; Zwamborn and van der Berg, 1994; Gan and Chew, 1995; Wang and Jin, 1998). Problems involving inhomogeneous media can usually be handled more efficiently using the finite element method (Jin, 1993).

8.4 Basis Functions

The second step in the moment method is to expand the unknown function of the integral equation in terms of **basis functions**. There are two classes of basis functions. The first class is defined over the entire solution domain and hence called the **entire-domain basis functions.** For most electromagnetic problems, the solution domain is complicated, and it is difficult to find entire-domain basis functions that can form approximately a complete set over the domain. For this reason, the entire-domain basis functions have limited use. Contrasted with the entire-domain basis functions is the second class defined over small parts of the solution domain. This class is called the **subdomain basis functions**. Although the unknown function over the entire solution domain can be complicated and cannot be represented by simple functions, its behavior over a sufficiently small region can be rather simple and hence representable with simple functions. For this reason, the subdomain basis functions are widely used in the moment method for a variety of electromagnetic problems. In the following subsections, we describe some commonly used subdomain basis functions.

8.4.1 Line Basis Functions

If the solution domain is a contour, it can first be divided into small segments denoted by $C_1, C_2, \ldots, C_N$. The simplest basis function is the **zero-order**, widely known as the pulse function in the electromagnetics community. This function is defined as:

$$P_n(s) = \begin{cases} 1 & s \in C_n. \\ 0 & \text{elsewhere.} \end{cases} \tag{8.47}$$

With this basis function, the unknown ϕ is approximated by a piecewise constant function, as illustrated in Figure 8.3. Pulse functions are widely used in the moment method because they lead to simple integrals that can be evaluated easily.

The next basis function is the **first-order**, commonly known as the triangle function. It is defined over two neighboring segments with a value of unity at the joint:

$$\Lambda_n(s) = \begin{cases} \dfrac{s - s_{n-1}}{s_n - s_{n-1}} & s \in C_n. \\ \dfrac{s_{n+1} - s}{s_{n+1} - s_n} & s \in C_{n+1}. \\ 0 & \text{elsewhere.} \end{cases} \tag{8.48}$$

The s_n denotes the joint between the segment of C_n and C_{n+1}. With this choice, the unknown ϕ is represented by a piecewise linear function (Figure 8.4).

The third basis function is the so-called piecewise sinusoidal, defined as:

$$S_n(s) = \begin{cases} \dfrac{\sin[k(s - s_{n-1})]}{\sin[k(s_n - s_{n-1})]} & s \in C_n. \\ \dfrac{\sin[k(s_{n+1} - s)]}{\sin[k(s_{n+1} - s_n)]} & s \in C_{n+1}. \\ 0 & \text{elsewhere.} \end{cases} \tag{8.49}$$

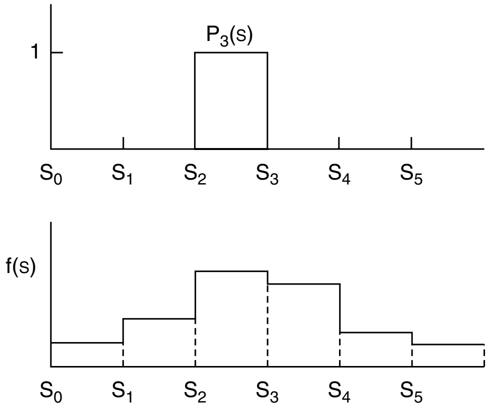

FIGURE 8.3 (A) A Pulse Function and (B) A Piecewise Constant Approximation

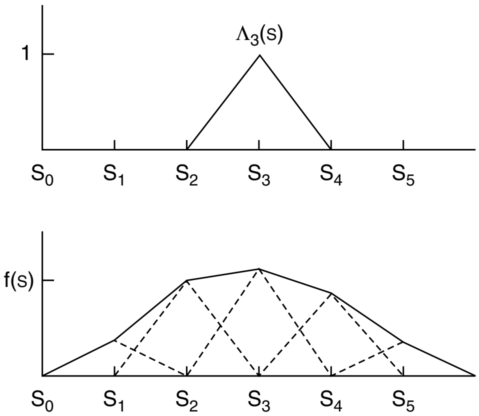

FIGURE 8.4 (A) A Triangle Function and (B) A Piecewise Linear Approximation

The k is the wave number. Obviously, when kC_n and kC_{n+1} are sufficiently small, the piecewise sinusoidal functions reduce to triangle ones.

It is also possible to introduce high-order basis functions such as the quadratic and cubic ones, in a manner similar to one used in the finite element method (Jin, 1993). The high-order functions can yield higher accuracy without increasing the number of unknowns.

8.4.2 Surface Basis Functions

If the solution domain is a surface, it can be divided into small triangular cells. In some special cases, a surface can also be divided into small rectangular cells. Triangular cells, however, are more flexible and accurate when representing an arbitrary surface. As in the case for one-dimensional segments, we can have the zero$^{\text{th}}$-order (pulse) basis function, which is a constant on one cell and zero elsewhere, and the first-order (linear) basis function, which is one at a node and decreases linearly to zero at the neighboring nodes (Figure 8.5).

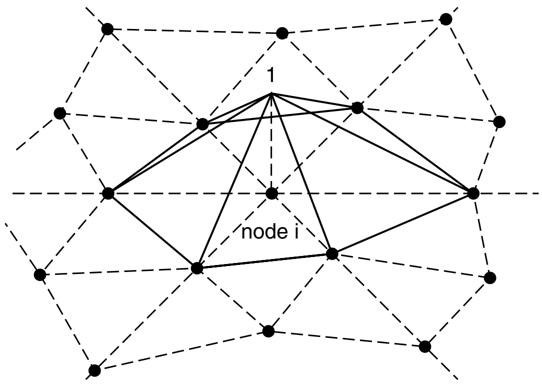

FIGURE 8.5 A First-Order Basis Function for Node i on a Surface

In most three-dimensional electrodynamic problems, the unknown function of an integral equation is the electric surface current density, which is a vector function. For such an unknown, basis functions must be constructed properly based on the properties of the current density. One of the most popular basis functions for this purpose is the so-called **rooftop function**. For a rectangular mesh in the x–y plane, the basis function for the x component of the current density is defined as:

$$f_n^x = \begin{cases} \dfrac{x - x_{i-1}}{x_i - x_{i-1}} & x_{i-1} \le x \le x_i,\ y_{j-1} \le y \le y_j. \\ \dfrac{x_{i+1} - x}{x_{i+1} - x_i} & x_i \le x \le x_{i+1},\ y_{j-1} \le y \le y_j. \\ 0 & \text{elsewhere.} \end{cases} \tag{8.50}$$

The basis function for the y component is defined as:

$$f_n^y = \begin{cases} \dfrac{y - y_{j-1}}{y_j - y_{j-1}} & x_{i-1} \le x \le x_i,\ y_{j-1} \le y \le y_j. \\ \dfrac{y_{j+1} - y}{y_{j+1} - y_j} & x_{i-1} \le x \le x_i,\ y_j \le y \le y_{j+1}. \\ 0 & \text{elsewhere.} \end{cases} \tag{8.51}$$

It is easy to see that the rooftop function is a product of a pulse and a triangle function: $f_n^x = \Lambda_i(x)P_j(y)$ and $f_n^y = P_i(x)\Lambda_j(y)$. The rooftop functions are sketched in Figure 8.6. They guarantee the continuity of current flow and permit the edge conditions to be satisfied approximately.

When a surface is divided into triangular elements, one may use the triangular rooftop function (Rao *et al.*, 1982) as the basis function to expand the surface current. This function is defined over two triangular elements joined at a common edge ℓ_n:

$$\boldsymbol{f}_n(\boldsymbol{r}) = \begin{cases} \frac{\ell_n}{2A_n^+}\boldsymbol{\rho}_n^+ & \boldsymbol{r} \in T_n^+. \\ \frac{\ell_n}{2A_n^-}\boldsymbol{\rho}_n^- & \boldsymbol{r} \in T_n^-. \\ 0 & \text{otherwise.} \end{cases} \tag{8.52}$$

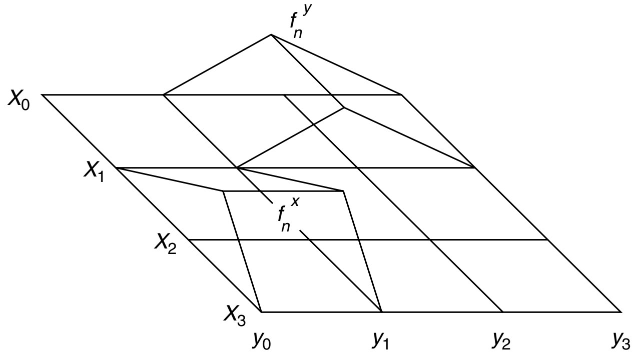

FIGURE 8.6 Rooftop Functions Defined on a Rectangular Mesh

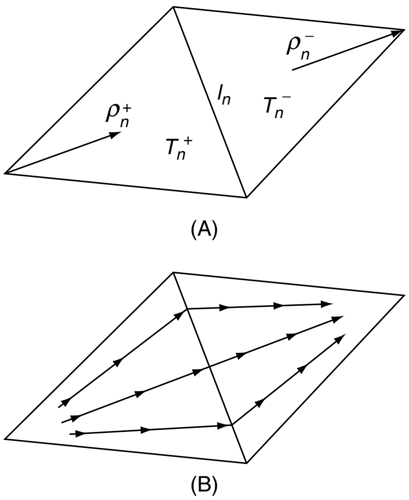

FIGURE 8.7 (A) Illustration of Two Joint Triangular Elements (B) Vector Plot of the Triangular Rooftop Function $\boldsymbol{f}_n$

the $T_n^{\pm}$ denote the two triangles associated with the nth edge, $A_n^{\pm}$ are the areas of triangles $T_n^{\pm}$, ℓ_n is the length of the nth edge, and $\boldsymbol{\rho}_n^{\pm}$ are the vectors defined in Figure 8.7(A). The vector plot of $\boldsymbol{f}_n(\boldsymbol{r})$ is illustrated in Figure 8.7(B). The most important feature of this basis function is that its normal component to edge ℓ_n is a constant (normalized to 1), whereas the normal components to other edges are zero. This feature guarantees the continuity of current flow over all edges, as in the case of the rooftop functions.

8.5 Testing Functions

To convert an integral equation into a matrix equation, we have to choose a set of **testing functions**. This set of functions should be approximately complete in the range of the integral operator. There are several commonly used testing functions that lead to several different formulations of the moment method.

The **first kind of testing** is the Dirac delta function:

$$w_m(\boldsymbol{r}) = \delta(\boldsymbol{r} - \boldsymbol{r}_m), \tag{8.53}$$

where $\boldsymbol{r}_m$ denotes a set of points in the solution domain. This testing is equivalent to satisfying the integral equation at a set of specific points. The resulting formulation is called **point collocation** which is better known as **point matching** in the electromagnetics community.

The **second kind of testing** is a constant over a subdomain and zero elsewhere:

$$w_m(\boldsymbol{r}) = \begin{cases} 1 & \boldsymbol{r} \in \Omega_m. \\ 0 & \text{elsewhere.} \end{cases} \tag{8.54}$$

The Ω_m denotes the mth subdomain. This testing is equivalent to satisfying the integral equation over each subdomain in the average sense. The resulting formulation is called **subdomain collocation**.

The **third kind of testing** is to use the basis functions as the testing functions, that is:

$$w_m(\boldsymbol{r}) = v_m(\boldsymbol{r}). \tag{8.55}$$

With this choice, the system matrix becomes symmetric when the integral operator is symmetric. This is known as **Galerkin's formulation**.

The **fourth kind of testing** is to use $\mathcal{L}v_m$ as the testing functions:

$$w_m(\boldsymbol{r}) = [\mathcal{L}v_m(\boldsymbol{r})]. \tag{8.56}$$

It can be shown that this is equivalent to minimizing the integral of the square of the residual of the governing equation. For this reason, it is called the **least squares formulation**.

Among the four kinds of testing functions described, the point-matching and Galerkin's formulations are widely used in the moment method. It was a common belief that Galerkin's formulation yields best accuracy; however, recent research indicates that the solution accuracy mainly depends on the basis functions and much less on the choice of testing functions (Peterson *et al.*, 1997).

8.6 Solution of Matrix Equations

The final step in the moment method is to solve the resulting matrix equation that represents a set of linear equations. Typical solution methods include **direct matrix inversion**, **factorization**, and **iteration**.

Both matrix inversion and factorization make use of Gaussian elimination. The matrix inversion finds the inverse of the matrix $[A]$, from which the solution to equation 8.12 is obtained as:

$$\{c\} = [A]^{-1}\{b\}. \tag{8.57}$$

This method requires $O(N^3)$ operations, where O stands for *on the order of*. The factorization method decomposes the matrix $[A]$ into the product of a lower triangular matrix, denoted as $[L]$, and an upper triangular matrix, denoted as $[U]$. The solution is then obtained by a forward substitution:

$$[L]\{y\} = \{b\}. \tag{8.58}$$

The solution is also obtained by a backward substitution:

$$[U]\{c\} = \{y\}. \tag{8.59}$$

The decomposition method also requires $O(N^3)$ operations. It is about three times faster, however, than the direct inversion. Once the system matrix is inverted or factorized, the solution for a new source vector $\{b\}$ can be obtained easily. Therefore, the inversion and factorization methods are suitable for cases when the solution is sought for many right-hand sides. This is their major advantage.

The third method is to solve the matrix equation through iteration by minimizing the residual vector:

$$\{r\} = \{b\} - [A]\{\tilde{c}\}, \tag{8.60}$$

where $\{\tilde{c}\}$ denotes an approximate solution. Commonly used iterative methods include the **conjugate gradient** (Hestenes and Stiefel, 1952), the **biconjugate gradient** (Fletcher, 1975), the **quasiminimal residual** (Freund and Nachtigal, 1991), the **generalized minimal residual** (Saad, 1986), and their variations, such as the **conjugate gradient stabilized** (Sonneveld, 1989), the **conjugate gradient normal residual** (Greenbaum, 1997), the **biconjugate gradient stabilized** (van der Vorst, 1992), and the **transpose-free quasiminimal residual** (Freund, 1993). The algorithms implementing these methods can be found in public literature and software packages of Barret (1993) and Saad (1995). For positive definite systems, the conjugate gradient method is the optimum iterative solver. For indefinite systems, such as most matrix equations for electromagnetic problems, it is not clear which is optimum. An iterative solver calculates one or two matrix-vector products for each iteration. Hence, it requires $O(N^2)$ operations per iteration, and the total computing time is proportional to $N_{\text{iter}}N^2$, where N_{iter} denotes the total number of iterations for convergence. If N_{iter} is small, an iterative solver can be faster than the LU decomposition method for one right-hand side. The interative solver, however, must repeat the process for every new right-hand side.

To achieve an efficient solution through iteration, it is critical to reduce the number of iterations and/or to reduce the operation count for computing the matrix–vector product. The first can be achieved by **preconditioning**, and the second can be achieved by using **fast Fourier transform** (Borup and Gandhi, 1984; Zwamborn and van der Berg, 1994; Gan and Chew, 1995; Wang and Jin, 1988), the **adaptive integral method** (Wang *et al.*, 1988), the **fast multipole method** (Rokhlin, 1990; Coifman *et al.*, 1993; Lu and Chew, 1993), and the **multilevel fast multipole algorithm** (Song and Chew, 1993; Dembart and Yip, 1995; Song *et al.*, 1997).

9.1 Introduction

9.1.1 Background

Prior to about 1990, the modeling of electromagnetic engineering systems was primarily implemented using solution techniques for the sinusoidal steady-state Maxwell's equations. Before about 1960, the principal approaches in this area involved closed-form and infinite-series analytical solutions, with numerical results from these analyses obtained using mechanical calculators. After 1960, the increasing availability of programmable electronic digital computers permitted such frequency-domain approaches to rise markedly in sophistication. Researchers were able to take advantage of the capabilities afforded by powerful new high-level programming languages such as Fortran, rapid random-access storage of large arrays of numbers, and computational speeds that were orders of magnitude faster than possible with mechanical calculators. In this period, the principal computational approaches for Maxwell's equations included the high-frequency asymptotic methods of Keller (1962) as well as Kouyoumjian and Pathak (1974) and the integral equation techniques of Harrington (1968).

However, these frequency-domain techniques have difficulties and trade-offs. For example, while asymptotic analyses are well suited for modeling the scattering properties of electrically large complex shapes, such analyses have difficulty treating nonmetallic material composition and volumetric complexity of a structure. While integral equation methods can deal with material and structural complexity, their need to construct and solve systems of linear equations limits the electrical size of possible models, especially those requiring detailed treatment of geometric details in a volume as opposed to just the surface shape.

While significant progress has been made in solving the ultra-large systems of equations generated by frequency-domain integral equations (Song and Chew 1998), the capabilities of even the latest such technologies are exhausted by many volumetrically complex structures of engineering interest. This also holds true for frequency-domain finite element techniques that generate sparse rather than dense matrices. Further, the very difficult incorporation of material and device nonlinearities into frequency-domain solutions of Maxwell's equations poses a significant problem as engineers seek to design active electromagnetic/electronic and electromagnetic/quantum-optical systems such as high-speed digital circuits, microwave and millimeter-wave amplifiers, and lasers.

9.1.2 Rise of Finite-Difference Time-Domain Methods

During the 1970s and 1980s, a number of researchers realized the limitations of frequency-domain integral equation solutions of Maxwell's equations. This led to early explorations of a novel alternative approach: direct time-domain solutions of Maxwell's differential (curl) equations on spatial grids or lattices. The **finite-difference time-domain** (FDTD) method, introduced by Yee (1966), was the first technique in this class and has remained the subject of continuous development (Taflove and Hagness [2000]).

There are seven primary reasons for the expansion of interest in FDTD and related computational solution approaches for Maxwell's equations:

1. FDTD uses no linear algebra. Being a fully explicit computation, FDTD avoids the difficulties with linear algebra that limit the size of a frequency-domain integral equation and finite-element electromagnetics models to generally fewer than 10^6 field unknowns. FDTD models with as many as 10^9 field unknowns have been run. There is no intrinsic upper bound to this number.
2. FDTD is accurate and robust. The sources of error in FDTD calculations are well understood and can be bounded to permit accurate models for a very large variety of electromagnetic wave interaction problems.
3. FDTD treats impulsive behavior naturally. Being a time-domain technique, FDTD directly calculates the impulse response of an electromagnetic system. Therefore, a single FDTD simulation can provide either ultrawideband temporal waveforms or the sinusoidal steady-state response at any frequency in the excitation spectrum.
4. FDTD treats nonlinear behavior naturally. Being a time-domain technique, FDTD directly calculates the nonlinear response of an electromagnetic system.
5. FDTD is a systematic approach. With FDTD, specifying a new structure to be modeled is reduced to a problem of mesh generation rather than the potentially complex reformulation of an integral equation. For example, FDTD requires no calculation of structure-dependent Green's functions.
6. Computer memory capacities are increasing rapidly. Although this trend positively influences all numerical techniques, it is of particular advantage to FDTD methods that are founded on discretizing space over a volume and that inherently require a large random access memory.
7. Computer visualization capabilities are increasing rapidly. Although this trend positively influences all numerical techniques, it is of particular advantage to FDTD methods that generate time-marched arrays of field quantities suitable for use in color videos to illustrate field dynamics.

An indication of the expanding level of interest in FDTD Maxwell's equations solvers is the hundreds of papers currently published in this area worldwide each year, as opposed to fewer than ten as recently as 1985 and prior to that year (Shlager and Schneider, 1998). This expansion continues as engineers and scientists in nontraditional electromagnetics-related areas such as digital systems and integrated optics become aware of the power of such direct solution techniques for Maxwell's equations.

9.1.3 Characteristics of FDTD and Related Space-Grid Time-Domain Techniques

FDTD and related space-grid time-domain techniques are direct solution methods for Maxwell's curl equations. These methods employ no potentials. Rather, they are based on volumetric sampling of the unknown electric and magnetic fields in and surrounding the structure of interest over a period of time. The sampling in space is at subwavelength resolution set by the user to properly sample the highest near-field spatial frequencies thought to be important in the physics of the problem. Typically, 10 to 20 samples per wavelength are needed. The sampling time is selected to ensure numerical stability of the algorithm.

Overall, FDTD and related techniques are marching-in-time procedures that simulate the continuous actual electromagnetic waves in a finite spatial region by sampled-data numerical analogs propagating in a computer data space. Time-stepping continues as the numerical wave analogs propagate in the space lattice to causally connect the physics of the modeled region. For simulations where the modeled region must extend to infinity, absorbing boundary conditions (ABCs) are employed at the outer lattice truncation planes, which ideally permit, all outgoing wave analogs to exit the region with negligible reflection. Phenomena such as induction of surface currents, scattering and multiple scattering, aperture penetration, and cavity excitation are modeled time-step by time-step by the action of the numerical analog to the curl equations. Self-consistency of these modeled phenomena is generally ensured if their spatial and temporal variations are well resolved by the space and time sampling process. In fact, the goal is to provide a self-consistent model of the mutual coupling of all of the electrically small volume cells constituting the structure and its near field, even if the structure spans tens of wavelengths in three dimensions and there are hundreds of millions of space cells.

Time-stepping is continued until the desired late-time pulse response is observed at the field points of interest. For linear wave interaction problems, the sinusoidal response at these field points can be obtained over a wide band of frequencies by discrete Fourier transformation of the computed field versus time waveforms at these points. Prolonged "ringing" of the computed field waveforms due to a high *Q*-factor or large electrical size of the structure being modeled requires a combination of extending the computational window in time and extrapolating the windowed data before Fourier transformation.

9.1.4 Classes of Algorithms

Current FDTD and related space-grid time-domain algorithms are fully explicit solvers employing highly vectorizable and parallel schemes for time-marching the six components of the electric and magnetic field vectors at each of the space cells. The explicit nature of the solvers is usually maintained by employing a leapfrog time-stepping scheme. Current methods differ primarily in how the space lattice is set up. In fact, gridding methods can be categorized according to the degree of structure or regularity in the mesh cells.

Almost Completely Structured

In this case, the space lattice is organized so that its unit cells are congruent wherever possible. The most basic example of such a mesh is the pioneering work of Yee (1966), who employed a uniform Cartesian grid having rectangular cells. Staircasing was used to approximate the surface of structural features not parallel to the grid coordinate axes. Later work showed that it is possible to modify the size and shape of the space cells located immediately adjacent to a structural feature to conformally fit its surface (Jurgens *et al.*, 1992; Dey and Mittra, 1997). This result is accurate and computationally efficient for large structures because the number of modified cells is proportional to the surface area of the structure. Thus, the number of modified cells becomes progressively smaller relative to the number of regular cells filling the structure volume as its size increases. As a result, the computer resources needed to implement a fully conformal model approximate those required for a staircased model. A key disadvantage of this technique, however, is that special mesh-generation software must be constructed.

Surface-Fitted

In this case, the space lattice is globally distorted to fit the shape of the structure of interest. The lattice can be divided into multiple zones to accommodate a set of distinct surface features (Shankar *et al.*, 1990). The major advantage of this approach is that well-developed mesh-generation software of this type is available. The major disadvantage, relative to the Yee algorithm, is the substantial added computer burden due to:

- Memory allocations for the position and stretching factors of each cell
- Extra computer operations to implement Maxwell's equations at each cell and to enforce field continuity at the interfaces of adjacent cells

Another disadvantage is the possible presence of numerical dissipation in the time-stepping algorithm used for such meshes. This can limit the range of electrical size of the structure being modeled due to numerical wave-attenuation artifacts.

Completely Unstructured

In an unstructured case, the space containing the structure of interest is completely filled with a collection of lattice cells of varying sizes and shapes but conforms to the structure surface (Madsen and Ziolkowski, 1990). As for the case of surface-fitted lattices, mesh-generation software is available and capable of modeling complicated three-dimensional shapes possibly having volumetric inhomogeneities. A key disadvantage of this approach is its potential for numerical inaccuracy and instability due to the unwanted generation of highly skewed space cells at random points in the lattice. A second disadvantage is the difficulty in mapping the unstructured mesh computations onto the architecture of either parallel vector computers or massively parallel machines. The structure-specific irregularity of the mesh mandates a robust preprocessing algorithm that optimally assigns specific mesh cells to specific processors.

At present, the best choice of a computational algorithm and mesh remains unclear. For the next several years, progress should continue in this area as various groups develop their favored approaches and perform validations.

9.1.5 Predictive Dynamic Range

For computational modeling of electromagnetic wave interaction structures using FDTD and related space-grid time-domain techniques, it is useful to consider the concept of a predictive dynamic range. Let the power density of the primary (incident) wave in the space grid be $P_0 \mathrm{W/m}^2$. Further, let the minimum observable power density of a secondary (scattered) wave be $P_S \mathrm{W/m}^2$, where "minimum observable" means that the accuracy of the field computation degrades due to numerical artifacts to poorer than n decibels (some desired figure of merit) at lower levels than P_S. Then, the predictive dynamic range can be defined as $10 \log_{10}(P_0/P_S)$dB.

This definition is well suited for FDTD and other space-grid time-domain codes for two reasons:

- It squares nicely with the concept of a "quiet zone" in an experimental anechoic chamber, which is intuitive to most electromagnetics engineers.
- It succinctly quantifies the fact that the desired numerical wave analogs propagating in the lattice exist in an additive noise environment due to nonphysical propagating wave analogs caused by the imperfect ABCs.

In addition to additive noise, the desired physical wave analogs undergo gradual progressive deterioration while propagating due to accumulating numerical dispersion artifacts, including phase velocity anisotropies and inhomogeneities in the mesh.

In the 1980s, researchers accumulated solid evidence for a predictive dynamic range on the order of 40 to 50 dB for FDTD codes. This value is reasonable if one considers the additive noise due to imperfect ABCs to be the primary limiting factor, because the analytical ABCs of this era (Mur, 1981) provided outer-boundary reflection coefficients in the range of about 0.3 to 3% (-30 to -50dB).

The 1990s saw the emergence of powerful, entirely new classes of ABCs, including the perfectly matched layer (PML) of Berenger (1994), the uniaxial anisotropic PML (UPML) of Sacks *et al.* (1995) and Gedney (1996), and the complementary operator methods (COM) of Ramah (1997, 1998). These ABCs were shown to have effective outerboundary reflection coefficients of better than -80dB for impinging pulsed electromagnetic waves having ultrawideband spectra. Solid capabilities were demonstrated to terminate free space lattices, multimoding and dispersive waveguiding structures, and lossy and dispersive materials.

However, for electrically large problems, the overall dynamic range was shown not to reach the maximum permitted by these new ABCs because of inaccuracies due to accumulating numerical dispersion artifacts generated by the basic grid-based solution of the curl equations. Fortunately, by the end of the 1990s, this problem was being attacked by a new generation of low-dispersion algorithms. Examples include the wavelet-based multiresolution time-domain (MRTD) technique introduced by Krumpholz and Katehi (1996) and the pseudo-spectral time-domain (PSTD) technique introduced by Liu, (1996, 1997). As a result of these advances, there is the possible emergence of FDTD and related space-grid time-domain methods, demonstrating predictive dynamic ranges of 80 dB or more in the first decade of the 21st century.

9.1.6 Scaling to Very Large Problem Sizes

Using FDTD and related methods, electromagnetic wave interaction problems can be modeled requiring the solution of considerably more than 10^8 field–vector unknowns. At this level of complexity, it is possible to develop detailed, three-dimensional models of complete engineering systems, including the following:

- Entire aircraft and missiles illuminated by radar at 1 GHz and above
- Entire multilayer circuit boards and multichip modules for digital signal propagation, cross talk, and radiation
- Entire microwave and millimeter-wave amplifiers, including the active and passive circuit components and packaging
- Entire integrated-optical structures, including lasers, waveguides, couplers, and resonators

A key goal for such large models is to achieve algorithm/computer-architecture scaling such that for N field unknowns to be solved on M processors, we approach an order (N/M) scaling of the required computational resources.

We now consider the factors involved in determining the computational burden for the class of FDTD and related space-grid time-domain solvers.

1. **Number of volumetric grid cells, N**: The six vector electromagnetic field components located at each lattice cell must be updated at every time-step. This yields by itself an order (N) scaling.
2. **Number of time steps, $n_{\max}$**: A self-consistent solution in the time domain mandates that the numerical wave analogs propagate over time scales sufficient to causally connect each portion of the structure of interest. Therefore, $n_{\max}$ must increase as the maximum electrical size of the structure. In three dimensions, it can be argued that $n_{\max}$ is a fractional power function of N such as $N^{1/3}$. Further, $n_{\max}$ must be adequate to step through "ring-up" and "ring-down" times of energy storage features such as cavities. These features vary from problem to problem and cannot be ascribed a dependence relative to N.

3. **Cumulative propagation errors**: Additional computational burdens may arise due to the need for either progressive mesh refinement or progressively higher accuracy algorithms to bound cumulative positional or phase errors for propagating numerical modes in progressively enlarged meshes. Any need for progressive mesh refinement would feed back to factor 1.

For most free space problems, factors 2 and 3 are weaker functions of the size of the modeled structure than factor 1. This is because geometrical features at increasing electrical distances from each other become decoupled due to radiative losses by the electromagnetic waves propagating between these features. Further, it can be shown that replacing second-order accurate algorithms by high-order versions sufficiently reduces numerical dispersion error to avoid the need for progressive mesh refinement for object sizes up to the order of 100 wavelengths. Overall, a computational burden of order $(N \cdot n_{\max})$ = order $(N^{4/3})$ is estimated for very large FDTD and related models.

9.2 Maxwell's Equations

In this section, we establish the fundamental equations and notation for the electromagnetic fields used in the remainder of this chapter.

9.2.1 Three-Dimensional Case

Using meter per second (MKS) units, the time-dependent Maxwell's equations in three dimensions are given in differential and integral form by:

Faraday's law:

$$\frac{\partial \vec{B}}{\partial t} = -\nabla \times \vec{E} - \vec{M}. \tag{9.1a}$$

$$\frac{\partial}{\partial t}\iint_A \vec{B} \cdot d\vec{A} = -\oint_\ell \vec{E} \cdot d\vec{\ell} - \iint_A \vec{M} \cdot d\vec{A}. \tag{9.1b}$$

Ampere's law:

$$\frac{\partial \vec{D}}{\partial t} = \nabla \times \vec{H} - \vec{J}. \tag{9.2a}$$

$$\frac{\partial}{\partial t}\iint_A \vec{D} \cdot d\vec{A} = \oint_\ell \vec{H} \cdot d\vec{\ell} - \iint_A \vec{J} \cdot d\vec{A}. \tag{9.2b}$$

Gauss' law for the electric field:

$$\nabla \cdot \vec{D} = 0. \tag{9.3a}$$

$$\oint\!\!\oint_A \vec{D} \cdot d\vec{A} = 0. \tag{9.3b}$$

Gauss' law for the magnetic field:

$$\nabla \cdot \vec{B} = 0. \tag{9.4a}$$

$$\oint\!\!\oint_A \vec{B} \cdot d\vec{A} = 0. \tag{9.4b}$$

For equations 9.1 through 9.4, the following symbols (and their MKS units) are defined:

$\vec{E}$: Electric field [volts/meter]
$\vec{D}$: Electric flux density [coulombs/meter^2]
$\vec{H}$: Magnetic field [amperes/meter]
$\vec{B}$: Magnetic flux density [webers/meter^2]
A : Arbitrary three-dimensional surface
$d\vec{A}$: Differential normal vector that characterizes surface A [meter^2]
ℓ : Closed contour that bounds surface A
$d\vec{\ell}$: Differential length vector that characterizes contour ℓ [meters]
$\vec{J}$: Electrical current density [amperes/meter^2]
$\vec{M}$: Equivalent magnetic current density [volts/meter^2]

In linear, isotropic, and nondispersive materials (i.e., materials having field-independent, direction-independent, and frequency-independent electric and magnetic properties), we can relate $\vec{D}$ to $\vec{E}$ and $\vec{B}$ to $\vec{H}$ using simple proportions:

$$\vec{D} = \varepsilon\vec{E} = \varepsilon_r\varepsilon_0\vec{E}; \quad \vec{B} = \mu\vec{H} = \mu_r\mu_0\vec{H}, \tag{9.5}$$

where the following applies:

ε : Electrical permittivity [farads/meter]
ε_r : Relative permittivity [dimensionless scalar]
ε_0 : Free-space permittivity [8.854×10^{-12} farads/meter]
μ : Magnetic permeability [henry/meter]
μ_r : Relative permeability [dimensionless scalar]
μ_0 : Free-space permeability [$4\pi \times 10^{-7}$ henry/meter]

Note that $\vec{J}$ and $\vec{M}$ can act as **independent sources** of E- and H-field energy, $\vec{J}_{\text{source}}$, and $\vec{M}_{\text{source}}$. We also allow for materials with isotropic, nondispersive electric, and magnetic losses that attenuate E- and H-fields via conversion to heat energy. This yields:

$$\vec{J} = \vec{J}_{\text{source}} + \sigma\vec{E}; \; \vec{M} = \vec{M}_{\text{source}} + \sigma^*\vec{H}, \tag{9.6}$$

where the following applies:

σ : Electric conductivity [siemens/meter]
σ^* : Equivalent magnetic loss [ohms/meter]

Finally, we substitute equations 9.5 and 9.6 into (9.1a) and (9.2a). This yields Maxwell's curl equations in linear, isotropic, nondispersive, and lossy materials:

$$\frac{\partial \vec{H}}{\partial t} = -\frac{1}{\mu}\nabla \times \ddot{E} - \frac{1}{\mu}\left(\vec{M}_{source} + \sigma^{*}\vec{H}\right). \qquad (9.7)$$

$$\frac{\partial \vec{E}}{\partial t} = \frac{1}{\varepsilon}\nabla \times \vec{H} - \frac{1}{\varepsilon}\left(\vec{J}_{source} + \sigma\vec{E}\right). \qquad (9.8)$$

We now write out the vector components of the curl operators of equations 9.7 and 9.8 in Cartesian coordinates. This yields the following system of six coupled scalar equations:

$$\frac{\partial H_x}{\partial t} = \frac{1}{\mu}\left[\frac{\partial E_y}{\partial z} - \frac{\partial E_z}{\partial y} - \left(M_{source_x} + \sigma^{*} H_x\right)\right]. \qquad (9.9a)$$

$$\frac{\partial H_y}{\partial t} = \frac{1}{\mu}\left[\frac{\partial E_z}{\partial x} - \frac{\partial E_x}{\partial z} - \left(M_{source_y} + \sigma^{*} H_y\right)\right]. \qquad (9.9b)$$

$$\frac{\partial H_z}{\partial t} = \frac{1}{\mu}\left[\frac{\partial E_x}{\partial y} - \frac{\partial E_y}{\partial x} - \left(M_{source_z} + \sigma^{*} H_z\right)\right]. \qquad (9.9c)$$

$$\frac{\partial E_x}{\partial t} = \frac{1}{\varepsilon}\left[\frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z} - \left(J_{source_x} + \sigma E_x\right)\right]. \qquad (9.10a)$$

$$\frac{\partial E_y}{\partial t} = \frac{1}{\varepsilon}\left[\frac{\partial H_x}{\partial z} - \frac{\partial H_z}{\partial x} - \left(J_{source_y} + \sigma E_y\right)\right]. \qquad (9.10b)$$

$$\frac{\partial E_z}{\partial t} = \frac{1}{\varepsilon}\left[\frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} - \left(J_{source_z} + \sigma E_z\right)\right]. \qquad (9.10c)$$

The system of six coupled partial differential equations of (9.9) and (9.10) forms the basis of the FDTD numerical algorithm for electromagnetic wave interactions with general three-dimensional objects. The FDTD algorithm need not explicitly enforce the Gauss's law relations indicating zero free electric and magnetic charge shown in equations 9.3 and 9.4. This is because these relations are theoretically a direct consequence of the curl equations, as can be readily shown. However, the FDTD space grid must be structured so that the Gauss's law relations are *implicit* in the positions of the *E*- and *H*-field vector components in the grid and in the numerical space-derivative operations upon these components that model the action of the curl operator. This will be discussed later in the context of the Yee mesh.

Before proceeding with the introduction of the Yee algorithm, it is instructive to consider simplified two-dimensional cases for Maxwell's equations. These cases demonstrate important electromagnetic wave phenomena and can yield insight into the analytical and algorithmic features of the general three-dimensional case.

9.2.2 Reduction to Two Dimensions

Let us assume that the structure being modeled extends to infinity in the *z* direction with no change in the shape or position of its transverse cross section. If the incident wave is also uniform in the *z* direction, then all partial derivatives of the fields with respect to *z* must equal zero. Under these conditions, the full set of Maxwell's curl equations given by equations 9.9 and 9.10 reduces to two modes: the **transverse-magnetic mode with respect to z** (TM$_z$) and the **transverse-electric mode with respect to z** (TE$_z$). The reduced sets of Maxwell's equations for these modes are as follows.

TM$_z$ Mode (Involving only H_x, H_y and E_z)

$$\frac{\partial H_x}{\partial t} = \frac{1}{\mu}\left[-\frac{\partial E_z}{\partial y} - \left(M_{\mathrm{source}_x} + \sigma^{*} H_x\right)\right]. \qquad (9.11a)$$

$$\frac{\partial H_y}{\partial t} = \frac{1}{\mu}\left[\frac{\partial E_z}{\partial x} - \left(M_{\mathrm{source}_y} + \sigma^{*} H_y\right)\right]. \qquad (9.11b)$$

$$\frac{\partial E_z}{\partial t} = \frac{1}{\varepsilon}\left[\frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} - \left(J_{\mathrm{source}_z} + \sigma E_z\right)\right]. \qquad (9.11c)$$

TE$_z$ Mode (Involving only E_x, E_y and H_z)

$$\frac{\partial E_x}{\partial t} = \frac{1}{\varepsilon}\left[\frac{\partial H_z}{\partial y} - \left(J_{\mathrm{source}_x} + \sigma E_x\right)\right]. \qquad (9.12a)$$

$$\frac{\partial E_y}{\partial t} = \frac{1}{\varepsilon}\left[-\frac{\partial H_z}{\partial x} - \left(J_{\mathrm{source}_y} + \sigma E_y\right)\right]. \qquad (9.12b)$$

$$\frac{\partial H_z}{\partial t} = \frac{1}{\mu}\left[\frac{\partial E_x}{\partial y} - \frac{\partial E_y}{\partial x} - \left(M_{\mathrm{source}_z} + \sigma^{*} H_z\right)\right]. \qquad (9.12c)$$

The TM$_z$ and TE$_z$ modes contain no common field vector components. Thus, these modes can exist simultaneously with *no* mutual interactions for structures composed of isotropic materials or anisotropic materials having no off-diagonal components in the constitutive tensors.

Physical phenomena associated with these two modes can be very different. The TE$_z$ mode can support propagating electromagnetic fields bound closely to, or guided by, the surface of a metal structure (the "creeping wave" being a classic example for curved metal surfaces). On the other hand, the TM$_z$ mode sets up an *E*-field which must be negligible at a metal surface. This diminishes or eliminates bound or guided near-surface propagating waves for metal surfaces. The presence or absence of surface-type waves can have important implications for scattering and radiation problems.

9.3 The Yee Algorithm

9.3.1 Basic Ideas

Yee (1966) originated a set of finite-difference equations for the time-dependent Maxwell's curl equations 9.9 and 9.10 for the lossless materials case $\sigma = 0$ and $\sigma^{*} = 0$. This section summarizes Yee's algorithm, which forms the basis of the

FDTD technique. Key ideas underlying the robust nature of the **Yee algorithm** are as follows:

1. The Yee algorithm solves for both electric and magnetic fields in time and space using the coupled Maxwell's curl equations rather than solving for the electric field alone (or the magnetic field alone) with a wave equation.
   - This is analogous to the combined-field integral equation formulation of the method of moments, wherein both $\vec{E}$ and $\vec{H}$ boundary conditions are enforced on the surface of a material structure.
   - Using both $\vec{E}$ and $\vec{H}$ information, the solution is more robust than using either alone (i.e., it is accurate for a wider class of structures). Both electric and magnetic material properties can be modeled in a straightforward manner. This is especially important when modeling radar cross section mitigation.
   - Features unique to each field (e.g., tangential $\vec{H}$ singularities near edges and corners; azimuthal [looping] $\vec{H}$ singularities near thin wires; and radial $\vec{E}$ singularities near points, edges; and thin wires) can be individually modeled if both electric and magnetic fields are available.
2. As illustrated in Figure 9.1, the Yee algorithm centers its $\vec{E}$ and $\vec{H}$ components in a three-dimensional space so that every $\vec{E}$ component is surrounded by four circulating $\vec{H}$ components and so that every $\vec{H}$ component is surrounded by four circulating $\vec{E}$ components.

   This provides a beautifully simple picture of a three-dimensional space being filled by an interlinked array of Faraday's law and Ampere's law contours. For example, it is possible to identify Yee $\vec{E}$ components associated with displacement current flux linking $\vec{H}$ loops as well as $\vec{H}$ components associated with magnetic flux linking $\vec{E}$ loops. In effect, the Yee algorithm simultaneously simulates the pointwise differential form *and* the macroscopic integral form of Maxwell's equations. The latter possibility is extremely useful in specifying field boundary conditions and singularities.

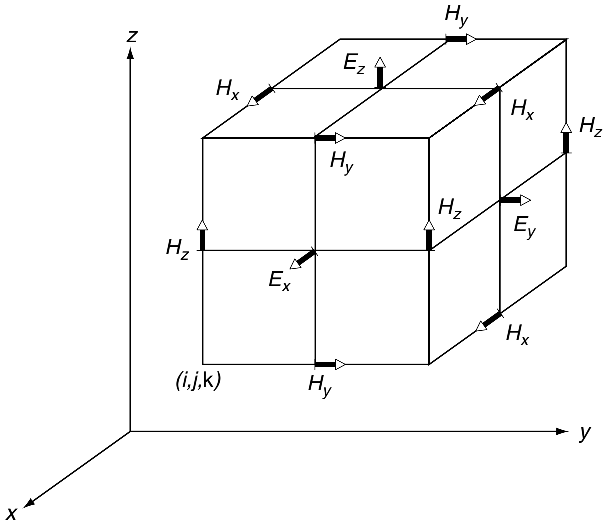

FIGURE 9.1 Position of the Electric and Magnetic Field Vector Components about a Cubic Unit Cell of the Yee Space Lattice. Adapted from Yee (1966).

In addition, we have the following attributes of the Yee space lattice:

- The finite-difference expressions for the space derivatives used in the curl operators are central different in nature and second-order accurate.
- Continuity of tangential $\vec{E}$ and $\vec{H}$ is naturally maintained across an interface of dissimilar materials if the interface is parallel to one of the lattice coordinate axes. For this case, there is no need to specially enforce field boundary conditions at the interface. At the beginning of the problem, we simply specify the material permittivity and permeability at each field component location. This yields a stepped or "staircase" approximation of the surface and internal geometry of the structure, with a space resolution set by the size of the lattice unit cell.
- The location of the $\vec{E}$ and $\vec{H}$ components in the Yee space lattice and the central-different operations on these components implicitly enforce the two Gauss's Law relations (Taflove and Hagness, 2000). Thus, the Yee mesh is divergence-free with respect to its E and H fields in the absence of free electric and magnetic charges.

3. As illustrated in Figure 9.2, the Yee algorithm also centers its $\vec{E}$ and $\vec{H}$ components in time in what is termed a **leapfrog arrangement**. All of the $\vec{E}$ computations in the modeled space are completed and stored in memory for a particular time point using previously stored $\vec{H}$ data. Then, all of the $\vec{H}$ computations in the space are completed and stored in memory using the $\vec{E}$ data just computed. The cycle begins again with the recomputation of the $\vec{E}$ components based on the newly obtained $\vec{H}$. This process continues until time-stepping is concluded.
   - Leapfrog time-stepping is fully explicit, thereby avoiding problems involved with simultaneous equations and matrix inversion.
   - The finite-difference expressions for the time derivatives are central different in nature and second-order accurate.
   - The time-stepping algorithm is nondissipative. That is, numerical wave modes propagating in the mesh do not spuriously decay due to a nonphysical artifact of the time-stepping algorithm.

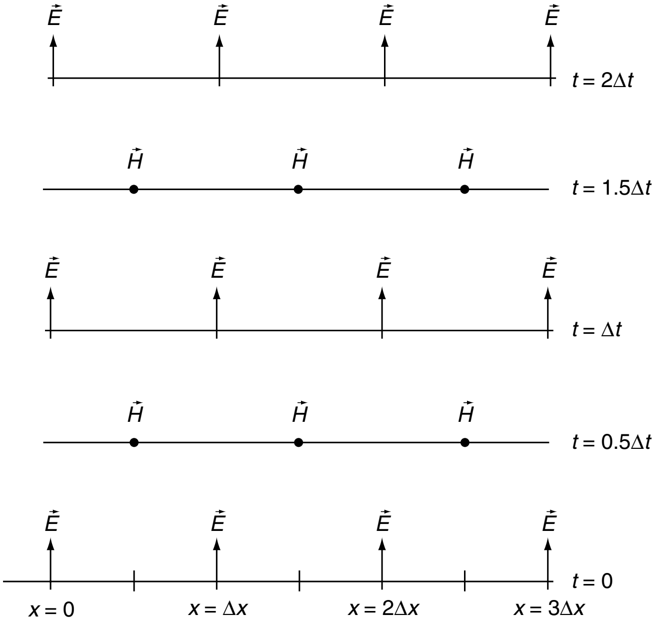

FIGURE 9.2 Space-Time Chart of the Yee Algorithm for a One-Dimensional Wave Propagation. This example shows the use of central differences for the space derivatives and leapfrog for the time derivatives. Initial conditions for both electric and magnetic fields are zero everywhere in the grid.

9.3.2 Finite Differences and Notation

Yee (1966) introduced the following notation for space points and functions of space and time. A space point in a uniform, rectangular lattice is denoted as:

$$(i,\ j,\ k) = (i\Delta x,\ j\Delta y,\ k\Delta z). \tag{9.13}$$

In equation 9.13, Δx, Δy, and Δz are, respectively, the lattice space increments in the x, y, and z coordinate directions, and i, j, and k are integers. Further, we denote any function u of space and time evaluated at a discrete point in the grid and at a discrete point in time as:

$$u(i\Delta x,\ j\Delta y,\ k\Delta z,\ n\Delta t) = u^n_{i,\,j,\,k,} \tag{9.14}$$

where Δt is the time increment that is assumed uniform over the observation interval, and n is an integer.

Yee (1966) used centered finite-difference (central-difference) expressions for the space and time derivatives that are both simply programmed and second-order accurate in the space and time increments. Consider his expression for the first partial space derivative of u in the x direction, evaluated at the fixed time $t_n = n\Delta t$:

$$\frac{\partial u}{\partial x}(i\Delta x,\ j\Delta y,\ k\Delta z,\ n\Delta t) = \frac{u^n_{i+1/2,\,j,\,k} - u^n_{i-1/2,\,j,\,k}}{\Delta x} + O\left[(\Delta x)^2\right]. \tag{9.15}$$

We note the $\pm 1/2$ increment in the i subscript (x coordinate) of u, denoting a space finite difference over $\pm\Delta x/2$. Yee's goal (1966) was second-order accurate central differencing, but it is apparent that he desired to take data for his central differences to the right and left of his observation point by only $\Delta x/2$, rather than a full Δx.

Yee chose this notation because he interleaved his $\vec{E}$ and $\vec{H}$ components in the space lattice at intervals of $\Delta x/2$. For example, the difference of two adjacent $\vec{E}$ components, separated by Δx and located $\pm\Delta x/2$ on either side of an $\vec{H}$ component, would be used to provide a numerical approximation for $\partial E/\partial x$ to permit stepping the $\vec{H}$ component in time. For completeness, it should be added that a numerical approximation analogous to equation 9.15 for $\partial u/\partial y$ or $\partial u/\partial z$ can be written simply by incrementing the j or k subscript of u by $\pm\Delta y/2$ or $\pm\Delta z/2$, respectively.

Yee's expression for the first time partial derivative of u, evaluated at the fixed space point $(i,\ j,\ k)$, follows by analogy:

$$\frac{\partial u}{\partial t}(i\Delta x,\ j\Delta y,\ k\Delta z,\ n\Delta t) = \frac{u^{n+1/2}_{i,\,j,\,k} - u^{n-1/2}_{i,j,k}}{\Delta t} + O\left[(\Delta t)^2\right]. \tag{9.16}$$

Now the $\pm 1/2$ increment is in the n superscript (time coordinate) of u, denoting a time finite difference over $\pm\Delta t/2$. Yee (1996) chose this notation because he wished to interleave his $\vec{E}$ and $\vec{H}$ components in time at intervals of $\Delta t/2$ for purposes of implementing a leapfrog algorithm.

9.3.3 Finite-Difference Expressions for Maxwell's Equations in Three Dimensions

We now apply the above ideas and notation to achieve a finite-difference numerical approximation of the Maxwell's curl equations in three dimensions given by equations 9.9 and 9.10. We begin by considering as an example the E_x field-component equation 9.10a. Referring to Figures 9.1 and 9.2, a typical substitution of central differences for the time and space derivatives in equation 9.10a at $E_x(i,\ j + 1/2,\ k + 1/2,\ n)$ yields the following expression:

$$\frac{E_x|^{n+1/2}_{i,\,j+1/2,\,k+1/2} - E_x|^{n-1/2}_{i,\,j+1/2,\,k+1/2}}{\Delta t} = \frac{1}{\varepsilon_{i,\,j+1/2,\,k+1/2}} \times \left(\begin{array}{c} \dfrac{H_z|^n_{i,\,j+1,\,k+1/2} - H_z|^n_{i,\,j,\,k+1/2}}{\Delta y} - \dfrac{H_y|^n_{i,\,j+1/2,\,k+1} - H_y|^n_{i,\,j+1/2,\,k}}{\Delta z} \\ -J_{\text{source}_x}|^n_{i,\,j+1/2,\,k+1/2} - \sigma_{i,\,j+1/2,\,k+1/2} E_x|^n_{i,\,j+1/2,\,k+1/2} \end{array} \right). \tag{9.17}$$

Note that all field quantities on the right-hand side are evaluated at time-step n, including the electric field E_x appearing due to the material conductivity σ. Since E_x values at time-step n are not assumed to be stored in the computer's memory (only the previous values of E_x at time-step $n - 1/2$ are assumed to be in memory), we need some way to estimate such terms. A very good way is as follows, using what we call a **semi-implicit approximation**:

$$E_x\big|^{n}_{i,\,j+1/2,\,k+1/2} = \frac{E_x\big|^{n+1/2}_{i,\,j+1/2,\,k+1/2} + E_x\big|^{n-1/2}_{i,\,j+1/2,\,k+1/2}}{2}. \tag{9.18}$$

Here E_x values at time-step n are assumed to be simply the arithmetic average of the stored values of E_x at time-step $n-1/2$ and the yet-to-be computed new values of E_x at time-step $n+1/2$. Substituting equation 9.18 into 9.17 and collecting terms yields the following explicit time-stepping relation for E_x (which is numerically stable for values of σ from zero to infinity):

$$\begin{aligned} E_x\big|^{n+1/2}_{i,\,j+1/2,\,k+1/2} &= \left(\frac{1-\dfrac{\sigma_{i,\,j+1/2,\,k+1/2}\Delta t}{2\varepsilon_{i,\,j+1/2,\,k+1/2}}}{1+\dfrac{\sigma_{i,\,j+1/2,\,k+1/2}\Delta t}{2\varepsilon_{i,\,j+1/2,\,k+1/2}}}\right) E_x\big|^{n-1/2}_{i,\,j+1/2,\,k+1/2} \\ &+ \left(\frac{\dfrac{\Delta t}{\varepsilon_{i,\,j+1/2,\,k+1/2}}}{1+\dfrac{\sigma_{i,\,j+1/2,\,k+1/2}\Delta t}{2\varepsilon_{i,\,j+1/2,\,k+1/2}}}\right) \times \left(\begin{array}{l} \dfrac{H_z\big|^{n}_{i,\,j+1,\,k+1/2} - H_z\big|^{n}_{i,\,j,\,k+1/2}}{\Delta y} \\ -\dfrac{H_y\big|^{n}_{i,\,j+1/2,\,k+1} - H_y\big|^{n}_{i,\,j+1/2,\,k}}{\Delta z} \\ -J_{\text{source}_x}\big|^{n}_{i,\,j+1/2,\,k+1/2} \end{array}\right). \end{aligned} \tag{9.19a}$$

Similarly, we can derive finite-difference expressions based on Yee's algorithm for the E_y and E_z field components given by Maxwell's equations 9.10b and 9.10c. Referring again to Figure 9.1, we have:

$$\begin{aligned} E_y\big|^{n+1/2}_{i-1/2,\,j+1,\,k+1/2} &= \left(\frac{1-\dfrac{\sigma_{i-1/2,\,j+1,\,k+1/2}\Delta t}{2\varepsilon_{i-1/2,\,j+1,\,k+1/2}}}{1+\dfrac{\sigma_{i-1/2,\,j+1,\,k+1/2}\Delta t}{2\varepsilon_{i-1/2,\,j+1,\,k+1/2}}}\right) E_y\big|^{n-1/2}_{i-1/2,\,j+1,\,k+1/2} \\ &+ \left(\frac{\dfrac{\Delta t}{\varepsilon_{i-1/2,\,j+1,\,k+1/2}}}{1+\dfrac{\sigma_{i-1/2,\,j+1,\,k+1/2}\Delta t}{2\varepsilon_{i-1/2,\,j+1,\,k+1/2}}}\right) \times \left(\begin{array}{l} \dfrac{H_x\big|^{n}_{i-1/2,\,j+1,\,k+1} - H_x\big|^{n}_{i-1/2,\,j+1,\,k}}{\Delta z} \\ -\dfrac{H_z\big|^{n}_{i,\,j+1,\,k+1/2} - H_z\big|^{n}_{i-1,\,j+1,\,k+1/2}}{\Delta x} \\ -J_{\text{source}_y}\big|^{n}_{i-1/2,\,j+1,\,k+1/2} \end{array}\right). \end{aligned} \tag{9.19b}$$

$$\begin{aligned} E_z\big|^{n+1/2}_{i-1/2,\,j+1/2,\,k+1} &= \left(\frac{1-\dfrac{\sigma_{i-1/2,\,j+1/2,\,k+1}\,\Delta t}{2\,\varepsilon_{i-1/2,\,j+1/2,\,k+1}}}{1+\dfrac{\sigma_{i-1/2,\,j+1/2,\,k+1}\,\Delta t}{2\,\varepsilon_{i-1/2,\,j+1/2,\,k+1}}}\right) E_z\big|^{n-1/2}_{i-1/2,\,j+1/2,\,k+1} \\ &+ \left(\frac{\dfrac{\Delta t}{\varepsilon_{i-1/2,\,j+1/2,\,k+1}}}{1+\dfrac{\sigma_{i-1/2,\,j+1/2,\,k+1}\,\Delta t}{2\,\varepsilon_{i-1/2,\,j+1/2,\,k+1}}}\right) \times \left(\begin{array}{l} \dfrac{H_y\big|^{n}_{i,\,j+1/2,\,k+1} - H_y\big|^{n}_{i-1,\,j+1/2,\,k+1}}{\Delta x} \\ -\dfrac{H_x\big|^{n}_{i-1/2,\,j+1,\,k+1} - H_x\big|^{n}_{i-1/2,\,j,\,k+1}}{\Delta y} \\ -J_{\text{source}_z}\big|^{n}_{i-1/2,\,j+1/2,\,k+1} \end{array}\right). \end{aligned} \tag{9.19c}$$

By analogy, we can derive finite-difference equations for equations 9.9a to 9.9c to time-step H_x, H_y, and H_z. Here $\sigma^* H$ represents a magnetic loss term on the right-hand side of each equation, which is estimated using a semi-implicit procedure analogous to equation 9.18. Referring again to Figures 9.1 and 9.2, we have, for example, the following time-stepping expressions for the H components located about the unit cell:

$$\begin{aligned} H_x\big|^{n+1}_{i-1/2,\,j+1,\,k+1} &= \left(\frac{1-\dfrac{\sigma^*_{i-1/2,\,j+1,\,k+1}\Delta t}{2\mu_{i-1/2,\,j+1,\,k+1}}}{1+\dfrac{\sigma^*_{i-1/2,\,j+1,\,k+1}\Delta t}{2\mu_{i-1/2,\,j+1,\,k+1}}}\right) H_x\big|^{n}_{i-1/2,\,j+1,\,k+1} \\ &+ \left(\frac{\dfrac{\Delta t}{\mu_{i-1/2,\,j+1,\,k+1}}}{1+\dfrac{\sigma^*_{i-1/2,\,j+1,\,k+1}\Delta t}{2\mu_{i-1/2,\,j+1,\,k+1}}}\right) \times \left(\begin{array}{l} \dfrac{E_y\big|^{n+1/2}_{i-1/2,\,j+1,\,k+3/2} - E_y\big|^{n+1/2}_{i-1/2,\,j+1,\,k+1/2}}{\Delta z} \\ -\dfrac{E_z\big|^{n+1/2}_{i-1/2,\,j+3/2,\,k+1} - E_z\big|^{n+1/2}_{i-1/2,\,j+1/2,\,k+1}}{\Delta y} \\ -M_{\text{source}_x}\big|^{n+1/2}_{i-1/2,\,j+1,\,k+1} \end{array}\right). \end{aligned} \tag{9.20a}$$

$$\begin{aligned} H_y\big|^{n+1}_{i,\,j+1/2,\,k+1} &= \left(\frac{1-\dfrac{\sigma^*_{i,\,j+1/2,\,k+1}\Delta t}{2\mu_{i,\,j+1/2,\,k+1}}}{1+\dfrac{\sigma^*_{i,\,j+1/2,\,k+1}\Delta t}{2\mu_{i,\,j+1/2,\,k+1}}}\right) H_y\big|^{n}_{i,\,j+1/2,\,k+1} \\ &+ \left(\frac{\dfrac{\Delta t}{\mu_{i,\,j+1/2,\,k+1}}}{1+\dfrac{\sigma^*_{i,\,j+1/2,\,k+1}\Delta t}{2\mu_{i,\,j+1/2,\,k+1}}}\right) \times \left(\begin{array}{l} \dfrac{E_z\big|^{n+1/2}_{i+1/2,\,j+1/2,\,k+1} - E_z\big|^{n+1/2}_{i-1/2,\,j+1/2,\,k+1}}{\Delta x} \\ -\dfrac{E_x\big|^{n+1/2}_{i,\,j+1/2,\,k+3/2} - E_x\big|^{n+1/2}_{i,\,j+1/2,\,k+1/2}}{\Delta z} \\ -M_{\text{source}_y}\big|^{n+1/2}_{i,\,j+1/2,\,k+1} \end{array}\right). \end{aligned} \tag{9.20b}$$

$$\begin{aligned} H_z\big|^{n+1}_{i,\,j+1,\,k+1/2} &= \left(\frac{1-\dfrac{\sigma^*_{i,\,j+1,\,k+1/2}\Delta t}{2\mu_{i,\,j+1,\,k+1/2}}}{1+\dfrac{\sigma^*_{i,\,j+1,\,k+1/2}\Delta t}{2\mu_{i,\,j+1,\,k+1/2}}}\right) H_z\big|^{n}_{i,\,j+1,\,k+1/2} \\ &+ \left(\frac{\dfrac{\Delta t}{\mu_{i,\,j+1,\,k+1/2}}}{1+\dfrac{\sigma^*_{i,\,j+1,\,k+1/2}\Delta t}{2\mu_{i,\,j+1,\,k+1/2}}}\right) \times \left(\begin{array}{l} \dfrac{E_x\big|^{n+1/2}_{i,\,j+3/2,\,k+1/2} - E_x\big|^{n+1/2}_{i,\,j+1/2,\,k+1/2}}{\Delta y} \\ -\dfrac{E_y\big|^{n+1/2}_{i+1/2,\,j+1,\,k+1/2} - E_y\big|^{n+1/2}_{i-1/2,\,j+1,\,k+1/2}}{\Delta x} \\ -M_{\text{source}_z}\big|^{n+1/2}_{i,\,j+1,\,k+1/2} \end{array}\right). \end{aligned} \tag{9.20c}$$

With the systems of finite-difference expressions of equations 9.19 and 9.20, the new value of an electromagnetic field vector component at any space lattice point depends only on its previous value, the previous values of the components of the other field vector at adjacent points, and the known electric and magnetic current sources. Therefore, at any given time step, the computation of a field vector can proceed either one point at a time, or, if p parallel processors are employed concurrently, p points at a time.

9.3.4 Reduction to the Two-Dimensional TM$_z$ and TE$_z$ Modes

The finite-difference systems of equations 9.19 and 9.20 can be reduced for the two-dimensional TM$_z$ and TE$_z$ modes of

Subsection 9.2.2. For consistency, we again consider the field vector components of the unit cell of Figure 9.1. Assuming now that all partial derivatives of the fields with respect to z are equal to zero, the following conditions hold:

1. The sets of (E_z, H_x, H_y) components located in each lattice-cut plane k, $k+1$, and so on, are identical and can be completely represented by any one of these sets, which we designate as the **TM$_z$ mode**.
2. The sets of (H_z, E_x, E_y) components located in each lattice-cut plane $k+1/2$, $k+3/2$, and so on, are identical and can be completely represented by any one of these sets, which we designate as the **TE$_z$ mode**.

The resulting finite-difference systems for the TM$_z$ and TE$_z$ modes are as follows:

TM$_z$ Mode, Corresponding to the System of Equation 9.11

$$H_x\Big|_{i-1/2,j+1}^{n+1} = \left(\frac{1-\dfrac{\sigma^*_{i-1/2,j+1}\Delta t}{2\mu_{i-1/2,j+1}}}{1+\dfrac{\sigma^*_{i-1/2,j+1}\Delta t}{2\mu_{i-1/2,j+1}}}\right) H_x\Big|_{i-1/2,j+1}^{n} + \left(\frac{\dfrac{\Delta t}{\mu_{i-1/2,j+1}}}{1+\dfrac{\sigma^*_{i-1/2,j+1}\Delta t}{2\mu_{i-1/2,j+1}}}\right)$$

$$\times\left(\frac{E_z\Big|_{i-1/2,j+1/2}^{n+1/2} - E_z\Big|_{i-1/2,j+3/2}^{n+1/2}}{\Delta y} - M_{\text{source}_x}\Big|_{i-1/2,j+1}^{n+1/2}\right). \tag{9.21a}$$

$$H_y\Big|_{i,j+1/2}^{n+1} = \left(\frac{1-\dfrac{\sigma^*_{i,j+1/2}\Delta t}{2\mu_{i,j+1/2}}}{1+\dfrac{\sigma^*_{i,j+1/2}\Delta t}{2\mu_{i,j+1/2}}}\right) H_y\Big|_{i,j+1/2}^{n} + \left(\frac{\dfrac{\Delta t}{\mu_{i,j+1/2}}}{1+\dfrac{\sigma^*_{i,j+1/2}\Delta t}{2\mu_{i,j+1/2}}}\right)$$

$$\times\left(\frac{E_z\Big|_{i+1/2,j+1/2}^{n+1/2} - E_z\Big|_{i-1/2,j+1/2}^{n+1/2}}{\Delta x} - M_{\text{source}_y}\Big|_{i,j+1/2}^{n+1/2}\right). \tag{9.21b}$$

$$E_z\Big|_{i-1/2,j+1/2}^{n+1/2} = \left(\frac{1-\dfrac{\sigma_{i-1/2,j+1/2}\Delta t}{2\varepsilon_{i-1/2,j+1/2}}}{1+\dfrac{\sigma_{i-1/2,j+1/2}\Delta t}{2\varepsilon_{i-1/2,j+1/2}}}\right) E_z\Big|_{i-1/2,j+1/2}^{n-1/2} + \left(\frac{\dfrac{\Delta t}{\varepsilon_{i-1/2,j+1/2}}}{1+\dfrac{\sigma_{i-1/2,j+1/2}\Delta t}{2\varepsilon_{i-1/2,j+1/2}}}\right)$$

$$\times\left(\begin{array}{ccc} \dfrac{H_y\big|_{i,j+1/2}^{n} - H_y\big|_{i-1,j+1/2}^{n}}{\Delta x} & + & \dfrac{H_x\big|_{i-1/2,j}^{n} - H_x\big|_{i-1/2,j+1}^{n}}{\Delta y} \\ & - & J_{\text{source}_z}\Big|_{i-1/2,j+1/2}^{n} \end{array}\right). \tag{9.21c}$$

TE$_z$ Mode, Corresponding to the System of Equation 9.12

$$E_x\Big|_{i,j+1/2}^{n+1/2} = \left(\frac{1-\dfrac{\sigma_{i,j+1/2}\Delta t}{2\varepsilon_{i,j+1/2}}}{1+\dfrac{\sigma_{i,j+1/2}\Delta t}{2\varepsilon_{i,j+1/2}}}\right) E_x\Big|_{i,j+1/2}^{n-1/2} + \left(\frac{\dfrac{\Delta t}{\varepsilon_{i,j+1/2}}}{1+\dfrac{\sigma_{i,j+1/2}\Delta t}{2\varepsilon_{i,j+1/2}}}\right)$$

$$\times\left(\frac{H_z\big|_{i,j+1}^{n} - H_z\big|_{i,j}^{n}}{\Delta y} - J_{\text{source}_x}\Big|_{i,j+1/2}^{n}\right). \tag{9.22a}$$

$$E_y\Big|_{i-1/2,j+1}^{n+1/2} = \left(\frac{1-\dfrac{\sigma_{i-1/2,j+1}\Delta t}{2\varepsilon_{i-1/2,j+1}}}{1+\dfrac{\sigma_{i-1/2,j+1}\Delta t}{2\varepsilon_{i-1/2,j+1}}}\right) E_y\Big|_{i-1/2,j+1}^{n-1/2} + \left(\frac{\dfrac{\Delta t}{\varepsilon_{i-1/2,j+1}}}{1+\dfrac{\sigma_{i-1/2,j+1}\Delta t}{2\varepsilon_{i-1/2,j+1}}}\right)$$

$$\times\left(\frac{H_z\big|_{i-1,j+1}^{n} - H_z\big|_{i,j+1}^{n}}{\Delta x} - J_{\text{source}_y}\Big|_{i-1/2,j+1}^{n}\right). \tag{9.22b}$$

$$H_z\Big|_{i,j+1}^{n+1} = \left(\frac{1-\dfrac{\sigma^*_{i,j+1}\Delta t}{2\mu_{i,j+1}}}{1+\dfrac{\sigma^*_{i,j+1}\Delta t}{2\mu_{i,j+1}}}\right) H_z\Big|_{i,j+1}^{n} + \left(\frac{\dfrac{\Delta t}{\mu_{i,j+1}}}{1+\dfrac{\sigma^*_{i,j+1}\Delta t}{2\mu_{i,j+1}}}\right)$$

$$\times\left(\begin{array}{ccc} \dfrac{E_x\big|_{i,j+3/2}^{n+1/2} - E_x\big|_{i,j+1/2}^{n+1/2}}{\Delta y} & + & \dfrac{E_y\big|_{i-1/2,j+1}^{n+1/2} - E_y\big|_{i+1/2,j+1}^{n+1/2}}{\Delta x} \\ & & -M_{\text{source}_z}\Big|_{i,j+1}^{n+1/2} \end{array}\right) \tag{9.22c}$$

9.4 Numerical Dispersion

9.4.1 Introduction

The FDTD algorithm for Maxwell's curl equations reviewed in Section 9.3 causes nonphysical results such as dispersion of the simulated waves in a free space computational lattice. That is, the phase velocity of numerical wave modes can differ from c by an amount varying with the wavelength, direction of propagation in the grid, and grid discretization. This artifact causes propagating numerical waves to accumulate delay or phase errors that can lead to nonphysical results, such as broadening and ringing of pulsed waveforms, imprecise cancellation of multiple scattered waves, anisotropy, and pseudorefraction. Numerical dispersion is a factor that must be accounted to understand the operation of FDTD algorithms and their accuracy limits, especially for electrically large structures.

9.4.2 Two-Dimensional Wave Propagation

We begin our discussion of **numerical dispersion** with an analysis of the two-dimensional TM$_z$, mode, assuming for simplicity no electric or magnetic loss. (It can easily be shown that the same results are obtained for the TE$_z$ mode.) The analysis procedure involves substitution of a plane, monochromatic, and sinusoidal traveling-wave mode into equations 9.21a through 9.21c. After algebraic manipulation, an equation is derived that relates the numerical wavevector components, the wave frequency, the time step, and the grid space increments. This equation, the numerical dispersion relation, can be solved for a variety of grid discretizations, wavevectors, and wave frequencies to illustrate the principal nonphysical results associated with numerical dispersion.

Initiating this procedure, we assume the following plane, monochromatic, and sinusoidal traveling wave for the TM$_z$ mode:

$$E_z\big|_{I,\,J}^{n} = E_{z_0} e^{j(\omega n\Delta t - \tilde{k}_x I\Delta x - \tilde{k}_y J\Delta y)}. \tag{9.23a}$$

$$H_x\big|_{I,\,J}^{n} = H_{x_0} e^{j(\omega n\Delta t - \tilde{k}_x I\Delta x - \tilde{k}_y J\Delta y)}. \tag{9.23b}$$

$$H_y\big|_{I,\,J}^{n} = H_{y_0} e^{j(\omega n\Delta t - \tilde{k}_x I\Delta x - \tilde{k}_y J\Delta y)}. \tag{9.23c}$$

The $\tilde{k}_x$ and $\tilde{k}_y$ in these equations are the x and y components of the numerical wavevector, and ω is the wave angular frequency. Substituting the traveling-wave expressions of equations 9.23 into the finite-difference equations of 9.21 yields, after simplification, the following relations for the lossless material case:

$$H_{x_0} = \frac{\Delta t E_{z_0}}{\mu \Delta y} \cdot \frac{\sin(\tilde{k}_y \Delta y/2)}{\sin(\omega \Delta t/2)}. \tag{9.24a}$$

$$H_{y_0} = -\frac{\Delta t E_{z_0}}{\mu \Delta x} \cdot \frac{\sin(\tilde{k}_x \Delta x/2)}{\sin(\omega \Delta t/2)}. \tag{9.24b}$$

$$E_{z_0} \sin\left(\frac{\omega \Delta t}{2}\right) = \frac{\Delta t}{\varepsilon}\left[\frac{H_{x_0}}{\Delta y}\sin\left(\frac{\tilde{k}_y \Delta y}{2}\right) - \frac{H_{y_0}}{\Delta x}\sin\left(\frac{\tilde{k}_x \Delta x}{2}\right)\right]. \tag{9.24c}$$

Upon substituting H_{x_0} of equation 9.24a and H_{y_0} of equation 9.24b into 9.24c we obtain:

$$\left[\frac{1}{c\Delta t}\sin\left(\frac{\omega\Delta t}{2}\right)\right]^2 = \left[\frac{1}{\Delta x}\sin\left(\frac{\tilde{k}_x \Delta x}{2}\right)\right]^2 + \left[\frac{1}{\Delta y}\sin\left(\frac{\tilde{k}_y \Delta y}{2}\right)\right]^2, \tag{9.25}$$

where $c = 1/\sqrt{\mu\varepsilon}$ is the speed of light in the material being modeled. Equation 9.25 is the general numerical dispersion relation of the Yee (1966) algorithm for the TM$_z$ mode.

We shall consider the important special case of a square-cell grid having $\Delta x = \Delta y = \Delta$. Then, defining the **Courant stability factor** $S = c\Delta t/\Delta$ and the **grid sampling density** $N_\lambda = \lambda_0/\Delta$, we rewrite equation 9.25 in a more useful form:

$$\frac{1}{S^2}\sin^2\left(\frac{\pi S}{N_\lambda}\right) = \sin^2\left(\frac{\Delta \cdot \tilde{k}\cos\phi}{2}\right) + \sin^2\left(\frac{\Delta \cdot \tilde{k}\sin\phi}{2}\right), \tag{9.26}$$

where ϕ is the propagation direction of the numerical wave with respect to the grid's x-axis. To obtain the numerical dispersion relation for the one-dimensional wave-propagation case, we can assume without loss of generality that $\phi = 0$ in equation 9.26, yielding:

$$\frac{1}{S}\sin\left(\frac{\pi S}{N_\lambda}\right) = \sin\left(\frac{\tilde{k}\Delta}{2}\right), \tag{9.27}$$

or equivalently:

$$\tilde{k} = \frac{2}{\Delta}\sin^{-1}\left[\frac{1}{S}\sin\left(\frac{\pi S}{N_\lambda}\right)\right]. \tag{9.28}$$

9.4.3 Extension to Three Dimensions: Cartesian Yee Lattice

The dispersion analysis presented in the previous subsection is now extended to the full three-dimensional case, following the analysis presented by Taflove and Brodwin (1975a). We consider a normalized, lossless region of space with $\mu = 1$, $\varepsilon = 1$, $\sigma = 0$, $\sigma^* = 0$, and $c = 1$. Letting $j = \sqrt{-1}$, we rewrite Maxwell's equations in compact form as:

$$j\nabla \times \left(\vec{H} + j\vec{E}\right) = \frac{\partial}{\partial t}\left(\vec{H} + j\vec{E}\right), \tag{9.29a}$$

or more simply as:

$$j\nabla \times \vec{V} = \frac{\partial \vec{V}}{\partial t}. \tag{9.29b}$$

In these equations, $\vec{V} = \vec{H} + j\vec{E}$. Substituting the vector–field traveling-wave expression:

$$\vec{V}\Big|_{I,\,J,\,K}^{n} = \vec{V}_0 e^{j\left(\omega n\Delta t - \tilde{k}_x I\Delta x - \tilde{k}_y J\Delta y - \tilde{k}_z K\Delta z\right)} \tag{9.30}$$

into the Yee space-time central-differencing realization of equation 9.29b, we obtain:

$$\begin{aligned}\left[\frac{\hat{x}}{\Delta x}\sin\left(\frac{\tilde{k}_x\Delta x}{2}\right) + \frac{\hat{y}}{\Delta y}\sin\left(\frac{\tilde{k}_y\Delta y}{2}\right) + \frac{\hat{z}}{\Delta z}\sin\left(\frac{\tilde{k}_z\Delta z}{2}\right)\right]& \\ \times \vec{V}\Big|_{I,\,J,\,K}^{n} = \frac{-j}{\Delta t}\vec{V}\Big|_{I,\,J,\,K}^{n}\sin\left(\frac{\omega\Delta t}{2}\right),&\end{aligned} \tag{9.31}$$

where $\hat{x}$, $\hat{y}$, and $\hat{z}$ are unit vectors in the x, y, and z coordinate directions. After performing the vector cross product in equation 9.31 and writing out the x, y, and z vector component equations, we obtain a homogeneous system (zero right-hand side) of three equations in the unknowns V_x, V_y, and V_z. Setting the determinant of this system equal to zero results in:

$$\begin{aligned}\left[\frac{1}{\Delta t}\sin\left(\frac{\omega\Delta t}{2}\right)\right]^2 = \left[\frac{1}{\Delta x}\sin\left(\frac{\tilde{k}_x\Delta x}{2}\right)\right]^2 + \left[\frac{1}{\Delta y}\sin\left(\frac{\tilde{k}_y\Delta y}{2}\right)\right]^2 \\ + \left[\frac{1}{\Delta z}\sin\left(\frac{\tilde{k}_z\Delta z}{2}\right)\right]^2.\end{aligned} \tag{9.32}$$

Finally, we denormalize to a nonunity c and obtain the general form of the numerical dispersion relation for the full vector–field Yee algorithm in three dimensions:

$$\begin{aligned}\left[\frac{1}{c\Delta t}\sin\left(\frac{\omega\Delta t}{2}\right)\right]^2 = \left[\frac{1}{\Delta x}\sin\left(\frac{\tilde{k}_x\Delta x}{2}\right)\right]^2 + \left[\frac{1}{\Delta y}\sin\left(\frac{\tilde{k}_y\Delta y}{2}\right)\right]^2 \\ + \left[\frac{1}{\Delta z}\sin\left(\frac{\tilde{k}_z\Delta z}{2}\right)\right]^2.\end{aligned} \tag{9.33}$$

This equation can reduce to equation 9.25, the numerical dispersion relation for the two-dimensional TM$_z$ mode, simply by letting $\tilde{k}_z = 0$.

9.4.4 Comparison with the Ideal Dispersion Case

In contrast to equation 9.33, the **analytical (ideal) dispersion relation** for a physical plane wave propagating in three dimensions in a homogeneous lossless medium is simply:

$$\left(\frac{\omega}{c}\right)^2 = (k_x)^2 + (k_y)^2 + (k_z)^2. \tag{9.34}$$

Although at first glance equation 9.33 bears little resemblance to the ideal case of equation 9.34, we can easily show that the two dispersion relations are identical in the limit as Δx, Δy, Δz, and Δt approach zero. Qualitatively, this suggests that numerical dispersion can be reduced to any degree that is desired if we only use fine enough FDTD gridding.

It can also be shown that equation 9.33 reduces to equation 9.34 if the Courant factor S and the wave-propagation direction are suitably chosen. For example, reduction to the ideal dispersion case can be demonstrated for a numerical plane wave propagating along a diagonal of a three-dimensional cubic lattice ($\tilde{k}_x = \tilde{k}_y = \tilde{k}_z = \tilde{k}/\sqrt{3}$) if $S = 1/\sqrt{3}$. Similarly, ideal dispersion results for a numerical plane wave propagating along a diagonal of a two-dimensional square grid ($\tilde{k}_x = \tilde{k}_y = \tilde{k}/\sqrt{2}$) if $S = 1/\sqrt{2}$. Finally, ideal dispersion results for any numerical wave in a one-dimensional grid if $S = 1$. These reductions to the ideal case have little practical value for two- and three-dimensional simulations, occurring only for diagonal propagation. However, the reduction to ideal dispersion in one dimension is very interesting, since it implies that the Yee algorithm (based on numerical finite-difference approximations) yields an *exact* solution for wave propagation.

9.4.5 Anisotropy of the Numerical Phase Velocity

This section probes a key implication of numerical dispersion relations of equations 9.26 and 9.33. Namely, numerical waves in a two- or three-dimensional Yee space lattice have a propagation velocity that is dependent on the direction of wave propagation. The space lattice thus represents an anisotropic medium.

Our strategy in developing an understanding of this phenomenon is to first calculate sample values of the numerical phase velocity $\tilde{v}_p$ versus wave-propagation direction ϕ to estimate the magnitude of the problem. Then, we will conduct an appropriate analysis to examine the issue more deeply.

Sample Values of Numerical Phase Velocity

We start with the simplest possible situation where numerical phase-velocity anisotropy arises: two-dimensional TM$_z$ modes propagating in a square-cell grid. Dispersion relation 9.26 can be solved directly for $\tilde{k}$ for propagation along the major axes of the grid: $\phi = 0°$, $90°$, $180°$, and $270°$. For this case, the solution for $\tilde{k}$ is given by equation 9.28, which is repeated here for convenience:

$$\tilde{k} = \frac{2}{\Delta}\sin^{-1}\left[\frac{1}{S}\sin\left(\frac{\pi S}{N_\lambda}\right)\right]. \quad \text{(propagation along major grid axes)} \tag{9.35a}$$

The corresponding numerical phase velocity is given by:

$$\tilde{v}_p = \frac{\omega}{\tilde{k}} = \frac{\pi}{N_\lambda \sin^{-1}\left[\frac{1}{S}\sin\left(\frac{\pi S}{N_\lambda}\right)\right]}\,c. \quad \text{(propagation along major grid axes)} \tag{9.35b}$$

Dispersion relation 9.27 can also be solved directly for $\tilde{k}$ for propagation along the diagonals of the grid $\phi = 45°$, $135°$, $225°$, and $315°$, yielding:

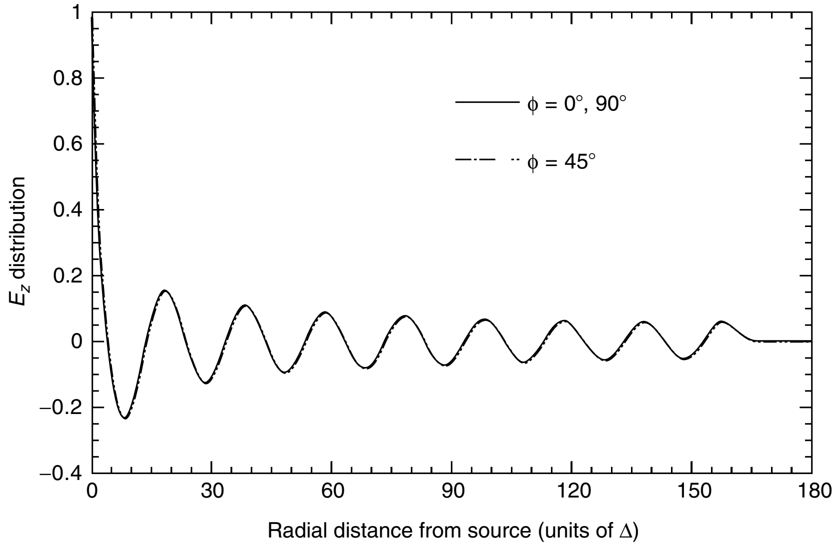
$$\tilde{k} = \frac{2\sqrt{2}}{\Delta}\sin^{-1}\left[\frac{1}{S\sqrt{2}}\sin\left(\frac{\pi S}{N_\lambda}\right)\right]. \quad \text{(propagation along grid diagonals)} \tag{9.36a}$$

$$\tilde{v}_p = \frac{\pi}{N_\lambda\sqrt{2}\sin^{-1}\left[\frac{1}{S\sqrt{2}}\sin\left(\frac{\pi S}{N_\lambda}\right)\right]}\,c. \quad \text{(propagation along grid diagonals)} \tag{9.36b}$$

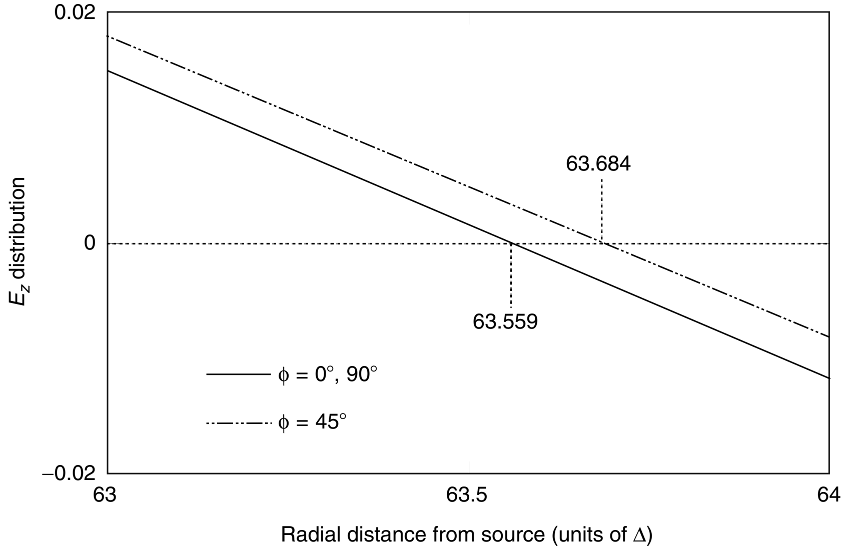
As an example, assume a grid having $S = 0.5$ and $N_\lambda = 20$. Then equation 9.35b and 9.36b provide unequal $\tilde{v}_p$ values of $0.996892c$ and $0.998968c$, respectively. The implication is that a sinusoidal numerical wave propagating obliquely in this grid has a speed that is $0.998968/0.996892 = 1.00208$ times that of a wave propagating along the major grid axes. This represents a velocity anisotropy of about 0.2% between oblique and along-axis numerical wave propagation.

Taflove and Hagness (2000) demonstrated that this theoretical anisotropy of the numerical phase velocity appears in FDTD simulations. Figure 9.3 presents their modeling results for a radially outward-propagating sinusoidal cylindrical wave in a two-dimensional TM$_z$ grid. The Taflove and Hagness, grid was configured with 360×360 square cells with $\Delta x = \Delta y = \Delta = 1.0$. A unity-amplitude sinusoidal excitation was provided to a single E_z component at the center of the grid. Choosing a grid-sampling density of $N_\lambda = 20$ and a Courant factor $S = 0.5$ permitted direct comparison of the FDTD modeling results with the theoretical results for the anisotropy of $\tilde{v}_p$, discussed immediately above.

Figure 9.3(A) illustrates snapshots of the E_z field distribution versus radial distance from the source at the center of the grid. Here, field observations are made along cuts through the grid passing through the source point and are either parallel to the principal grid axes $\phi = 0°$ and $90°$ or parallel to the grid diagonal $\phi = 45°$. (Note that, by the $90°$ rotational symmetry of the Cartesian grid geometry, identical field distributions are obtained along $\phi = 0°$ and $\phi = 90°$.) The snapshots are taken $328\Delta t$ after the beginning of time-stepping. At this time, the



(A) Comparison of Calculated Wave Propagation Along the Grid Axes and Along a Grid Diagonal.



(B) Expanded View of (A) at Distances Between 63 and 64 Grid Cells from the Source.

FIGURE 9.3 Effect of Numerical Dispersion on a Radially Propagating Cylindrical Wave in a 2-D TM Yee Grid. The grid is excited at its center by applying a unity-amplitude sinusoidal time function to a single E_z field component. The value of $S = 0.5$, and the grid sampling density is $N_\lambda = 20$.

wave has not yet reached the outer grid boundary, and the calculated E_z field distribution is free of error due to outer-boundary reflections.

Figure 9.3(B) is an expanded view of Figure 9.3(A) at radial distances between 63Δ and 64Δ from the source. This enables evaluation (with three-decimal-place precision) of the locations of the zero-crossings of the E_z distributions along the two observation cuts through the grid. From the data shown in Figure 9.3(B) the sinusoidal wave along the $\phi = 45°$ cut passes through zero at 63.684Δ cells, whereas the wave along the $\phi = 0°$, 90° cut passes through zero at 63.559Δ cells. Taking the difference, we see that the obliquely propagating wave "leads" the on-axis wave by 0.125Δ cells. This yields a numerical phase-velocity anisotropy $\Delta\tilde{v}_p/\tilde{v}_p \cong 0.125/63.6 = 0.197\%$. This number is only about 5% less than the 0.208% value obtained using equations 9.35b and 9.36b.

To permit determination of $\tilde{k}$ and $\tilde{v}_p$ for any wave-propagation direction ϕ, it would be very useful to derive closed-form equations analogous to equations 9.35 and 9.36. However, for this general case, the underlying dispersion relation 9.26 is a transcendental equation. Taflove (1995) provided a useful alternative approach for obtaining sample values of $\tilde{v}_p$ by applying the following Newton's method iterative procedure to equation 9.26:

$$\tilde{k}_{\text{icount}+1} = \tilde{k}_{\text{icount}} - \frac{\sin^2(A\tilde{k}_{\text{icount}}) + \sin^2(B\tilde{k}_{\text{icount}}) - C}{A\sin(2A\tilde{k}_{\text{icount}}) + B\sin(2B\tilde{k}_{\text{icount}})}. \quad (9.37)$$

Here, $\tilde{k}_{\text{icount}+1}$ is the improved estimate of $\tilde{k}$, and $\tilde{k}_{\text{icount}}$ is the previous estimate of $\tilde{k}$. The A, B, and C are coefficients given by:

$$A = \frac{\Delta \cdot \cos\phi}{2}, \quad B = \frac{\Delta \cdot \sin\phi}{2}, \quad C = \frac{1}{S^2}\sin^2\left(\frac{\pi S}{N_\lambda}\right). \quad (9.38)$$

Additional simplicity results if Δ is normalized to the free space wavelength, λ_0. This is equivalent to setting $\lambda_0 = 1$. Then, a very good starting guess for the iterative process is simply 2π. For this case, $\tilde{v}_p$ is given by:

$$\frac{\tilde{v}_p}{c} = \frac{2\pi}{\tilde{k}_{\text{final icount}}}. \quad (9.39)$$

Usually, only two or three iterations are required for convergence.

Figure 9.4 graphs results obtained using this procedure that illustrate the variation of $\tilde{v}_p$ with propagation direction ϕ. Here, for the Courant factor fixed at $S = 0.5$, three different grid sampling densities N_λ are examined: $N_\lambda = 5$ points per λ_0, $N_\lambda = 10$, and $N_\lambda = 20$. We see that $\tilde{v}_p < c$ and is a function of both ϕ and N_λ. The $\tilde{v}_p$ is maximum for waves propagating obliquely within the grid ($\phi = 45°$) and is minimum for waves propagating along either grid axis ($\phi = 0°, 90°$).

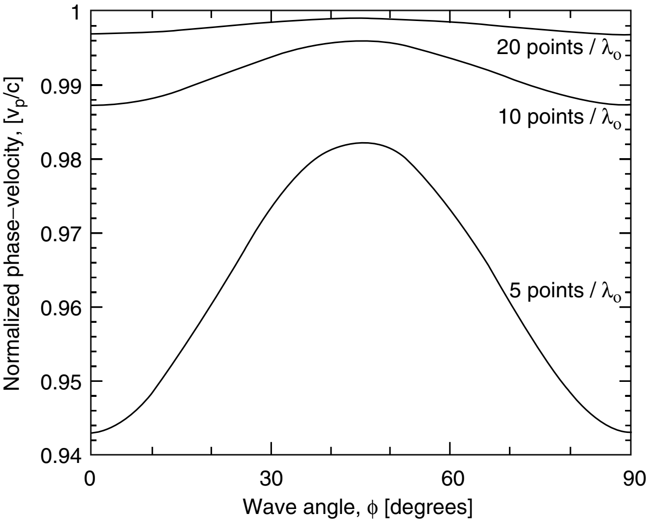


FIGURE 9.4 Variation of the Numerical Phase–Velocity with Wave Propagation Angle. The angle is in a 2-D FDTD grid for three sampling densities of the square unit cells. For all cases, $S = c\Delta t/\Delta = 0.5$.

It is useful to summarize the algorithmic dispersive-error performance by defining two normalized error measures: (1) the physical phase–velocity error $\Delta\tilde{v}_{\text{physical}}$, and (2) the velocity–anisotropy error $\Delta\tilde{v}_{\text{aniso}}$. These are given by:

$$\Delta\tilde{v}_{\text{physical}}\big|_{N_\lambda} = \frac{\min\left[\tilde{v}_p(\phi)\right] - c}{c} \times 100\%. \quad (9.40)$$

$$\Delta\tilde{v}_{\text{aniso}}\big|_{N_\lambda} = \frac{\max\left[\tilde{v}_p(\phi)\right] - \min\left[\tilde{v}_p(\phi)\right]}{\min\left[\tilde{v}_p(\phi)\right]} \times 100\%. \quad (9.41)$$

The $\Delta\tilde{v}_{\text{physical}}$ is useful in quantifying the phase lead or lag that numerical modes suffer relative to physical modes propagating at c. For example, from Figure 9.4 and equation 9.35b, $\Delta\tilde{v}_{\text{physical}} = -0.31\%$ for $N_\lambda = 20$. This means that a sinusoidal numerical wave traveling over a $10\lambda_0$ distance in the grid (200 cells) could develop a lagging phase error up to 11°. We note that $\Delta\tilde{v}_{\text{physical}}$ is a function of N_λ. Because the grid cell size Δ is fixed, for an impulsive wave-propagation problem there exists a spread of effective N_λ values for the spectral components comprising the pulse. This causes a spread of $\Delta\tilde{v}_{\text{physical}}$ over the pulse spectrum, which in turn yields a temporal dispersion of the pulse evidenced in the spreading and distortion of its waveform as it propagates.

The $\Delta\tilde{v}_{\text{aniso}}$ is useful in quantifying wavefront distortion. For example, a circular cylindrical wave would suffer progressive distortion of its wavefront since the portions propagating along the grid diagonals would travel slightly faster than the portions traveling along the major grid axes. For example, from Figure 9.4 and equations 9.35b and 9.36b, $\Delta\tilde{v}_{\text{aniso}} = 0.208\%$ for $N_\lambda = 20$. The wavefront distortion due to this anisotropy would total about 2.1 cells for each 1,000 cells of propagation distance.

It is clear that errors due to inaccurate numerical velocities are cumulative (i.e., they increase linearly with the wave-propagation distance). These errors represent a fundamental limitation of *all* grid-based Maxwell's equations' algorithms and can be troublesome when modeling electrically large structures. A positive aspect seen in Figure 9.4 is that both $\Delta\tilde{v}_{\text{physical}}$ and $\Delta\tilde{v}_{\text{aniso}}$ decrease by approximately a 4:1 factor each time the grid-sampling density doubles, indicative of the second-order accuracy of the Yee algorithm. Therefore, finer meshing is one way to control the dispersion error.

As discussed in Taflove and Hagness (2000), there are proposed means to improve the accuracy of FDTD algorithms to allow much larger structures to be modeled. Specifically, using pseudo-spectral techniques (Y. Liu, 1996, 1997), $\Delta\tilde{v}_{\text{aniso}}$ can be reduced to very low levels approaching zero. In this case, residual errors involve primarily the dispersion of $\Delta\tilde{v}_{\text{physical}}$ with N_λ, which can be optimized by the proper choice of Δt. The new approaches presently have limitations regarding their ability to model material discontinuities, however, and require more research.

Intrinsic Grid Velocity Anisotropy

Following Taflove and Hagness (2000), this section provides a deeper discussion of the numerical phase–velocity errors of the Yee algorithm. We will find that the nature of the grid discretization, in a manner virtually independent of the time-stepping scheme, determines the velocity anisotropy $\Delta\tilde{v}_{\text{aniso}}$.

Relation of the Time and Space Discretizations in Generating Numerical Velocity Error

In the previous section we determined that $\Delta\tilde{v}_{\text{aniso}} = 0.208\%$ for a two-dimensional Yee algorithm having $N_\lambda = 20$ and $S = 0.5$. An important and revealing question is how is $\Delta\tilde{v}_{\text{aniso}}$ affected by the choice of S, assuming that N_λ is fixed at 20?

To begin to answer this question, we first choose (what will later be shown to be) the largest possible value of S for numerical stability in two dimensions, $S = 1/\sqrt{2}$. Substituting this value of S into equations 9.35b and 9.36b yields:

$$\left.\begin{array}{l}\tilde{v}_p(\phi = 0^\circ) = 0.997926\,c\\ \tilde{v}_p(\phi = 45^\circ) = c\end{array}\right\}\Delta\tilde{v}_{\text{aniso}} = \frac{c - 0.997926\,c}{0.997926\,c} \times 100\% = 0.208\%.$$

To three decimal places, there is no change in $\Delta\tilde{v}_{\text{aniso}}$ from the previous value, $S = 0.5$. We next choose a very small value $S = 0.01$ for substitution into equations 9.35b and 9.36c:

$$\left.\begin{array}{l}\tilde{v}_p(\phi = 0^\circ) = 0.995859\,c\\ \tilde{v}_p(\phi = 45^\circ) = 0.997937\,c\end{array}\right\}\Delta\tilde{v}_{\text{aniso}} = \frac{0.997937\,c - 0.995859\,c}{0.995859\,c} \times 100\% = 0.208\%.$$

Again, there is no change in $\Delta\tilde{v}_{\text{aniso}}$ to three decimal places.

We now suspect that, for a given N_λ, $\Delta\tilde{v}_{\text{aniso}}$ is at most a weak function of S and, therefore, is only weakly dependent on Δt. In fact, this is the case. More generally, Y. Liu, (1996) has shown that $\Delta\tilde{v}_{\text{aniso}}$ is only weakly dependent on the specific type of time-marching scheme used, whether leapfrog, Runge-Kutta, or other schemes. Thus, we can say that $\Delta\tilde{v}_{\text{aniso}}$ is virtually an intrinsic characteristic of the space–lattice discretization. Following Y. Liu (1996), three key points should be made in this regard:

- Numerical-dispersion errors associated with the time discretization are isotropic relative to the propagation direction of the wave.
- The choice of time discretization has little effect on the phase–velocity anisotropy $\Delta\tilde{v}_{\text{aniso}}$ for $N_\lambda > 10$.
- The choice of time discretization does influence $\Delta\tilde{v}_{\text{physical}}$. However, it is not always true that higher order time-marching schemes, such as Runge-Kutta, yield less $\Delta\tilde{v}_{\text{physical}}$ than simple Yee leapfrogging. Errors in $\Delta\tilde{v}_{\text{physical}}$ are caused separately by the space and time discretizations and can either partially reinforce or cancel each other. Thus, the use of fourth-order Runge-Kutta may actually shift the $\tilde{v}_p(\phi)$ profile away from c, representing an increased $\Delta\tilde{v}_{\text{physical}}$ relative to ordinary leapfrogging.

Approximate Analytical Expression

Y. Liu (1996) has shown that, to determine the relative velocity anisotropy characteristic intrinsic to a space grid, it is useful to set up an eigenvalue problem for the matrix that delineates the spatial derivatives used in the numerical algorithm. Consider as an example the case of two-dimensional FDTD modeling of electromagnetic wave propagation. Following the development in Taflove and Hagness (2000), it can be shown that Y. Liu's (1996) technique leads to a simple approximate analytical expression for $\Delta\tilde{v}_{\text{aniso}}$ that is useful for $N_\lambda > 10$:

$$\Delta\tilde{v}_{\text{aniso}} \cong \frac{\pi^2}{12(N_\lambda)^2} \times 100\%. \tag{9.42}$$

For example, equation 9.42 provides $\Delta\tilde{v}_{\text{aniso}} \cong 0.206\%$ for $N_\lambda = 20$. This is very close to the 0.208% value previously obtained using equations 9.35b and 9.36b, the exact solutions of the full numerical dispersion relation for $\phi = 0^\circ$ and $\phi = 45^\circ$, respectively.

9.4.6 Complex-Valued Numerical Wave Numbers

Schneider and Wagner (1999) found that the Yee algorithm has a low sampling-density regime that allows complex-valued numerical wavenumbers. In this regime, spatially decaying numerical waves can propagate faster than light, causing a weak, nonphysical signal to appear ahead of the nominal leading edges of sharply defined pulses. This subsection reviews the theory underlying this phenomenon as related in Taflove and Hagness (2000).

Case 1: Numerical Wave Propagation Along the Principal Lattice Axes

Consider again numerical wave propagation along the major axes of a Yee space grid. For convenience, we rewrite equation 9.35a, the corresponding numerical dispersion relation:

$$\tilde{k} = \frac{2}{\Delta}\sin^{-1}\left[\frac{1}{S}\sin\left(\frac{\pi S}{N_\lambda}\right)\right] \equiv \frac{2}{\Delta}\sin^{-1}(\zeta), \tag{9.43}$$

where:

$$\zeta = \frac{1}{S}\sin\left(\frac{\pi S}{N_\lambda}\right). \tag{9.44}$$

Schneider and Wagner (1999) realized that, in evaluating numerical dispersion relations such as equation 9.43, it is possible to choose S and N_λ such that $\tilde{k}$ is complex. In the case of this equation, it can be shown that the transition between real and complex values of $\tilde{k}$ occurs when $\zeta = 1$. Solving for N_λ at this transition results in:

$$N_\lambda|_{\text{transition}} = \frac{\pi S}{\sin^{-1}(S)}. \tag{9.45}$$

For a grid sampling density greater than this value (i.e., $N_\lambda > N_\lambda|_{\text{transition}}$, $\tilde{k}$ is a real number, and the numerical wave undergoes no attenuation while propagating in the grid). Here, $\tilde{v}_p < c$. For a coarser grid-sampling density $N_\lambda < N_\lambda|_{\text{transition}}$, $\tilde{k}$ is a complex number, and the numerical wave undergoes a nonphysical exponential decay while propagating. Further, in this coarse-resolution regime, $\tilde{v}_p$ can exceed c.

We now discuss how $\tilde{k}$ and $\tilde{v}_p$ vary with grid sampling N_λ, both above and below the transition between real and complex numerical wavenumbers.

Real Numerical Wave Number Regime

For $N_\lambda > N_\lambda|_{\text{transition}}$, we have from equation 9.43:

$$\tilde{k}_{\text{real}} = \frac{2}{\Delta}\sin^{-1}\left[\frac{1}{S}\sin\left(\frac{\pi S}{N_\lambda}\right)\right]; \quad \tilde{k}_{\text{imag}} = 0 \tag{9.46a, b}$$

The numerical phase–velocity is given by:

$$\tilde{v}_p = \frac{\omega}{\tilde{k}_{\text{real}}} = \frac{\pi}{N_\lambda \sin^{-1}\left[\frac{1}{S}\sin\left(\frac{\pi S}{N_\lambda}\right)\right]}\,c. \tag{9.47}$$

This is exactly the expression from equation 9.35b. The wave-amplitude multiplier per grid cell of propagation is given by:

$$e^{\tilde{k}_{\text{imag}}\Delta} \equiv e^{-\alpha\Delta} = e^0 = 1. \tag{9.48}$$

Thus, there is a constant wave amplitude with spatial position for this range of N_λ.

Complex Numerical Wave Number Regime

For $N_\lambda < N_\lambda|_{\text{transition}}$, we observe that $\zeta > 1$ in equation 9.43. Here, the following relation for the complex-valued arc–sine function given by Churchill *et al.* (1976) is useful:

$$\sin^{-1}(\zeta) = -j\ln\left(j\zeta + \sqrt{1-\zeta^2}\right). \tag{9.49}$$

Substituting equation 9.49 into 9.43 yields after some algebraic manipulation:

$$\tilde{k}_{\text{real}} = \frac{\pi}{\Delta}; \quad \tilde{k}_{\text{imag}} = -\frac{2}{\Delta}\ln\left(\zeta + \sqrt{\zeta^2-1}\right). \tag{9.50a, b}$$

The numerical phase–velocity is then:

$$\tilde{v}_p = \frac{\omega}{\tilde{k}_{\text{real}}} = \frac{\omega}{(\pi/\Delta)} = \frac{2\pi f\Delta}{\pi} = \frac{2f\lambda_0}{N_\lambda} = \frac{2}{N_\lambda}c. \tag{9.51}$$

The wave-amplitude multiplier per grid cell of propagation is given by:

$$e^{\tilde{k}_{\text{imag}}\Delta} \equiv e^{-\alpha\Delta} = e^{-2\ln\left(\zeta+\sqrt{\zeta^2-1}\right)} = \frac{1}{\left(\zeta + \sqrt{\zeta^2-1}\right)^2}. \tag{9.52}$$

Because $\zeta > 1$, the numerical wave amplitude decays exponentially with spatial position.

We now consider the possibility of $\tilde{v}_p$ exceeding c in this situation. Nyquist theory states that any physical or numerical process that obtains samples of a time waveform every Δt seconds can reproduce the original waveform without aliasing for spectral content up to $f_{\max} = 1/(2\Delta t)$. In the present case, the corresponding minimum free space wavelength that can be sampled without aliasing is therefore:

$$\lambda_{0,\,\min} = c/f_{\max} = 2c\Delta t. \tag{9.53a}$$

The corresponding minimum spatial-sampling density is as follows:

$$N_{\lambda,\,\min} = \lambda_{0,\,\min}/\Delta = 2c\Delta t/\Delta = 2S. \tag{9.53b}$$

Then, from equation 9.51, the maximum numerical phase velocity is given by:

$$\tilde{v}_{p,\,\max} = \frac{2}{N_{\lambda,\,\min}}c = \frac{2}{2S}c = \frac{c}{S}. \tag{9.54a}$$

From the definition of S, this maximum phase velocity can also be expressed as:

$$\tilde{v}_{p,\,\max} = \frac{1}{S}c = \left(\frac{\Delta}{c\Delta t}\right)c = \frac{\Delta}{\Delta t}. \tag{9.54b}$$

This relation tells us that in one Δt, a numerical value can propagate at most one Δ. This is intuitively correct given the local nature of the spatial differences used in the Yee algorithm. That is, a field point more than one Δ away from a source point that undergoes a sudden change cannot possibly "feel" the effect of that change during the next Δt. Note that $\tilde{v}_{p,\,\max}$ is independent of material parameters and is an inherent property of the grid and its method of obtaining space derivatives.

Case 2: Numerical Wave Propagation Along a Grid Diagonal

We next explore the possibility of complex-valued wavenumbers arising for oblique numerical wave propagation in a square-cell grid. For convenience, we rewrite equation 9.36a, the corresponding numerical dispersion relation:

$$\tilde{k} = \frac{2\sqrt{2}}{\Delta}\sin^{-1}\left[\frac{1}{S\sqrt{2}}\sin\left(\frac{\pi S}{N_\lambda}\right)\right] \equiv \frac{2\sqrt{2}}{\Delta}\sin^{-1}(\zeta), \qquad (9.55)$$

where:

$$\zeta = \frac{1}{S\sqrt{2}}\sin\left(\frac{\pi S}{N_\lambda}\right), \qquad (9.56)$$

Similar to the previous case of numerical wave propagation along the principal lattice axes, it is possible to choose S and N_λ such that $\tilde{k}$ is complex. In the specific case of equation 9.55, the transition between real and complex values of $\tilde{k}$ occurs when $\zeta = 1$. Solving for N_λ at this transition results in:

$$N_\lambda|_{\text{transition}} = \frac{\pi S}{\sin^{-1}\left(S\sqrt{2}\right)}. \qquad (9.57)$$

We now discuss how $\tilde{k}$ and $\tilde{v}_p$ vary with grid sampling N_λ, both above and below the transition between real and complex numerical wavenumbers.

Real Numerical Wave Number Regime

For $N_\lambda \geq N_\lambda|_{\text{transition}}$, we have from equation 9.55:

$$\tilde{k}_{\text{real}} = \frac{2\sqrt{2}}{\Delta}\sin^{-1}\left[\frac{1}{S\sqrt{2}}\sin\left(\frac{\pi S}{N_\lambda}\right)\right]; \quad \tilde{k}_{\text{imag}} = 0. \qquad (9.58\text{a, b})$$

The numerical phase velocity is given by:

$$\tilde{v}_p = \frac{\omega}{\tilde{k}_{\text{real}}} = \frac{\pi}{N_\lambda\sqrt{2}\sin^{-1}\left[\frac{1}{S\sqrt{2}}\sin\left(\frac{\pi S}{N_\lambda}\right)\right]}c. \qquad (9.59)$$

This is exactly expression 9.36b. The wave-amplitude multiplier per grid cell of propagation is given by:

$$e^{\tilde{k}_{\text{imag}}\Delta} \equiv e^{-\alpha\Delta} = e^0 = 1. \qquad (9.60)$$

Thus, there is a constant wave amplitude with spatial position for this range of N_λ.

Complex Numerical Wave Number Regime

For $N_\lambda < N_\lambda|_{\text{transition}}$, we observe that $\zeta > 1$ in equation 9.55. Substituting the complex-valued arc–sine function of equation 9.49 into 9.55 into yields after some algebraic manipulation gives the following:

$$\tilde{k}_{\text{real}} = \frac{\pi\sqrt{2}}{\Delta}; \quad \tilde{k}_{\text{imag}} = -\frac{2\sqrt{2}}{\Delta}\ln\left(\zeta + \sqrt{\zeta^2 - 1}\right). \qquad (9.61\text{a, b})$$

The numerical phase velocity for this case is as follows:

$$\tilde{v}_p = \frac{\omega}{\tilde{k}_{\text{real}}} = \frac{\omega}{\left(\pi\sqrt{2}/\Delta\right)} = \frac{\sqrt{2}f\lambda_0}{N_\lambda} = \frac{\sqrt{2}}{N_\lambda}c, \qquad (9.62)$$

and the wave-amplitude multiplier per grid cell of propagation is as follows:

$$e^{\tilde{k}_{\text{imag}}\Delta} \equiv e^{-\alpha\Delta} = e^{-2\sqrt{2}\ln\left(\zeta+\sqrt{\zeta^2-1}\right)} = \frac{1}{\left(\zeta + \sqrt{\zeta^2 - 1}\right)^{2\sqrt{2}}}. \qquad (9.63)$$

Since $\zeta > 1$, the numerical wave amplitude decays exponentially with spatial position.

We again consider the possibility of $\tilde{v}_p$ exceeding c. From our previous discussion of equations 9.53a and 9.53b, the minimum free space wavelength that can be sampled without aliasing is $\lambda_{0,\,\text{min}} = c/f_{\text{max}} = 2c\Delta t$, and the corresponding minimum spatial-sampling density is $N_{\lambda,\,\text{min}} = \lambda_{0,\,\text{min}}/\Delta = 2S$. Then from equation 9.62, the maximum numerical phase velocity is given by:

$$\tilde{v}_{p,\ \text{max}} = \frac{\sqrt{2}}{N_{\lambda,\ \text{min}}}c = \frac{\sqrt{2}}{2S}c. \qquad (9.64\text{a})$$

From the definition of S, this maximum phase velocity can also be expressed as:

$$\tilde{v}_{p,\ \text{max}} = \frac{\sqrt{2}}{2}\left(\frac{\Delta}{c\Delta t}\right)c = \frac{\sqrt{2}\Delta}{2\Delta t}. \qquad (9.64\text{b})$$

This relation tells us that in $2\Delta t$, a numerical value can propagate at most $\sqrt{2}\Delta$ along the grid diagonal. We can show that this upper bound on $\tilde{v}_p$ is intuitively correct given the local nature of the spatial differences used in the Yee algorithm. Consider two nearest neighbor field points $P_{i,\,j}$ and $P_{i+1,\,j+1}$ along a grid diagonal and how a sudden change at $P_{i,\,j}$ could be communicated to $P_{i+1,\,j+1}$. Now, a basic principle is that the Yee algorithm can communicate field data only along Cartesian (x and y) grid lines and not along grid diagonals. Thus, at the minimum, $1\Delta t$ would be needed to transfer any part of the field perturbation at $P_{i,\,j}$ over a distance of 1Δ in the x direction to $P_{i+1,\,j}$. Then, a second Δt would be needed, at the minimum, to transfer any part of the resulting field perturbation at $P_{i+1,\,j}$ over a distance of 1Δ in the y direction to reach $P_{i+1,\,j+1}$. Because the distance between $P_{i,\,j}$ and $P_{i+1,\,j+1}$ is $\sqrt{2}\Delta$, the maximum effective velocity of signal transmission between the two points is $\sqrt{2}\Delta/2\Delta t$. By this reasoning, we see that $\tilde{v}_{p,\ \text{max}}$ is an inherent property of the FDTD grid.

Example of Calculation of Numerical Phase–Velocity and Attenuation

This subsection provides sample calculations of values of the numerical phase–velocity and the exponential attenuation

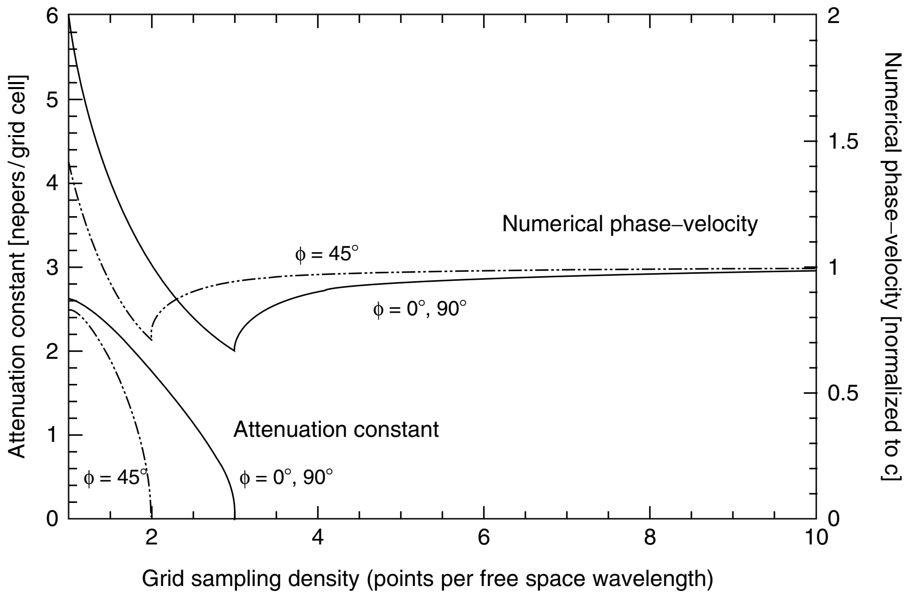

FIGURE 9.5 Normalized Numerical Phase–Velocity and Exponential Attenuation Constant per Grid Cell. These quantities are plotted versus the grid sampling density for on-axis and oblique wave propagation. The value of $S = 0.5$.

constant for the case of a two-dimensional square-cell Yee grid. These calculations are based on the numerical dispersion analyses of the previous two sections.

Figure 9.5 graphs the normalized numerical phase–velocity and the exponential attenuation constant per grid cell as a function of grid sampling density N_λ. A Courant factor $S = 0.5$ is assumed. From this figure, we note that:

- For propagation along the principal grid axes $\phi = 0°$, $90°$, a minimum value of $\tilde{v}_p = (2/3)c$ is reached at $N_\lambda = 3$. This sampling density is also the onset of attenuation. As N_λ is reduced below 3, $\tilde{v}_p$ increases inversely with N_λ. Eventually, $\tilde{v}_p$ exceeds c for $N_\lambda < 2$ and reaches a limiting velocity of $2c$ as $N_\lambda \rightarrow 1$. In this limit, as well, the attenuation constant approaches a value of 2.634 nepers/cell.
- For propagation along the grid diagonal at $\phi = 45°$, a minimum value of $\tilde{v}_p = (\sqrt{2}/2)c$ is reached at $N_\lambda = 2$. This point is also the onset of exponential attenuation. As N_λ is reduced below 2, $\tilde{v}_p$ increases inversely with N_λ. Eventually, $\tilde{v}_p$ exceeds c for $N_\lambda < \sqrt{2}$ and reaches a limiting velocity of $\sqrt{2}c$ as $N_\lambda \rightarrow 1$. In this limit, as well, the attenuation constant approaches a value of 2.493 nepers/cell.

Overall, for both the on-axis and oblique cases of numerical wave propagation, we see that very coarsely resolved wave modes in the grid can propagate at superluminal speeds but are rapidly attenuated.

Figure 9.6 graphs the percent error in the numerical phase–velocity relative to c for lossless wave propagation along the principal grid axes $\phi = 0°, 90°$. In the present example wherein $S = 0.5$, this lossless propagation regime exists for $N_\lambda \geq 3$. Figure 9.6 also graphs the percent velocity error for lossless wave propagation along the grid diagonal $\phi = 45°$. This lossless regime exists for $N_\lambda \geq 2$ for $S = 0.5$. As $N_\lambda \gg 10$, we see that the numerical phase–velocity error at each wave-propagation angle diminishes as the inverse square of N_λ. This is indicative of the second-order-accurate nature of the Yee algorithm.

Examples of Calculations of Pulse Propagation in a One-Dimensional Grid

Figure 9.7(A) graphs examples of the calculated propagation of a 40-cell-wide rectangular pulse in free space for two cases of the Courant factor: $S = 1$ (i.e., Δt is equal to the value for dispersionless propagation in a one-dimensional grid) and $S = 0.99$. To permit a direct comparison of these results, both "snapshots" are taken at the same absolute time after the onset of time-stepping. There are three key observations:

1. When $S = 1$, the rectangular shape and spatial width of the pulse are completely preserved. For this case, the abrupt step discontinuities of the propagating pulse are modeled perfectly. In fact, this is expected since $\tilde{v}_p \equiv c$ for all numerical modes in the grid.
2. When $S = 0.99$, there is appreciable "ringing" located behind the leading and trailing edges of the pulse. This is due to short-wavelength numerical modes in the grid generated at the step discontinuities of the wave. These numerical modes are poorly sampled in space and,

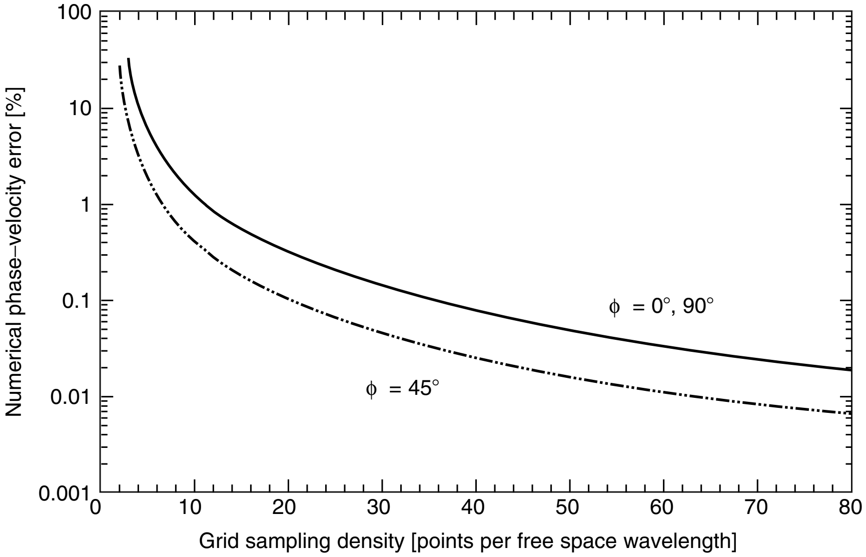

FIGURE 9.6 Percent Numerical Phase–Velocity Error Relative to the Free Space Speed of Light. This quantity is plotted as a function of the grid sampling density for on-axis and oblique wave propagation. The value of $S = 0.5$.

hence, travel slower than c, thereby lagging behind the causative discontinuities.

3. When $S = 0.99$, a weak superluminal response propagates just ahead of the leading edge of the pulse. This is again due to short-wavelength numerical modes in the grid generated at the step-function wavefront. These modes, however have spatial wavelengths even shorter than those noted in point 2. These are in fact so short that their grid sampling density drops below the upper bound for complex wavenumbers and the modes appear in the superluminal and exponentially decaying regime.

Figure 9.7(B) repeats the examples of Figure 9.7(A), but for the Courant factors $S = 1$ and $S = 0.5$. We see that the duration and periodicity of the ringing is greater than that for $S = 0.99$. Further, the superluminal response is more pronounced and less damped.

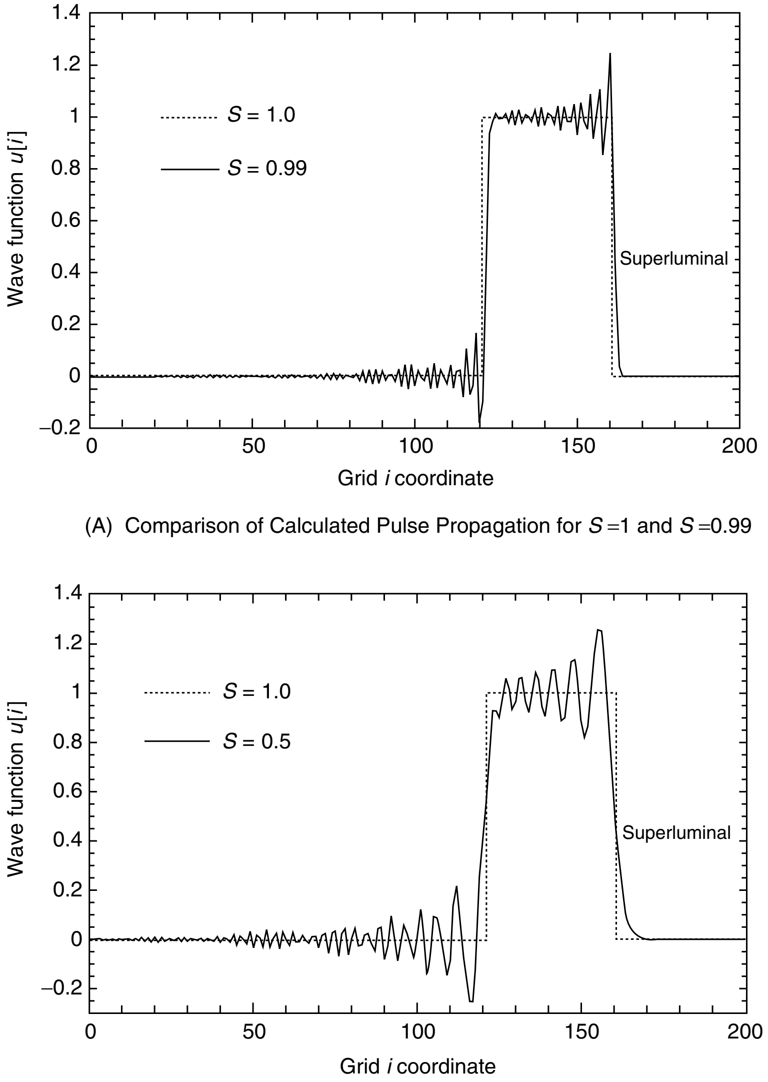
Figures 9.8(A) and 9.8(B) repeat the above examples but for a Gaussian pulse having a 40-grid-cell spatial width between its $1/e$ points. We see that the calculated pulse propagation for $S = 0.99$ shows no observable difference relative to the perfect propagation case of $S = 1$. Even for $S = 0.5$, the calculated propagation shows only a slight retardation relative to the exact solution, as expected, because $\tilde{v}_p < c$ for virtually all modes in the grid. Further, there is no observable superluminal precursor. All of these phenomena result from the fact that, for this case, virtually the entire spatial spectrum of propagating wavelengths in the grid is well resolved by the grid's sampling process. As a result, almost all numerical phase-velocity errors relative to c are well below 1%. This allows the Gaussian pulse to "hold together" while propagating over significant distances in the grid.

Example of Calculation of Pulse Propagation in a Two-Dimensional Grid

Figure 9.9 presents an example of the calculation of a radially outward-propagating cylindrical wave in a two-dimensional TM$_z$ grid. A 360 × 360 – cell square grid with $\Delta x = \Delta y = \Delta = 1.0$ is used in this example. The grid is numerically excited at its center point by applying a unit-step time-function to a single E_z field component. We assume the Courant factor $S = \sqrt{2}/2$, which yields dispersionless propagation for numerical plane-wave modes propagating along the grid diagonals $\phi = 45°, 135°, 225°$, and $315°$. In Figure 9.9(A), we graph snapshots of the E_z distribution versus radial distance from the source. Here, field observations are made along cuts through the grid passing through the source and either parallel to the principal grid axes $\phi = 0°, 90°$ or parallel to the grid diagonal $\phi = 45°$. The snapshots are taken $232\Delta t$ after the beginning of time-stepping. At this time, the wave has not yet reached the outer grid boundary.

Figure 9.9(A) illustrates two nonphysical artifacts arising from numerical dispersion. First, for both observation cuts, the leading edge of the wave exhibits an oscillatory spatial jitter superimposed upon the normal field falloff profile. Second, for the observation cuts along the grid axes, the leading edge of the wave exhibits a small, spatially decaying, superluminal component.

To see these artifacts more easily, Figure 9.9(B) shows an expanded view of the leading edge of the wave. Consider first the oscillatory jitter. Similar to the results shown in Figure 9.7, the jitter is due to short-wavelength numerical modes in the grid generated at the step-function wave front. According to our dispersion theory, these numerical modes are poorly



(A) Comparison of Calculated Pulse Propagation for S =1 and S =0.99

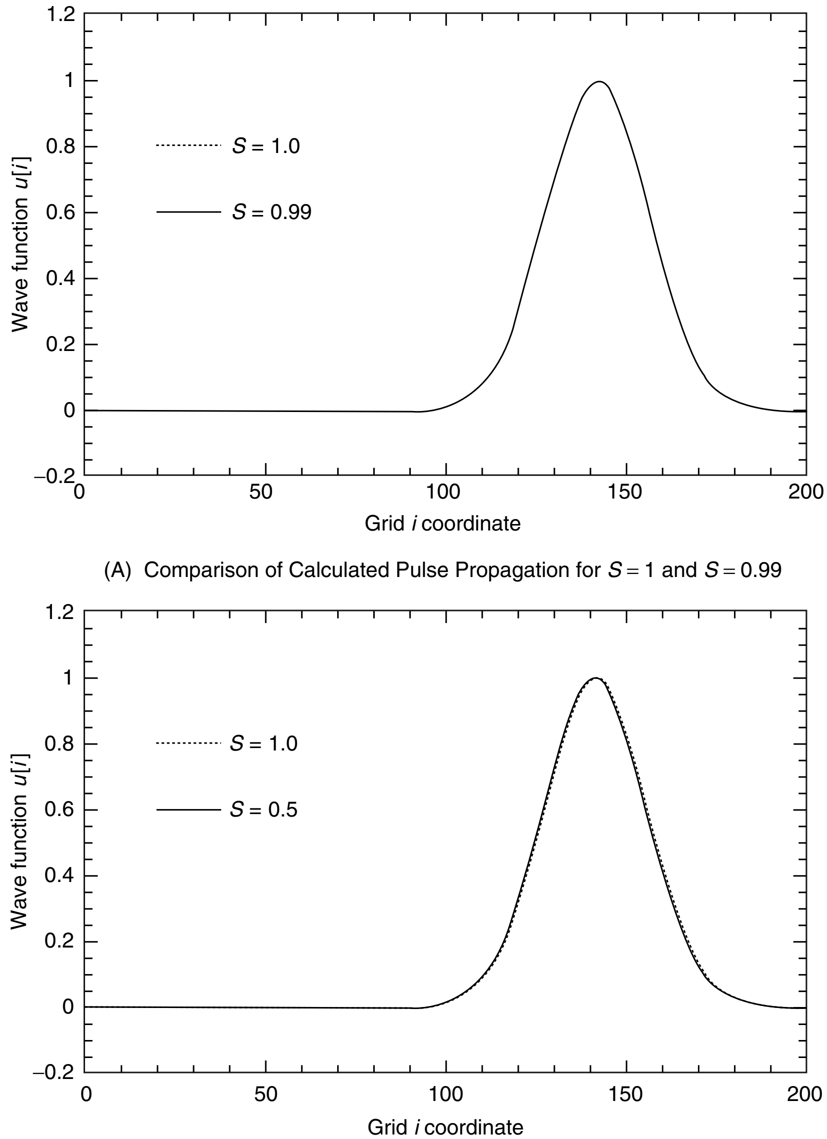
(B) Comparison of Calculated Pulse Propagation for S =1 and S =0.5

FIGURE 9.7 Effect of Numerical Dispersion on a Rectangular Pulse Propagating in Free Space. This occurs in a 1-D grid for three different Courant factors: $S = 1$, $S = 0.99$, and $S = 0.5$.

sampled in space and, hence, travel slower than c, thereby lagging behind the actual wavefront. While the jitter is most pronounced along the grid axes $\phi = 0°, 90°$, it is nonetheless finite along $\phi = 45°$ despite the choice of $S = \sqrt{2}/2$ (which implies dispersionless propagation along grid diagonals).

In Figure 9.9(B), the apparent anomaly of observing dispersion-induced jitter along what should be a dispersionless wave path at $\phi = 45°$ is resolved by noting that numerical dispersion introduces a slightly anisotropic propagation characteristic of the background free space in the grid versus azimuth angle ϕ. The resulting inhomogeneity of the free space background scatters part of the radially propagating numerical wave into the ϕ direction. Thus, no point behind the wavefront can avoid the short-wavelength numerical jitter.

Consider next the superluminal artifact present at the leading edge of the wave shown in Figure 9.9(B) for $\phi = 0°, 90°$ but not for $\phi = 45°$. This is again due to short-wavelength numerical modes in the grid generated at the leading edge of the outgoing step-function wave. However, these modes have spatial wavelengths so short that their grid sampling density drops below the threshold delineated in equation 9.45, and the modes appear in the superluminal and exponentially decaying regime. With $S = \sqrt{2}/2$ in the present example, we conclude that the lack of a superluminal artifact along the $\phi = 45°$ cut (and the consequent exact modeling of the step discontinuity at the leading edge of the wave) is due to a dispersionless numerical wave propagation along grid diagonals.



(A) Comparison of Calculated Pulse Propagation for $S = 1$ and $S = 0.99$

(B) Comparison of Calculated Pulse Propagation for $S = 1$ and $S = 0.5$

9.5 Numerical Stability

9.5.1 Introduction

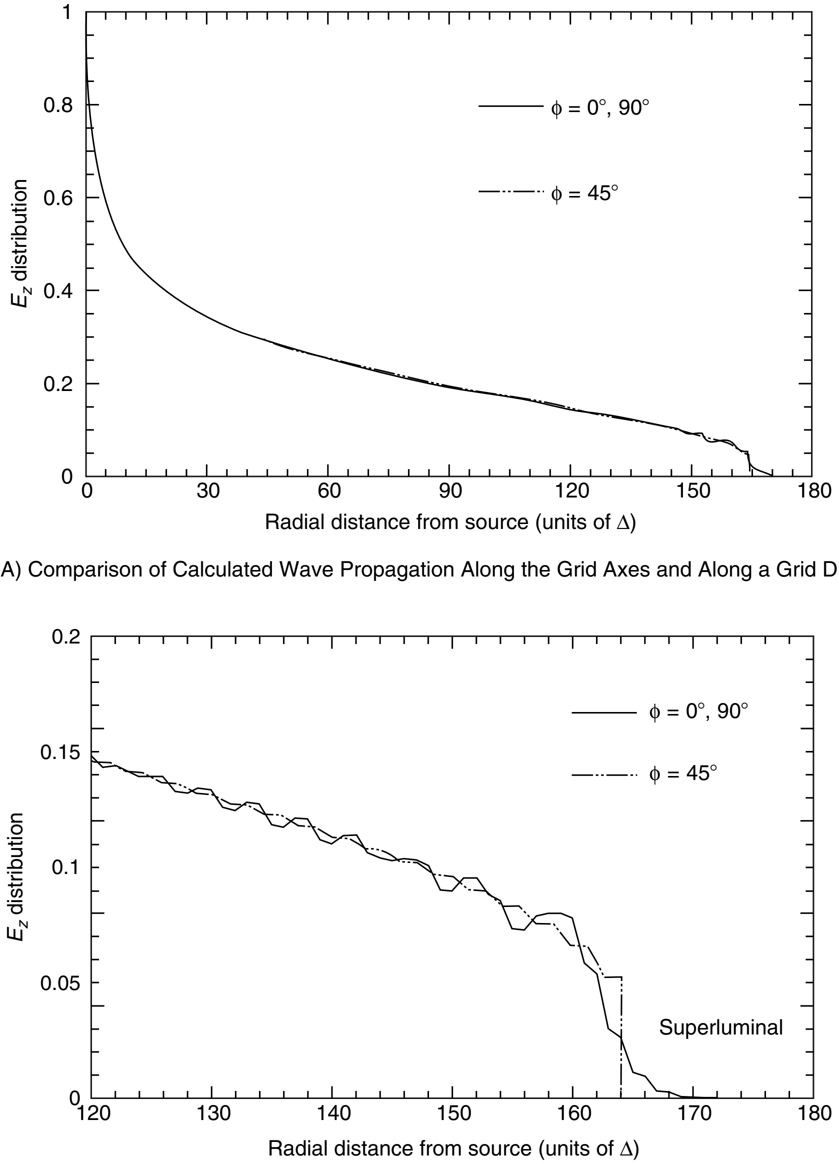
In Section 9.4, we saw that the choice of Δ and Δt can affect the propagation characteristics of numerical waves in the FDTD space lattice and, therefore, the numerical error. In this section, we show that, in addition, Δt must be bounded to ensure numerical stability. Our approach to determine the upper bound on Δt is based on the complex-frequency analysis reported by Taflove and Hagness (2000). This technique allows straightforward estimates of the exponential growth rate of unstable numerical solutions.

9.5.2 Complex-Frequency Analysis

We first postulate a sinusoidal traveling wave present in the three-dimensional FDTD space lattice and discretely sampled at (x_I, y_J, z_K, t_n), allowing for the possibility of a complex-valued numerical angular frequency, $\tilde{\omega} = \tilde{\omega}_{\text{real}} + j\tilde{\omega}_{\text{imag}}$. A field vector in this wave can be written as:

$$\begin{aligned} \vec{V}\big|_{I,\,J,\,K}^{n} &= \vec{V}_0 e^{j\left[(\tilde{\omega}_{\text{real}}+j\tilde{\omega}_{\text{imag}})n\Delta t-\tilde{k}_x I\Delta x-\tilde{k}_y J\Delta y-\tilde{k}_z K\Delta z\right]} \\ &= \vec{V}_0 e^{-\tilde{\omega}_{\text{imag}} n\Delta t} e^{j\left(\tilde{\omega}_{\text{real}} n\Delta t-\tilde{k}_x I\Delta x-\tilde{k}_y J\Delta y-\tilde{k}_z K\Delta z\right)}, \end{aligned} \tag{9.65}$$

where $\tilde{k}$ is the wavenumber of the numerical sinusoidal traveling wave. We note that equation 9.65 permits either a constant



(A) Comparison of Calculated Wave Propagation Along the Grid Axes and Along a Grid Diagonal

(B) Expanded View of (A) at Distances Between 120Δ and 180Δ Grid Cells from the Source

FIGURE 9.9 Effect of Numerical Dispersion on a Radially Propagating Cylindrical Wave in a 2-D Square Cell TM$_z$ Yee Grid. The grid is excited at its center point by applying a unit-step time-function to a single E_z field component. The Courant factor is $S = \sqrt{2}/2$.

wave amplitude with time ($\tilde{\omega}_{\text{imag}} = 0$), an exponentially decreasing amplitude with time ($\tilde{\omega}_{\text{imag}} > 0$), or an exponentially increasing amplitude with time ($\tilde{\omega}_{\text{imag}} < 0$).

Given this basis, we proceed to analyze the numerical dispersion relation of equation 9.33, allowing for a complex-valued angular frequency:

$$\left[\frac{1}{c\Delta t}\sin\left(\frac{\tilde{\omega}\Delta t}{2}\right)\right]^2 = \left[\frac{1}{\Delta x}\sin\left(\frac{\tilde{k}_x\Delta x}{2}\right)\right]^2 + \left[\frac{1}{\Delta y}\sin\left(\frac{\tilde{k}_y\Delta y}{2}\right)\right]^2 + \left[\frac{1}{\Delta z}\sin\left(\frac{\tilde{k}_z\Delta z}{2}\right)\right]^2. \qquad (9.66)$$

We first solve equation 9.66 for $\tilde{\omega}$. This yields:

$$\tilde{\omega} = \frac{2}{\Delta t}\sin^{-1}(\xi), \qquad (9.67)$$

where:

$$\xi = c\Delta t\sqrt{\frac{1}{(\Delta x)^2}\sin^2\left(\frac{\tilde{k}_x\Delta x}{2}\right) + \frac{1}{(\Delta y)^2}\sin^2\left(\frac{\tilde{k}_y\Delta y}{2}\right) + \frac{1}{(\Delta z)^2}\sin^2\left(\frac{\tilde{k}_z\Delta z}{2}\right)}. \qquad (9.68)$$

We observe from equation 9.68 that:

$$0 \le \xi \le c\Delta t\sqrt{\frac{1}{(\Delta x)^2}+\frac{1}{(\Delta y)^2}+\frac{1}{(\Delta z)^2}} \equiv \xi_{\text{upper bound}}, \qquad (9.69)$$

for all possible real values of $\tilde{k}$ (i.e., those numerical waves having zero exponential attenuation per grid space cell). The $\xi_{\text{upper bound}}$ is obtained when each $\sin^2$ term under the square root of 9.68 simultaneously reaches a value of 1. This occurs for the propagating numerical wave having the wave vector components:

$$\tilde{k}_x = \pm\frac{\pi}{\Delta x}; \quad \tilde{k}_y = \pm\frac{\pi}{\Delta y}; \quad \tilde{k}_z = \pm\frac{\pi}{\Delta z}. \qquad (9.70\text{a, b, c})$$

It is clear that $\xi_{\text{upper bound}}$ can exceed 1 depending upon the choice of Δt. This yields complex values of $\sin^{-1}(\xi)$ in equation 9.67 and, therefore, complex values of $\tilde{\omega}$. To investigate further, we divide the range of ξ given in equation 9.69 into two subranges.

Stable Range: $0 \le \boldsymbol{\xi} \le 1$

Here, $\sin^{-1}(\xi)$ is real-valued, and real values of $\tilde{\omega}$ are obtained in equation 9.67. With $\tilde{\omega}_{\text{imag}} = 0$, equation 9.65 yields a constant wave amplitude with time.

Unstable Range: $1 < \boldsymbol{\xi} < \boldsymbol{\xi}_{\textbf{upper bound}}$

This subrange exists only if:

$$\xi_{\text{upper bound}} = c\Delta t\sqrt{\frac{1}{(\Delta x)^2}+\frac{1}{(\Delta y)^2}+\frac{1}{(\Delta z)^2}} > 1. \qquad (9.71)$$

The unstable range is defined in an equivalent manner by:

$$\Delta t > \frac{1}{c\sqrt{\frac{1}{(\Delta x)^2}+\frac{1}{(\Delta y)^2}+\frac{1}{(\Delta z)^2}}} \equiv \Delta t_{\substack{\text{stable}\\ \text{limit/3-D}}} \qquad (9.72)$$

To prove the claim of instability for the range $\xi > 1$, we substitute the complex-valued $\sin^{-1}(\xi)$ function of equation 9.49 into 9.67 and solve for $\tilde{\omega}$. This yields:

$$\tilde{\omega} = \frac{-j2}{\Delta t}\ln\left(j\xi + \sqrt{1-\xi^2}\right). \qquad (9.73)$$

Upon taking the natural logarithm, we obtain:

$$\tilde{\omega}_{\text{real}} = \frac{\pi}{\Delta t}; \quad \tilde{\omega}_{\text{imag}} = -\frac{2}{\Delta t}\ln\left(\xi + \sqrt{\xi^2-1}\right). \qquad (9.74)$$

Substituting equation 9.74 into 9.65 yields:

$$\begin{aligned}\vec{V}\big|^n_{I,J,K} &= \vec{V}_0 e^{2n\ln\left(\xi+\sqrt{\xi^2-1}\right)}\, e^{j\left[(\pi/\Delta t)(n\Delta t)-\tilde{k}_x I\Delta x-\tilde{k}_y J\Delta y-\tilde{k}_z K\Delta z\right]}\\ &= \vec{V}_0\left(\xi+\sqrt{\xi^2-1}\right)^{**2n} e^{j\left[(\pi/\Delta t)(n\Delta t)-\tilde{k}_x I\Delta x-\tilde{k}_y J\Delta y-\tilde{k}_z K\Delta z\right]},\end{aligned} \qquad (9.75)$$

where $^{**}2n$ denotes the $2n$'th power. From equation 9.75, we define the following multiplicative factor greater than 1 that amplifies the numerical wave every time-step:

$$q_{\text{growth}} \equiv \left(\xi+\sqrt{\xi^2-1}\right)^2. \qquad (9.76)$$

Equations 9.75 and 9.76 define an exponential growth of the numerical wave with time-step number n. We see that the dominant exponential growth occurs for the most positive possible value of ξ (i.e., $\xi_{\text{upper bound}}$ defined in equation 9.69).

Example of Calculating a Stability Bound: Three-Dimensional Cubic-Cell Lattice

Consider the practical case of a three-dimensional (3-D) cubic-cell space lattice with $\Delta x = \Delta y = \Delta z = \Delta$. From equation 9.72, numerical instability arises when:

$$\Delta t > \frac{1}{c\sqrt{\frac{1}{(\Delta)^2}+\frac{1}{(\Delta)^2}+\frac{1}{(\Delta)^2}}} = \frac{1}{c\sqrt{\frac{3}{(\Delta)^2}}} = \frac{\Delta}{c\sqrt{3}}. \qquad (9.77)$$

We define an equivalent Courant stability limit for the cubic-cell lattice case:

$$S_{\substack{\text{stability}\\ \text{limit/3-D}}} = \frac{1}{\sqrt{3}}. \qquad (9.78)$$

From equation 9.70, the dominant exponential growth is seen to occur for numerical waves propagating along the lattice diagonals. The relevant wave vectors are as follows:

$$\vec{\tilde{k}} = \frac{\pi}{\Delta}(\pm\hat{x}\pm\hat{y}\pm\hat{z}) \to \left|\vec{\tilde{k}}\right| = \frac{\pi\sqrt{3}}{\Delta} \to \tilde{\lambda} = \left(\frac{2\sqrt{3}}{3}\right)\Delta, \qquad (9.79)$$

where $\hat{x}$, $\hat{y}$, and $\hat{z}$ are unit vectors defining the major lattice axes. Further, equation 9.69 yields:

$$\xi_{\substack{\text{upper}\\ \text{bound}}} = c\Delta t\sqrt{\frac{1}{(\Delta)^2}+\frac{1}{(\Delta)^2}+\frac{1}{(\Delta)^2}} = \left(\frac{c\Delta t}{\Delta}\right)\sqrt{3} = S\sqrt{3}. \qquad (9.80)$$

From equation 9.76, this implies the following maximum possible growth factor per time step under conditions of numerical instability:

$$\left.q_{\text{growth}} \equiv \left[S\sqrt{3}+\sqrt{\left(S\sqrt{3}\right)^2-1}\right]^2 \quad\right\} \text{ for } S \ge \frac{1}{\sqrt{3}}. \qquad (9.81)$$

Courant Factor Normalization and Extension to Two- and One-Dimensional Grids

It is instructive to use the results of equation 9.78 to normalize the Courant factor S in equation 9.81. This will permit us to generalize the three-dimensional results for the maximum growth factor q to two-dimensional and one-dimensional (1-D) Yee (1966) grids. In this spirit, we define:

$$S_{\text{norm 3-D}} \equiv \frac{S}{S_{\substack{\text{stability}\\ \text{limit 3-D}}}} = \frac{S}{\left(1/\sqrt{3}\right)} = S\sqrt{3}. \tag{9.82}$$

Then, equation 9.81 can be written as:

$$q_{\text{growth}} = \left[S_{\text{norm 3-D}} + \sqrt{\left(S_{\text{norm 3-D}}\right)^2 - 1}\,\right]^2 \Bigg\} \text{for } S_{\text{norm 3-D}} \geq 1. \tag{9.83}$$

Given this notation, it can be shown that analogous expressions for the Courant stability limit and the growth factor under conditions of numerical instability are given by:

Two-Dimensional Square Yee Grid

$$S_{\substack{\text{stability}\\ \text{limit 2-D}}} = \frac{1}{\sqrt{2}}. \tag{9.84}$$

$$S_{\text{norm 2-D}} \equiv \frac{S}{S_{\substack{\text{stability}\\ \text{limit 2-D}}}} = \frac{S}{\left(1/\sqrt{2}\right)} = S\sqrt{2}. \tag{9.85}$$

Here, dominant exponential growth occurs for numerical waves propagating along the grid diagonals. The relevant wavevectors are the following:

$$\tilde{\vec{k}} = \frac{\pi}{\Delta}(\pm\hat{x} \pm \hat{y}) \rightarrow \left|\tilde{\vec{k}}\right| = \frac{\pi\sqrt{2}}{\Delta} \rightarrow \tilde{\lambda} = \sqrt{2}\Delta. \tag{9.86}$$

This yields the following solution growth factor per time-step:

$$q_{\text{growth}} = \left[S_{\text{norm 2-D}} + \sqrt{\left(S_{\text{norm 2-D}}\right)^2 - 1}\,\right]^2 \Bigg\} \text{ for } S_{\text{norm 2-D}} \geq 1. \tag{9.87}$$

One-Dimensional Uniform Yee Grid

$$S_{\substack{\text{stability}\\ \text{limit 1-D}}} = 1. \tag{9.88}$$

$$S_{\text{norm1-D}} \equiv \frac{S}{S_{\substack{\text{stability}\\ \text{limit 1-D}}}} = \frac{S}{1} = S. \tag{9.89}$$

Dominant exponential growth occurs for the wave vectors:

$$\tilde{\vec{k}} = \pm\frac{\pi}{\Delta}\hat{x} \rightarrow \left|\tilde{\vec{k}}\right| = \frac{\pi}{\Delta} \rightarrow \tilde{\lambda} = 2\Delta. \tag{9.90}$$

This yields the following solution growth factor per time-step:

$$q_{\text{growth}} = \left(S + \sqrt{S^2 - 1}\right)^2 \Bigg\} \text{ for } S \geq 1. \tag{9.91}$$

We see from the above discussion that the solution growth factor q under conditions of numerical instability is the same, regardless of the dimensionality of the FDTD space lattice if the same normalized Courant factor is used. A normalized Courant factor equal to 1 yields no exponential solution growth for any dimensionality grid. However, a normalized Courant factor only 0.05% larger, yields a multiplicative solution growth of 1.0653 every time-step for each dimensionality grid:

- $S = 1.0005$ for a uniform, one-dimensional grid
- $S = 1.0005 \times (1/\sqrt{2}) = 0.707460$ for a uniform, square, two-dimensional grid
- $S = 1.0005 \times (1/\sqrt{3}) = 0.577639$ for a uniform, cubic, three-dimensional grid

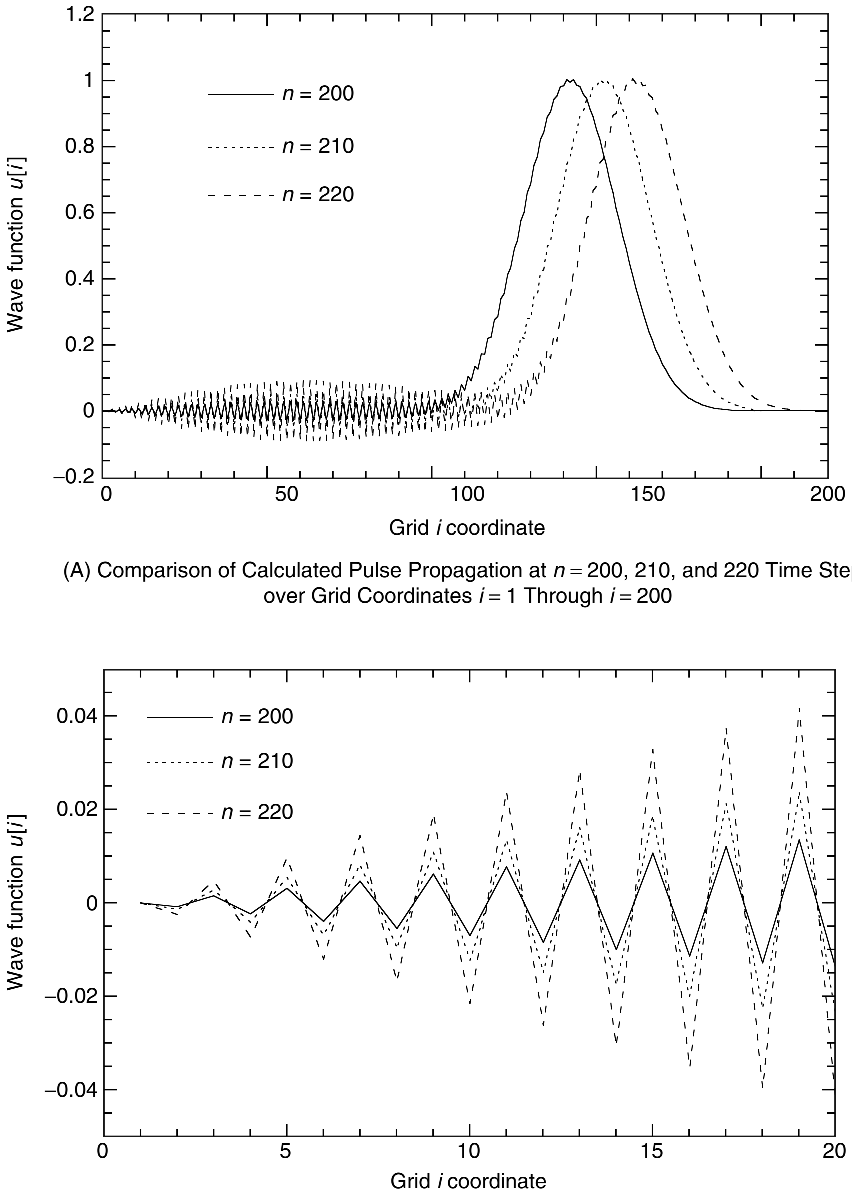
This is equivalent to a solution growth of 1.8822 every 10 time-steps, 558.7 every 100 time-steps, and 2.96×10^{27} every 1,000 time-steps.

9.5.3 Examples of Calculations Involving Numerical Instability in a 1-D Grid

We first consider an example of the beginning of a numerical instability arising because the Courant stability condition is violated equally at *every* point in a uniform one-dimensional grid. Figure 9.10(A) graphs three snapshots of the free space propagation of a Gaussian pulse in a grid having the Courant factor $S = 1.0005$. The exciting pulse waveform has a $40\Delta t$ temporal width between its $1/e$ points and reaches its peak value of 1.0 at time-step $n = 60$. Graphs of the wavefunction $u(i)$ versus the grid coordinate i are shown at time-steps $n = 200$, $n = 210$, and $n = 220$.

From Figure 9.10(A), we see that the trailing edge of the Gaussian pulse is contaminated by a rapidly oscillating and growing noise component that does not exist in Figure 9.8(A), which shows the same Gaussian pulse at the same time but with $S \leq 1.0$. In fact, the noise component in Figure 9.10(A) results from the onset of numerical instability in the grid due to $S = 1.0005 > 1.0$. Because this noise grows exponentially with time-step number n, it quickly overwhelms the desired numerical results for the propagating Gaussian pulse. Shortly thereafter, the exponential growth of the noise increases the calculated field values beyond the dynamic range of the computer being used, resulting in run-time floating-point overflows and errors.

Figure 9.10(B) is an expanded view of Figure 9.10(A) between grid points $i = 1$ and $i = 20$, showing a segment of the numerical noise on the trailing edge of the Gaussian pulse. We see that the noise oscillates with a spatial period of 2 grid cells



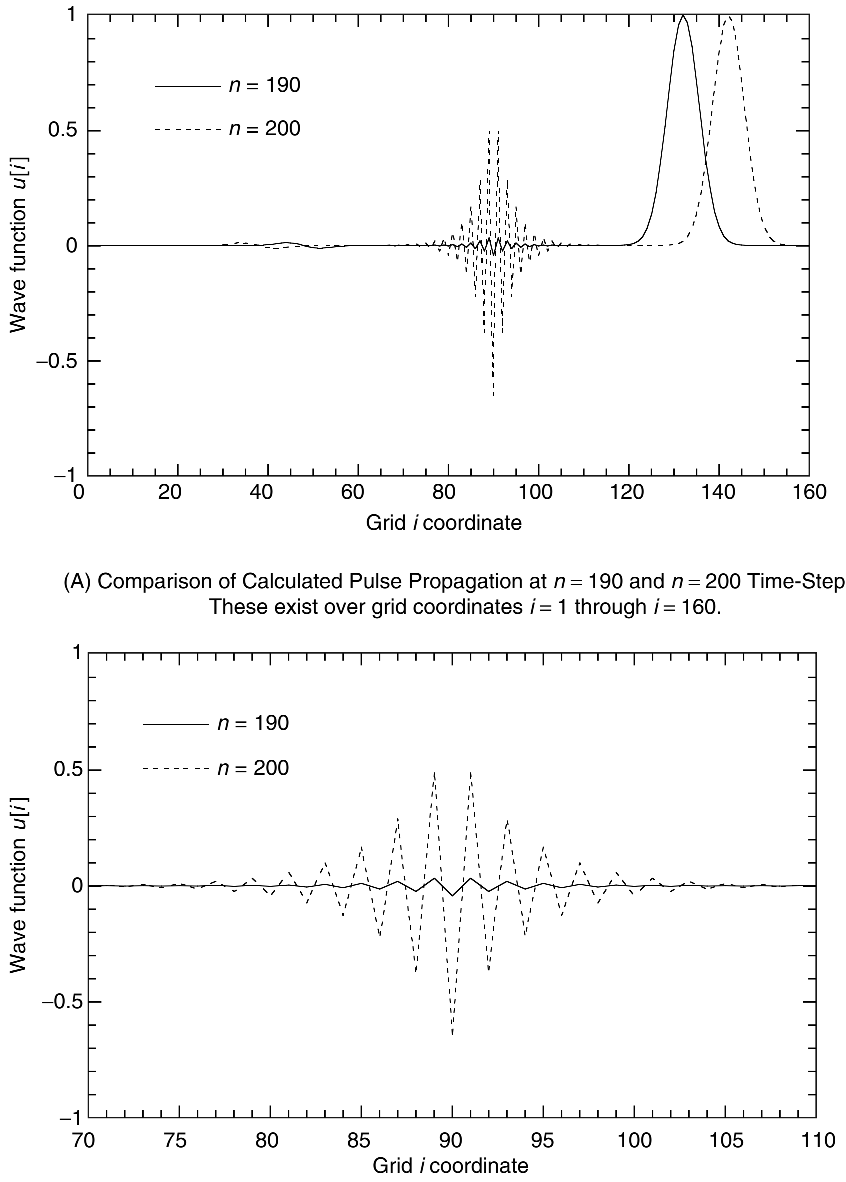
(A) Comparison of Calculated Pulse Propagation at $n = 200$, 210, and 220 Time Steps over Grid Coordinates $i = 1$ Through $i = 200$

(B) Expanded View of (A) over Grid Coordinates $i = 1$ Through $i = 20$

FIGURE 9.10 The Beginning of Numerical Instability for a Gaussian Pulse Propagating in a Uniform, Free Space 1-D Grid. The Courant factor is $S = 1.0005$ at each grid point.

(i.e., $\tilde{\lambda} = 2\Delta x$) in accordance with equation 9.90. In addition, when analyzing the raw data underlying Figure 9.10(B), it is observed that the growth factor q is in the range 1.058 to 1.072 per time-step. This compares favorably with the theoretical value of 1.0653 determined using equation 9.91.

We next consider an example of the beginning of a numerical instability arising because the Courant stability condition is violated at only a *single* point in a uniform one-dimensional grid. Figure 9.11(A) graphs two snapshots of the free space propagation of a narrow Gaussian pulse in a grid having the Courant factor $S = 1.0$ at all points except at $i = 90$, where $S = 1.2075$. The exciting pulse has a $10\Delta t$ temporal width between its $1/e$ points and reaches its peak value of 1.0 at time-step $n = 60$. Graphs of the wave function $u(i)$ versus the grid coordinate i are shown at time-steps $n = 190$ and $n = 200$. In contrast to Figure 9.10(A), the rapidly oscillating and growing noise component due to numerical instability originates at just a single grid point along the trailing edge of



(A) Comparison of Calculated Pulse Propagation at $n = 190$ and $n = 200$ Time-Steps. These exist over grid coordinates $i = 1$ through $i = 160$.

(B) Expanded View of (A) over Grid Coordinates $i = 70$ Through $i = 110$

FIGURE 9.11 The Beginning of Numerical Instability for a Gaussian Pulse Propagating in a Uniform, Free Space 1-D Grid. The Courant factor is $S = 1$ at all grid points but $i = 90$, where $S = 1.2075$.

the Gaussian pulse ($i = 90$), where S exceeds 1.0, rather than along the entirety of the trailing edge. Despite this localization of the source of the instability, the noise again grows exponentially with time-step number n. In this case, the noise propagates symmetrically in both directions from the unstable point. Ultimately, the noise again fills the entire grid, overwhelms the desired numerical results for the propagating Gaussian pulse, and causes run-time floating-point overflows.

Figure 9.11(B) is an expanded view of Figure 9.11(A) between grid points $i = 70$ and $i = 110$, showing how the calculated noise due to the numerical instability originates at $i = 90$. Again, in accordance with equation 9.90, the noise oscillates with a spatial period of two grid cells (i.e. $\tilde{\lambda} = 2\Delta x$). However, the rate of exponential growth here is much less than that predicted by equation 9.91, wherein *all* grid points were assumed to violate Courant stability. Upon analyzing the raw data underlying Figure 9.11(B), a growth factor of $q \cong 1.31$ is observed per time-step. This compares to $q \cong 3.55$ per time-step determined by substituting $S = 1.2075$ into equation 9.91. Thus, it is clear that a grid having one or just a few localized points of numerical instability can "blow up" much more slowly than a uniformly unstable grid having a comparable or even smaller Courant factor S.

9.5.4 Example of Calculation Involving Numerical Instability in a Two-Dimensional Grid

We next consider an FDTD modeling example where the Courant stability condition is violated equally at every point in a uniform two-dimensional TM$_z$ grid. To allow direct comparison with a previous example of stable pulse propagation, the same grid in Figure 9.9 is used. The overall grid size is again 360 × 360 square cells with $\Delta x = \Delta y = 1.0 \equiv \Delta$. Numerical excitation to the grid is again provided by specifying a unit-step time-function for the center E_z component. The only condition that differs from those assumed in the original grid is that the Courant factor S is increased above the threshold for numerical instability given by equation 9.84.

Figure 9.12(A) visualizes the two-dimensional E_z distribution at $n = 40$ time-steps for $S = 1.005 \times (1/\sqrt{2})$. This value of S quickly generates a region of numerical instability spreading out radially from the source, where the field amplitudes are large enough to mask the normal wave propagation. Individual E_z components in the grid are depicted as square pixels. We see that the unstable field pattern has the form of a checkerboard, wherein dark and gray pixels denote positive and negative E_z values, respectively. Here, pixel saturation denotes the relative amplitude of its positive or negative value.

Figure 9.12(B) graphs the variation of E_z versus radial distance from the source at $n = 200$ time-steps for $S = 1.0005 \times (1/\sqrt{2})$. Two distinct plots are shown. The solid line graph exhibits a rapid spatial oscillation with the period 2Δ. This is the E_z behavior along the $\phi = 0°, 90°$ (and similar on-axis) cuts through the grid. The smooth dashed-dotted curve with no spatial oscillation represents the E_z behavior along the $\phi = 45°$ (and similar oblique) cuts through the grid. Analysis of the underlying data reveals growth factors in the range 1.060 to 1.069 per time-step along the leading edge of the instability region. This agrees very well with $q_{\text{growth}} = 1.0653$ calculated using equation 9.87 and is an excellent validation of the Courant-factor-normalization theory.

An interesting observation in Figure 9.12(B) is that the smooth E_z variation along $\phi = 45°$ forms the envelope of the oscillatory E_z distribution observed along the grid's major axes. This difference in behavior is confirmed in Figure 9.12(A), which shows that the $\phi = 45°$ cut lies entirely within a diagonal string of dark (positive) pixels, whereas the $\phi = 0°$ cut passes through alternating dark (positive) and gray (negative) pixels. We attribute this behavior to equation 9.86, which states that the exponential growth along the grid diagonal has $\tilde{\lambda} = \sqrt{2}\Delta$. That is, the numerical wavelength along the 45° observation cut for the unstable mode is exactly the diagonal length across one $\Delta \times \Delta$ grid cell. Thus, there exists 2π (or equivalently, 0) phase shift of the unstable mode between adjacent observation points along the $\phi = 45°$ cut. Adjacent E_z values along $\phi = 45°$ cannot change sign. In contrast, equation 9.86 reduces to $\tilde{k} = \pi/\Delta$, (i.e., $\tilde{\lambda} = 2\Delta$) for the unstable mode along the $\phi = 0°, 90°$ cuts. Therefore, there is π phase shift of the unstable mode between adjacent observation points along $\phi = 0°, 90°$, yielding the point-by-point sign reversals (rapid spatial oscillations) seen in Figure 9.12(B).

9.5.5 Linear Instability When the Normalized Courant Factor Equals 1

The general field vector postulated in equation 9.65 permits a numerical wave amplitude that is either constant, exponentially growing, or exponentially decaying as time-stepping progresses. Min and Teng (2001) have identified a linear growth mode, (i.e., a linear instability) that can occur if the normalized Courant factor equals exactly 1. While this growth mode is much slower than the exponential instability discussed previously, the analyst should proceed with caution when using $S_{\text{norm}} = 1$.

9.6 Perfectly Matched Layer Absorbing Boundary Conditions

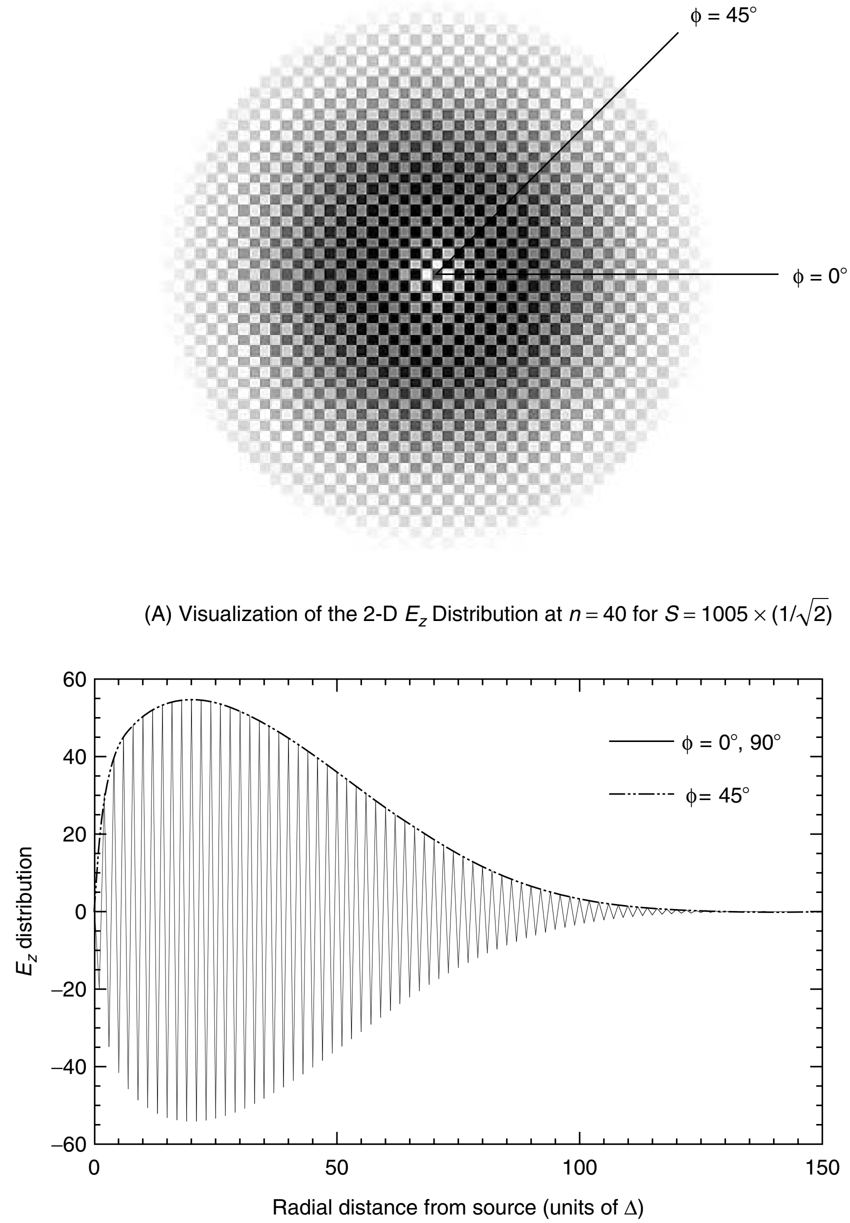
9.6.1 Introduction

Many electromagnetic wave interaction problems are defined on "open" regions where the spatial domain is partially or completely unbounded. Since no computer can store an unlimited data set, FDTD space lattices for such problems must somehow be truncated without introducing error due to spurious reflection of outward-propagating numerical waves. Grid truncation conditions of this type are popularly called **absorbing boundary conditions** (ABCs) because of their requirement to absorb outward-propagating numerical modes with negligible reflection.

ABCs cannot be directly obtained from the Yee algorithm (1966) because it requires field data on both sides of an observation point and, hence, cannot be implemented at the outermost planes of a space lattice. Although backward finite differences could conceivably be used here, these are generally of lower accuracy for a given space discretization and have not been used in any major FDTD software.

Research in this area since 1970 has resulted in two principal categories of ABCs for FDTD simulations:

1. The first category is special analytical boundary conditions imposed on the electromagnetic field at the outermost planes of the space lattice. This category was reviewed by Taflove and Hagness (2000).
2. The second category is incorporation of **perfectly matched layer** (PML) absorbing media adjacent to the



(A) Visualization of the 2-D E_z Distribution at $n = 40$ for $S = 1005 \times (1/\sqrt{2})$

(B) E_z Distributions Along the Grid Axes and Grid Diagonal at $n = 200$ for $S = 1.005 \times (1/\sqrt{2})$. The theoretical and measured growth factor is $q_{\text{growth}} \cong 1.065$ per time-step.

FIGURE 9.12 Effect of Numerical Instability on a 2-D Pulse-Propagation Model.

outer planes of the space lattice (by analogy with the treatment of the walls of an anechoic chamber). ABCs of this type have excellent capabilities for truncation of FDTD lattices in free space, in lossy or dispersive materials, or in metal or dielectric waveguides. Extremely small numerical wave reflection coefficients in the order of 10^{-4} to 10^{-6} can be attained with an acceptable computational burden, allowing the possibility of achieving FDTD simulations having a dynamic range of 70 dB or more.

This section reviews the formulation and application of PML ABCs. The review is based on the publication by Gedney and Taflove (2000).

9.6.2 Brief History

Consider implementing an ABC by using an impedance-matched electromagnetic wave absorbing layer adjacent to the outer planes of the FDTD space lattice. Ideally, the absorbing medium is only a few lattice cells thick, reflectionless to all impinging waves over their full frequency spectrum, highly absorbing, and effective in the near field of a source or a scatterer. An early attempt at implementing such an absorbing material boundary condition was reported by Holland and Williams (1983) who utilized a conventional lossy, dispersionless, and absorbing medium. The difficulty with this tactic is that such an absorbing layer is matched only to normally incident plane waves.

Berenger (1994) provided the seminal insight that a nonphysical PML could be implemented at the outer boundary of an FDTD grid to completely absorb outgoing waves regardless of their frequency, angle of incidence, and polarization. The key was to exploit additional degrees of freedom arising from a novel split-field formulation of Maxwell's equations. Here, each field vector component is split into two orthogonal components, and the 12 resulting field components are expressed as satisfying two coupled first-order partial differential equations. By choosing loss parameters consistent with a dispersionless medium, a perfectly matched planar interface is derived.

Following Berenger's work, many papers appeared validating his technique as well as applying FDTD with the PML medium. An important advance was made by Chew and Weedon (1994), who restated the original split-field PML concept in a stretched-coordinate form. Subsequently, this allowed Teixeira and Chew (1997) to extend PML to cylindrical and spherical coordinate systems. A second important advance was made by Sacks *et al.* (1995) and Gedney (1995, 1996), who reposed the split-field PML as a lossy, uniaxial anisotropic medium having both magnetic permeability and electric permittivity tensors. The uniaxial PML, or UPML, is intriguing because it is based on a potentially physically realizable material formulation rather than Berenger's nonphysical mathematical model.

9.6.3 Berenger's Perfectly Matched Layer

Two-Dimensional TE$_z$ Case

This section reviews the theoretical basis of Berenger's PML for the case of a TE$_z$-polarized plane wave incident from region 1, the lossless material half-space $x < 0$, onto region 2, the PML half-space $x > 0$.

Field-Splitting Modification of Maxwell's Equations

Within region 2, Maxwell's curl equations (9.12a through 9.12c) as modified by Berenger are expressed in their time-dependent form as:

$$\varepsilon_2 \frac{\partial E_x}{\partial t} + \sigma_y E_x = \frac{\partial H_z}{\partial y}. \qquad (9.92a)$$

$$\varepsilon_2 \frac{\partial E_y}{\partial t} + \sigma_x E_y = -\frac{\partial H_z}{\partial x}. \qquad (9.92b)$$

$$\mu_2 \frac{\partial H_{zx}}{\partial t} + \sigma_x^* H_{zx} = -\frac{\partial E_y}{\partial x}. \qquad (9.92c)$$

$$\mu_2 \frac{\partial H_{zy}}{\partial t} + \sigma_y^* H_{zy} = \frac{\partial E_x}{\partial y}. \qquad (9.92d)$$

Here, H_z is assumed to be split into two additive subcomponents:

$$H_z = H_{zx} + H_{zy}. \qquad (9.93)$$

Further, the parameters σ_x and σ_y denote electric conductivities, and the parameters σ_x^* and σ_y^* denote magnetic losses.

Berenger's formulation represents a generalization of normally modeled physical media. If $\sigma_x = \sigma_y = 0$ and $\sigma_x^* = \sigma_y^* = 0$, equations 9.92a through 9.92d reduce to Maxwell's equations in a lossless medium. If $\sigma_x = \sigma_y = \sigma$ and $\sigma_x^* = \sigma_y^* = 0$, equations 9.92a through 9.92d describe an electrically conductive medium. If $\varepsilon_2 = \varepsilon_1$, $\mu_2 = \mu_1$, $\sigma_x = \sigma_y = \sigma$, $\sigma_x^* = \sigma_y^* = \sigma^*$, and:

$$\sigma^*/\mu_1 = \sigma/\varepsilon_1 \quad \rightarrow \quad \sigma^* = \sigma\mu_1/\varepsilon_1 = \sigma(\eta_1)^2, \qquad (9.94)$$

then equations 9.92a through 9.92d describe an absorbing medium that is impedance-matched to region 1 for normally incident plane waves.

Additional possibilities present themselves, however. If $\sigma_y = \sigma_y^* = 0$, the medium can absorb a plane wave having field components (E_y, H_{zx}) propagating along *x*, but it does not absorb a wave having field components (E_x, H_{zy}) propagating along *y*, since in the first case propagation is governed by equations 9.92b and 9.92c and in the second case by equations 9.92a and 9.92d. The converse situation is true for waves (E_y, H_{zx}) and (E_x, H_{zy}) if $\sigma_x = \sigma_x^* = 0$. These properties of particular Berenger media characterized by the pairwise parameter sets (σ_x, σ_x^*, 0, 0) and (0, 0, σ_y, σ_y^*) are closely related to the fundamental premise of this novel ABC, as proved later in this chapter. That is, if the pairwise electric and magnetic losses satisfy equation 9.94, then at interfaces normal to *x* and *y*, respectively, the Berenger media have zero reflection of electromagnetic waves.

Now consider equations 9.92a through 9.92d expressed in their time-harmonic form in the Berenger medium. Letting the hat symbol denote a phasor quantity, we write:

$$j\omega\varepsilon_2 \left(1 + \frac{\sigma_y}{j\omega\varepsilon_2}\right) \breve{E}_x = \frac{\partial}{\partial y}\left(\breve{H}_{zx} + \breve{H}_{zy}\right). \qquad (9.95a)$$

$$j\omega\varepsilon_2 \left(1 + \frac{\sigma_x}{j\omega\varepsilon_2}\right) \breve{E}_y = -\frac{\partial}{\partial x}\left(\breve{H}_{zx} + \breve{H}_{zy}\right). \qquad (9.95b)$$

$$j\omega\mu_2\left(1+\frac{\sigma_x^*}{j\omega\mu_2}\right)\breve{H}_{zx}=-\frac{\partial\breve{E}_y}{\partial x}. \tag{9.95c}$$

$$j\omega\mu_2\left(1+\frac{\sigma_y^*}{j\omega\mu_2}\right)\breve{H}_{zy}=\frac{\partial\breve{E}_x}{\partial y}. \tag{9.95d}$$

The notation is simplified by introducting the variables:

$$s_w=\left(1+\frac{\sigma_w}{j\omega\varepsilon_2}\right)\ ;\quad s_w^*=\left(1+\frac{\sigma_w^*}{j\omega\mu_2}\right)\ :\ w=x,\ y. \tag{9.96}$$

Then, equations 9.95a and 9.95b are rewritten as:

$$j\omega\varepsilon_2 s_y\breve{E}_x=\frac{\partial}{\partial y}\left(\breve{H}_{zx}+\breve{H}_{zy}\right). \tag{9.97a}$$

$$j\omega\varepsilon_2 s_x\breve{E}_y=-\frac{\partial}{\partial x}\left(\breve{H}_{zx}+\breve{H}_{zy}\right). \tag{9.97b}$$

Plane-Wave Solution in the Berenger Medium

The next step is to derive the plane-wave solution in the Berenger medium. To this end, equation 9.97a is differentiated with respect to y and equation 9.97b with respect to x. Substituting the expressions for $\partial\breve{E}_y/\partial x$ and $\partial\breve{E}_x/\partial y$ from equations 9.95c and 9.95d leads to:

$$-\omega^2\mu_2\varepsilon_2\breve{H}_{zx}=-\frac{1}{s_x^*}\frac{\partial}{\partial x}\frac{1}{s_x}\frac{\partial}{\partial x}\left(\breve{H}_{zx}+\breve{H}_{zy}\right). \tag{9.98a}$$

$$-\omega^2\mu_2\varepsilon_2\breve{H}_{zy}=-\frac{1}{s_y^*}\frac{\partial}{\partial y}\frac{1}{s_y}\frac{\partial}{\partial y}\left(\breve{H}_{zx}+\breve{H}_{zy}\right). \tag{9.98b}$$

Adding these together and using equation 9.93 leads to the representative wave equation:

$$\frac{1}{s_x^*}\frac{\partial}{\partial x}\frac{1}{s_x}\frac{\partial}{\partial x}\breve{H}_z+\frac{1}{s_y^*}\frac{\partial}{\partial y}\frac{1}{s_y}\frac{\partial}{\partial y}\breve{H}_z+\omega^2\mu_2\varepsilon_2\breve{H}_z=0. \tag{9.99}$$

This wave equation supports the solutions:

$$\breve{H}_z=H_0\tau e^{-j\sqrt{s_xs_x^*}\beta_{2_x}x-j\sqrt{s_ys_y^*}\beta_{2_y}y}, \tag{9.100}$$

with the dispersion relationship:

$$(\beta_{2_x})^2+\left(\beta_{2_y}\right)^2=(k_2)^2\ \rightarrow\ \beta_{2_x}=\left[(k_2)^2-\left(\beta_{2_y}\right)^2\right]^{1/2}. \tag{9.101}$$

Then, from equations 9.97a, 9.97b, and 9.93, we have:

$$\breve{E}_x=-H_0\tau\frac{\beta_{2_y}}{\omega\varepsilon_2}\sqrt{\frac{s_y^*}{s_y}}e^{-j\sqrt{s_xs_x^*}\beta_{2_x}x-j\sqrt{s_ys_y^*}\beta_{2_y}y}. \tag{9.102}$$

$$\breve{E}_y=H_0\tau\frac{\beta_{2_x}}{\omega\varepsilon_2}\sqrt{\frac{s_x^*}{s_x}}e^{-j\sqrt{s_xs_x^*}\beta_{2_x}x-j\sqrt{s_ys_y^*}\beta_{2_y}y}. \tag{9.103}$$

Despite the field splitting, continuity of the tangential electric and magnetic fields must be preserved across the $x=0$ interface. To enforce this field continuity, we have $s_y=s_y^*=1$ or, equivalently, $\sigma_y=0=\sigma_y^*$. This yields the phase-matching condition $\beta_{2_y}=\beta_{1_y}=k_1\sin\theta$. Further, we derive the H-field reflection and transmission coefficients as:

$$\Gamma=\left(\frac{\beta_{1_x}}{\omega\varepsilon_1}-\frac{\beta_{2_x}}{\omega\varepsilon_2}\sqrt{\frac{s_x^*}{s_x}}\right)\times\left(\frac{\beta_{1_x}}{\omega\varepsilon_1}+\frac{\beta_{2_x}}{\omega\varepsilon_2}\sqrt{\frac{s_x^*}{s_x}}\right)^{-1};\ \tau=1+\Gamma. \tag{9.104a, b}$$

Reflectionless Matching Condition

Now, assume $\varepsilon_1=\varepsilon_2$, $\mu_1=\mu_2$, and $s_x=s_x^*$. This is equivalent to $k_1=k_2$, $\eta_1=\sqrt{\mu_1/\varepsilon_1}=\sqrt{\mu_2/\varepsilon_2}$, and $\sigma_x/\varepsilon_1=\sigma_x^*/\mu_1$ (i.e., σ_x and σ_x^* satisfying equation 9.94 in a pairwise manner). With $\beta_{2_y}=\beta_{1_y}$, equation 9.101 now yields $\beta_{2_x}=\beta_{1_x}$. Substituting into 9.104a gives the reflectionless condition $\Gamma=0$ for *all* incident angles regardless of frequency ω. For this case, equations 9.100, 9.102, 9.103, and 9.104b specify the following transmitted fields in the Berenger medium:

$$\breve{H}_z=H_0e^{-js_x\beta_{1_x}x-j\beta_{1_y}y}=H_0e^{-j\beta_{1_x}x-j\beta_{1_y}y}e^{-\sigma_x x\eta_1\cos\theta}. \tag{9.105}$$

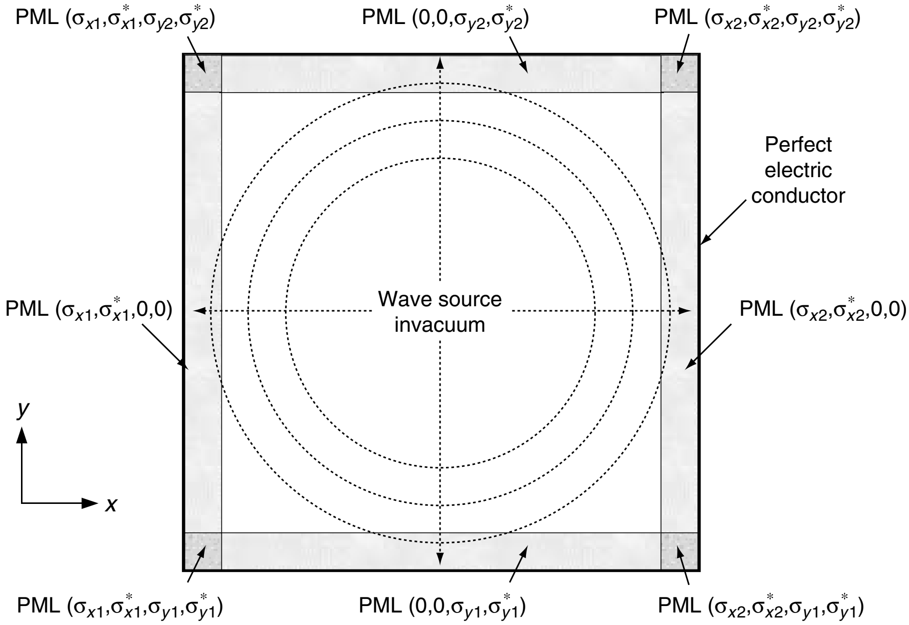
$$\breve{E}_x=-H_0\eta_1\sin\theta e^{-j\beta_{1_x}x-j\beta_{1_y}y}e^{-\sigma_x x\eta_1\cos\theta}. \tag{9.106}$$

$$\breve{E}_y=H_0\eta_1\cos\theta e^{-j\beta_{1_x}x-j\beta_{1_y}y}e^{-\sigma_x x\eta_1\cos\theta}. \tag{9.107}$$

Within the matched Berenger medium, the transmitted wave propagates with the same speed and direction as the impinging wave while simultaneously undergoing exponential decay along the x-axis normal to the interface between regions 1 and 2. Further, the attenuation factor $\sigma_x\eta_1\cos\theta$ is independent of frequency. These desirable properties apply to all angles of incidence. Hence, Berenger's coining of the term "perfectly matched layer" makes excellent sense.

Structure of an FDTD Grid Employing Berenger's PML ABC

The analysis in the previous paragraphs can be repeated for PMLs that are normal to the y direction. This permitted Berenger to propose the two-dimensional TE$_z$ FDTD grid shown in Figure 9.13, which uses PMLs to greatly reduce outer-boundary reflections. Here, a free-space computation zone is surrounded by PML backed by perfect electric conductor (PEC) walls. At the left and right sides of the grid (x_1 and x_2), each PML has σ_x and σ_x^* matched according to equation 9.94 along with $\sigma_y=0=\sigma_y^*$ to permit reflectionless transmission across the interface between the free space and PML regions. At the lower and upper sides of the grid (y_1 and y_2), each PML has σ_y and σ_y^* matched according to



PML (σ_{x1},σ^*_{x1},σ_{y2},σ^*_{y2})
PML (0,0,σ_{y2},σ^*_{y2})
PML (σ_{x2},σ^*_{x2},σ_{y2},σ^*_{y2})
Perfect electric conductor
PML (σ_{x1},σ^*_{x1},0,0)
Wave source invacuum
PML (σ_{x2},σ^*_{x2},0,0)
y
x
PML (σ_{x1},σ^*_{x1},σ_{y1},σ^*_{y1})
PML (0,0,σ_{y1},σ^*_{y1})
PML (σ_{x2},σ^*_{x2},σ_{y1},σ^*_{y1})

FIGURE 9.13 Structure of a 2-D TE$_z$FDTD Grid Employing the Berenger PML ABC. Figure adapted from Berenger (1994).

equation 9.94 along with $\sigma_x = 0 = \sigma_x^*$. At the four corners of the grid where there is overlap of two PMLs, all four losses (σ_x, σ_x^*, σ_y, and σ_y^*) are present and set equal to those of the adjacent PMLs.

Two-Dimensional TM$_z$ Case

The analysis of the previous section can be repeated for the case of a TM$_z$-polarized incident wave wherein we implement the field splitting $E_z = E_{zx} + E_{zy}$. Analogous to equations 9.92, Maxwell's curl equations 9.11a to 9.11c as modified by Berenger are expressed in their time-dependent form as:

$$\mu_2 \frac{\partial H_x}{\partial t} + \sigma_y^* H_x = -\frac{\partial E_z}{\partial y}. \tag{9.108a}$$

$$\mu_2 \frac{\partial H_y}{\partial t} + \sigma_x^* H_y = \frac{\partial E_z}{\partial x}. \tag{9.108b}$$

$$\varepsilon_2 \frac{\partial E_{zx}}{\partial t} + \sigma_x E_{zx} = \frac{\partial H_y}{\partial x}. \tag{9.108c}$$

$$\varepsilon_2 \frac{\partial E_{zy}}{\partial t} + \sigma_y E_{zy} = -\frac{\partial H_x}{\partial y}. \tag{9.108d}$$

A derivation of the PML properties conducted in a manner analogous to that of the TE$_z$ case yields slightly changed results. In most of the equations, the change is only a permutation of ε_2 with μ_2 and of σ with σ^*. However, the PML matching conditions are unchanged. This permits an absorbing reflectionless layer to be constructed adjacent to the outer grid boundary, as in the TE$_z$ case.

Three-Dimensional Case

Katz *et al.* (1994) showed that Berenger's PML can be realized in three dimensions by splitting all six Cartesian field vector components. For example, the modified Ampere's law is given by:

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_y\right) E_{xy} = \frac{\partial}{\partial y}(H_{zx} + H_{zy}). \tag{9.109a}$$

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_z\right) E_{xz} = -\frac{\partial}{\partial z}(H_{yx} + H_{yz}). \tag{9.109b}$$

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_z\right) E_{yz} = \frac{\partial}{\partial z}(H_{xy} + H_{xz}). \tag{9.109c}$$

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_x\right) E_{yx} = -\frac{\partial}{\partial x}(H_{zx} + H_{zy}). \tag{9.109d}$$

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_x\right) E_{zx} = \frac{\partial}{\partial x}(H_{yx} + H_{yz}). \tag{9.109e}$$

$$\left(\varepsilon \frac{\partial}{\partial t} + \sigma_y\right) E_{zy} = -\frac{\partial}{\partial y}(H_{xy} + H_{xz}). \tag{9.109f}$$

Similarly, the modified Faraday's law is given by:

$$\left(\mu \frac{\partial}{\partial t} + \sigma_y^*\right) H_{xy} = -\frac{\partial}{\partial y}(E_{zx} + E_{zy}). \tag{9.110a}$$

$$\left(\mu \frac{\partial}{\partial t} + \sigma_z^*\right) H_{xz} = \frac{\partial}{\partial z}(E_{yx} + E_{yz}). \tag{9.110b}$$

$$\left(\mu\frac{\partial}{\partial t}+\sigma_z^*\right)H_{yz} = -\frac{\partial}{\partial z}(E_{xy}+E_{xz}). \qquad (9.110c)$$

$$\left(\mu\frac{\partial}{\partial t}+\sigma_x^*\right)H_{yx} = \frac{\partial}{\partial x}(E_{zx}+E_{zy}). \qquad (9.110d)$$

$$\left(\mu\frac{\partial}{\partial t}+\sigma_x^*\right)H_{zx} = -\frac{\partial}{\partial x}(E_{yx}+E_{yz}). \qquad (9.110e)$$

$$\left(\mu\frac{\partial}{\partial t}+\sigma_y^*\right)H_{zy} = \frac{\partial}{\partial y}(E_{xy}+E_{xz}). \qquad (9.110f)$$

PML matching conditions analogous to the two-dimensional cases discussed previously are used. Specifically, if we denote $w = x, y, z$, the matching condition at a normal-to-w PML interface has the parameter pair (σ_w, σ_w^*) to satisfy equation 9.94. This causes the transmitted wave in the PML to undergo exponential decay in the $\pm w$ directions. All other (σ_w, σ_w^*) pairs in this PML are zero. In a corner region, the PML is provided with each matched (σ_w, σ_w^*) pair that is assigned to the overlapping PMLs forming the corner. Thus, PML media located in dihedral corner overlapping regions have two nonzero and one zero (σ_w, σ_w^*) pairs. PML media located in trihedral corner overlapping regions have three nonzero (σ_w, σ_w^*) pairs.

9.6.4 An Anisotropic PML Absorbing Medium

The split-field PML introduced by Berenger is a hypothetical, nonphysical medium based on a mathematical model. Due to the coordinate dependence of the loss terms, if such a physical medium exists, it must be anisotropic.

Indeed, a physical model based on an anisotropic, perfectly matched medium can be formulated. This was first discussed by Sacks *et al.* (1995). For a single interface, the anisotropic medium is uniaxial and is composed of both electric and magnetic constitutive tensors. This uniaxial PML, or UPML, performs as well as Berenger's PML while avoiding its nonphysical field splitting. Further, as summarized in Gedney and Taflove (2000), UPML has capabilities exceeding Berenger's PML by providing additional degrees of freedom which permit it to attenuate evanescent waves and terminate conductive and dispersive materials. The next subsection summarizes the frequency- and time-domain realizations of the UPML ABC.

Generalized Three-Dimensional Formulation: Frequency Domain

Following Gedney and Taflove (2000), we can write the time-harmonic Maxwell's curl equations in a three-dimensional UPML medium as:

$$\nabla \times \breve{\vec{H}} = j\omega\varepsilon\bar{\bar{s}}\breve{\vec{E}}; \quad \nabla \times \breve{\vec{E}} = -j\omega\mu\bar{\bar{s}}\breve{\vec{H}}, \qquad (9.111a, b)$$

where $\bar{\bar{s}}$ is the diagonal tensor defined by:

$$\bar{\bar{s}} = \begin{bmatrix} s_x^{-1} & 0 & 0 \\ 0 & s_x & 0 \\ 0 & 0 & s_x \end{bmatrix} \begin{bmatrix} s_y & 0 & 0 \\ 0 & s_y^{-1} & 0 \\ 0 & 0 & s_y \end{bmatrix} \begin{bmatrix} s_z & 0 & 0 \\ 0 & s_z & 0 \\ 0 & 0 & s_z^{-1} \end{bmatrix}$$
$$= \begin{bmatrix} s_y s_z s_x^{-1} & 0 & 0 \\ 0 & s_x s_z s_y^{-1} & 0 \\ 0 & 0 & s_x s_y s_z^{-1} \end{bmatrix} \qquad (9.112)$$

Allowing for a nonunity real part κ, the multiplicative components of the diagonal elements of $\bar{\bar{s}}$ are given by:

$$s_x = \kappa_x + \frac{\sigma_x}{j\omega\varepsilon}; \; s_y = \kappa_y + \frac{\sigma_y}{j\omega\varepsilon}; \; s_z = \kappa_z + \frac{\sigma_z}{j\omega\varepsilon}. \qquad (9.113a, b, c)$$

If desired, the UPML medium can be specialized to apply throughout the entire FDTD space lattice. The following lists all of the possible special cases.

Lossless, Isotropic Interior Zone

The tensor $\bar{\bar{s}}$ is an identity tensor realized by setting $s_x = s_y = s_z = 1$ in equation 9.112. This requires $\sigma_x = \sigma_y = \sigma_z = 0$ and $\kappa_x = \kappa_y = \kappa_z = 1$ in equations 9.113.

UPML absorbers at x_{min} and x_{max} outer-boundary planes:

We set $s_y = s_z = 1$ in equation 9.112. This requires $\sigma_y = \sigma_z = 0$ and $\kappa_y = \kappa_z = 1$ in equations 9.113

UPML absorbers at y_{min} and y_{max} outer-boundary planes:

We set $s_x = s_z = 1$ in equation 9.112. This requires $\sigma_x = \sigma_z = 0$ and $\kappa_x = \kappa_z = 1$ in equations 9.113.

UPML absorbers at z_{min} and z_{max} outer-boundary planes:

We set $s_x = s_y = 1$ in equation 9.112. This requires $\sigma_x = \sigma_y = 0$ and $\kappa_x = \kappa_y = 1$ in equations 9.113.

Overlapping UPML absorbers at x_{min}, x_{max} and y_{min}, y_{max} dihedral corners:

We set $s_z = 1$ in equation 9.112. This requires $\sigma_z = 0$ and $\kappa_z = 1$ in equations 9.113.

Overlapping UPML absorbers at x_{min}, x_{max} and z_{min}, z_{max} dihedral corners:

We set $s_y = 1$ in equation 9.112. This requires $\sigma_y = 0$ and $\kappa_y = 1$ in equations 9.113.

Overlapping UPML absorbers at y_{min}, y_{max} and z_{min}, z_{max} dihedral corners:

We set $s_x = 1$ in equation 9.112. This requires $\sigma_x = 0$ and $\kappa_x = 1$ in equations 9.113.

Overlapping UPML absorbers at all trihedral corners:

We use the complete general tensor in equation 9.112.

Note that the generalized constitutive tensor defined in equation 9.112 is not uniaxial by strict definition but rather is anisotropic. The anisotropic PML, however, is still referenced as uniaxial since it is uniaxial in the nonoverlapping PML regions.

Efficient Implementation of UPML in FDTD

Starting with equations 9.111a and 9.112, Ampere's law in a matched UPML is expressed as:

$$\begin{bmatrix} \frac{\partial \breve{H}_z}{\partial y} - \frac{\partial \breve{H}_y}{\partial z} \\ \frac{\partial \breve{H}_x}{\partial z} - \frac{\partial \breve{H}_z}{\partial x} \\ \frac{\partial \breve{H}_y}{\partial x} - \frac{\partial \breve{H}_x}{\partial y} \end{bmatrix} = j\omega\varepsilon \begin{bmatrix} \frac{s_y s_z}{s_x} & 0 & 0 \\ 0 & \frac{s_x s_z}{s_y} & 0 \\ 0 & 0 & \frac{s_x s_y}{s_z} \end{bmatrix} \begin{bmatrix} \breve{E}_x \\ \breve{E}_y \\ \breve{E}_z \end{bmatrix}, \qquad (9.114)$$

where s_x, s_y, and s_z are defined in equations 9.113. Directly inserting equation 9.113 into equation 9.114 and then transforming into the time domain would lead to a convolution between the tensor coefficients and the E-field. This is not advisable because implementing this convolution would be computationally intensive. As shown by Gedney (1995, 1996), a much more efficient approach is to define the proper constitutive relationship to decouple the frequency-dependent terms. Specifically, let:

$$\breve{D}_x = \varepsilon \frac{s_z}{s_x} \breve{E}_x; \quad \breve{D}_y = \varepsilon \frac{s_x}{s_y} \breve{E}_y; \quad \breve{D}_z = \varepsilon \frac{s_y}{s_z} \breve{E}_z. \qquad (9.115\text{a, b, c})$$

Then, equation 9.114 is rewritten as:

$$\begin{bmatrix} \frac{\partial \breve{H}_z}{\partial y} - \frac{\partial \breve{H}_y}{\partial z} \\ \frac{\partial \breve{H}_x}{\partial z} - \frac{\partial \breve{H}_z}{\partial x} \\ \frac{\partial \breve{H}_y}{\partial x} - \frac{\partial \breve{H}_x}{\partial_y} \end{bmatrix} = j\omega \begin{bmatrix} s_y & 0 & 0 \\ 0 & s_z & 0 \\ 0 & 0 & s_x \end{bmatrix} \begin{bmatrix} \breve{D}_x \\ \breve{D}_y \\ \breve{D}_z \end{bmatrix}. \qquad (9.116)$$

Now, we substitute s_x, s_y, and s_z from equations 9.113 into 9.116, and then apply the inverse Fourier transform using the identity $j\omega f(\omega) \rightarrow (\partial/\partial t) f(t)$. This yields an equivalent system of time-domain differential equations for equation 9.116:

$$\begin{bmatrix} \frac{\partial H_z}{\partial y} - \frac{\partial H_y}{\partial z} \\ \frac{\partial H_x}{\partial z} - \frac{\partial H_z}{\partial x} \\ \frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} \end{bmatrix} = \frac{\partial}{\partial t} \begin{bmatrix} \kappa_y & 0 & 0 \\ 0 & \kappa_z & 0 \\ 0 & 0 & \kappa_x \end{bmatrix} \begin{bmatrix} D_x \\ D_y \\ D_z \end{bmatrix} + \frac{1}{\varepsilon} \begin{bmatrix} \sigma_y & 0 & 0 \\ 0 & \sigma_z & 0 \\ 0 & 0 & \sigma_x \end{bmatrix} \begin{bmatrix} D_x \\ D_y \\ D_z \end{bmatrix}. \qquad (9.117)$$

The system of 9.117 equations can be discretized on the standard Yee lattice. It is suitable to use normal leapfrogging in time wherein the loss terms are time-averaged according to the semi-implicit scheme. This leads to explicit time-stepping expressions for D_x, D_y, and D_z. For example, the D_x update is given by:

$$D_x\big|^{n+1}_{i+1/2,\,j,\,k} = \left(\frac{2\varepsilon\kappa_y - \sigma_y\Delta t}{2\varepsilon\kappa_y + \sigma_y\Delta t}\right) D_x\big|^{n}_{i+1/2,\,j,\,k} + \left(\frac{2\varepsilon\Delta t}{2\varepsilon\kappa_y + \sigma_y\Delta t}\right) \times \left(\frac{H_z\big|^{n+1/2}_{i+1/2,j+1/2,k} - H_z\big|^{n+1/2}_{i+1/2,j-1/2,k}}{\Delta y} - \frac{H_y\big|^{n+1/2}_{i+1/2,j,k+1/2} - H_y\big|^{n+1/2}_{i+1/2,j,k-1/2}}{\Delta z} \right) \qquad (9.118)$$

Next, we focus on equations 9.115a through 9.115c. For example, we consider 9.115a. After multiplying both sides by s_x and substituting for s_x and s_z from 9.113a and 9.113c, we have:

$$\left(\kappa_x + \frac{\sigma_x}{j\omega\varepsilon}\right) \breve{D}_x = \varepsilon\left(\kappa_z + \frac{\sigma_z}{j\omega\varepsilon}\right) \breve{E}_x. \qquad (9.119)$$

Multiplying both sides by $j\omega$ and transforming into the time domain leads to:

$$\frac{\partial}{\partial t}(\kappa_x D_x) + \frac{\sigma_x}{\varepsilon} D_x = \varepsilon\left[\frac{\partial}{\partial t}(\kappa_z E_x) + \frac{\sigma_z}{\varepsilon} E_x\right]. \qquad (9.120\text{a})$$

Similarly, from equations 9.115b and 9.115c, we obtain:

$$\frac{\partial}{\partial t}(\kappa_y D_y) + \frac{\sigma_y}{\varepsilon} D_y = \varepsilon\left[\frac{\partial}{\partial t}(\kappa_x E_y) + \frac{\sigma_x}{\varepsilon} E_y\right]. \qquad (9.120\text{b})$$

$$\frac{\partial}{\partial t}(\kappa_z D_z) + \frac{\sigma_z}{\varepsilon} D_z = \varepsilon\left[\frac{\partial}{\partial t}(\kappa_y E_z) + \frac{\sigma_y}{\varepsilon} E_z\right]. \qquad (9.120\text{c})$$

The time derivatives in equations 9.120 are discretized using standard Yee leapfrogging and time-averaging the loss terms. This yields explicit time-stepping expressions for E_x, E_y, and E_z. For example, the E_x update is given by:

$$E_x\big|^{n+1}_{i+1/2,j,k} = \left(\frac{2\varepsilon\kappa_z - \sigma_z\Delta t}{2\varepsilon\kappa_z + \sigma_z\Delta t}\right) E_x\big|^{n}_{i+1/2,j,k} + \left[\frac{1}{(2\varepsilon\kappa_z + \sigma_z\Delta t)\varepsilon}\right] \times \left[(2\varepsilon\kappa_x + \sigma_x\Delta t) D_x\big|^{n+1}_{i+1/2,j,k} - (2\varepsilon\kappa_x - \sigma_x\Delta t) D_x\big|^{n}_{i+1/2,j,k}\right] \qquad (9.121)$$

Overall, updating the components of $\vec{E}$ in the UPML requires two steps in sequence: (1) obtaining the new values of the components of $\vec{D}$ according to equation 9.118, and (2) using these new $\vec{D}$ components to obtain new values of the $\vec{E}$ components according to equation 9.121.

A similar two-step procedure is required to update the components of $\vec{H}$ in the UPML. Starting with Faraday's law in equations 9.111b and 9.112, the first step involves developing the updates for the components of $\vec{B}$. A procedure analogous to that followed in obtaining equation 9.118 yields, for example, the following update for B_x:

$$B_x\big|_{i,j+1/2,k+1/2}^{n+3/2} = \left(\frac{2\varepsilon\kappa_y - \sigma_y\Delta t}{2\varepsilon\kappa_y + \sigma_y\Delta t}\right) B_x\big|_{i,j+1/2,k+1/2}^{n+1/2} - \left(\frac{2\varepsilon\Delta t}{2\varepsilon\kappa_y + \sigma_y\Delta t}\right) \times \left(\frac{E_z\big|_{i,j+1,k+1/2}^{n+1} - E_z\big|_{i,j,k+1/2}^{n+1}}{\Delta y} - \frac{E_y\big|_{i,j+1/2,k+1}^{n+1} - E_y\big|_{i,j+1/2,k}^{n+1}}{\Delta z}\right) \tag{9.122}$$

The second step involves updating the $\vec{H}$ components in the UPML using the values of the $\vec{B}$ components just obtained with equation 9.122 and similar expressions for B_y and B_z. For example, employing the dual constitutive relation $\breve{B}_x = \mu(s_z/s_x)\breve{H}_x$, a procedure analogous to that followed in obtaining equation 9.121 yields the following update for H_x:

$$H_x\big|_{i,j+1/2,k+1/2}^{n+3/2} = \left(\frac{2\varepsilon\kappa_z - \sigma_z\Delta t}{2\varepsilon\kappa_z + \sigma_z\Delta t}\right) H_x\big|_{i,j+1/2,k+1/2}^{n+1/2} + \left[\frac{1}{(2\varepsilon\kappa_z + \sigma_z\Delta t)\mu}\right] \times \left[(2\varepsilon\kappa_x + \sigma_x\Delta t) B_x\big|_{i,j+1/2,k+1/2}^{n+3/2} - (2\varepsilon\kappa_x - \sigma_x\Delta t) B_x\big|_{i,j+1/2,k+1/2}^{n+1/2}\right] \tag{9.123}$$

Similar expressions can be derived for H_y and H_z.

Nehrbass *et al.* (1996) showed that such an algorithm is numerically stable within the Courant limit. Further, Abarbanel and Gottlieb (1997) showed that the resulting discrete fields satisfy Gauss's law, and the UPML is well posed. Finally, Gedney and Taflove (2000) discussed how the UPML formulation in both the frequency domain and the time domain can be extended to terminate material regions in the FDTD space grid that are either electrically lossy or have frequency-dispersive dielectric parameters.

9.6.5 Theoretical Performance of the PML

The Continuous Space

When used to truncate an FDTD lattice, the PML has a thickness d and is terminated by the outer boundary of the lattice. If the outer boundary is assumed to be a PEC wall, finite power reflects back into the primary computation zone. For a wave impinging on the PML at angle θ relative to the w-directed surface normal, this reflection can be computed using transmission line analysis, yielding:

$$R(\theta) = e^{-2\sigma_w \eta d \cos\theta} \tag{9.124}$$

Here, η and σ_w are, respectively, the PML's characteristic wave impedance and its conductivity, referred to propagation in the w direction. In the context of an FDTD simulation, $R(\theta)$ is referred to as the "reflection error" since it is a nonphysical reflection due to the PEC wall that backs the PML. We note that the reflection error is the same for both the split-field PML and the UPML, because both support the same wave equation. This error decreases exponentially with σ_w and d. However, the reflection error increases as $\exp(\cos\theta)$, reaching the worst case for $\theta = 90°$. At this grazing angle of incidence, $R = 1$ and the PML is completely ineffective. To be useful in an FDTD simulation, we want $R(\theta)$ to be as small as possible. Clearly, for a thin PML, we must have σ_w as large as possible to reduce $R(\theta)$ to acceptably small levels, especially for θ approaching 90°.

The Discrete Space

Grading of the PML Loss Parameters

Theoretically, reflectionless wave transmission can take place across a PML interface regardless of the local step-discontinuity in σ and σ^* presented to the continuous impinging electromagnetic field. However, in FDTD or any discrete representation of Maxwell's equations, numerical artifacts arise due to the finite spatial sampling. Consequently, implementing PML as a single-step discontinuity of σ and σ^* in the FDTD lattice leads to significant spurious wave reflection at the PML surface.

To reduce this reflection error, Berenger (1994) proposed that the PML losses gradually rise from zero along the direction normal to the interface. Assuming such a grading, the PML remains matched. Pursuing this idea, we consider as an example an x-directed plane wave impinging at angle θ upon a PEC-backed PML slab of thickness d, with the front planar interface located in the $x = 0$ plane. Assuming the graded PML conductivity profile $\sigma_x(x)$, we can obtain:

$$R(\theta) = e^{-2\eta\cos\theta \int_0^d \sigma_x(x)dx}. \tag{9.125}$$

Several profiles have been suggested for grading $\sigma_x(x)$ (and $\kappa_x(x)$ in the context of the UPML). One of the most successful uses a polynomial variation of the PML loss with depth x. Polynomial grading is simply:

$$\sigma_x(x) = (x/d)^m \sigma_{x,\max}\ ;\ \kappa_x(x) = 1 + (\kappa_{x,\max} - 1)\cdot(x/d)^m. \tag{9.126a, b}$$

This increases the value of the PML σ_x from zero at $x = 0$ (the surface of the PML) to $\sigma_{x,\ \max}$ at $x = d$ (the PEC outer boundary). Similarly, for the UPML, κ_x increases from one at $x = 0$ to $\kappa_{x,\ \max}$ at $x = d$. Substituting equation 9.126a into 9.125 yields:

$$R(\theta) = e^{-2\eta\sigma_{x,\ \max} d\cos\theta/(m+1)}. \tag{9.127}$$

For a fixed d, polynomial grading provides two parameters: $\sigma_{x,\ \max}$ and m. A large m yields a $\sigma_x(x)$ distribution that is relatively flat near the PML surface. However, deeper in the

PML, σ_x increases more rapidly than for small m. In this region, the field amplitudes are substantially decayed and reflections due to the discretization error contribute less. Typically, $3 \leq m \leq 4$ has been found to be nearly optimal for many FDTD simulations (Berenger, 1996).

For polynomial grading, the PML parameters can be readily determined for a given error estimate. For example, let m, d, and the desired reflection error $R(0)$ be known. Then, from equation 9.127, $\sigma_{x,\ \max}$ is computed as:

$$\sigma_{x,\max} = -\frac{(m+1)\ln[R(0)]}{2\eta d}. \tag{9.128}$$

Discretization Error

The design of an effective PML requires balancing the theoretical reflection error $R(\theta)$ and the numerical discretization error. For example, equation 9.128 provides $\sigma_{x,\ \max}$ for a polynomial-graded conductivity given a predetermined $R(0)$ and m. If $\sigma_{x,\ \max}$ is too small, the primary reflection from the PML is due to its PEC backing, and equation 9.125 provides a fairly accurate approximation of the reflection error. However, if $\sigma_{x,\ \max}$ is too large, the discretization error due to the FDTD approximation dominates, and the actual reflection error is potentially much higher than what equation 9.125 predicts. Consequently, there is an optimal choice for $\sigma_{x,\ \max}$ that balances reflection from the PEC outer boundary and discretization error.

Through extensive numerical experimentation, Gedney (1996) and He (1997) found that, for a broad range of applications, an optimal choice for a 10-cell-thick, polynomial-graded PML is $R(0) \approx e^{-16}$. For a 5-cell-thick PML, $R(0) \approx e^{-8}$ is optimal. From equation 9.128, this leads to an optimal $\sigma_{x,\ \max}$ for polynomial grading:

$$\sigma_{x,\text{opt}} \approx -\frac{(m+1)\cdot(-16)}{(2\eta)\cdot(10\Delta)} = \frac{0.8(m+1)}{\eta\Delta}. \tag{9.129}$$

This expression has proven to be adequate for many applications. Its value, however, may be too large when the PML terminates highly elongated resonant structures or sources with a very long time duration. For detailed discussions and examples of PML performance over a wide range of possible loss profiles, see Gedney (1998) and Gedney and Taflove (2000).

9.7 Examples of FDTD Modeling Applications

Current examples of FDTD modeling applications span much of the electromagnetic spectrum. A worldwide FDTD developer/user community is involved in numerical simulation of electrodynamic phenomena ranging from extremely low-frequency (ELF) propagation about the entire earth to the lasing behavior of aggregates of micron-scale particles exhibiting four-level quantum-system characteristics. Such applications of FDTD vividly illustrate the principle that "Maxwell's equations work from dc to light." The goal of this section is to provide examples of current and emerging FDTD applications that literally span this range.

9.7.1 Global ELF Propagation in the Earth's Ionosphere Waveguide

Global propagation of extremely low-frequency (ELF: 3 Hz – 3 *kHz*) and very low-frequency (VLF: 3–30 kHz) electromagnetic waves in the earth-ionosphere waveguide is a problem having a rich history of theoretical investigation extending over many years (Wait, 1965). ELF/VLF propagation phenomena form the physics basis of submarine communications and remote-sensing investigations of lightning and sprites, global temperature change, subsurface structures, and potential earthquake precursors.

Most theoretical techniques for modeling ELF/VLF propagation in the earth-ionosphere waveguide are based on frequency-domain waveguide mode theory. However, these techniques cannot account for arbitrary horizontal as well as vertical geometrical and electrical inhomogeneities of the ionosphere, continents, and oceans. Recently, Simpson and Taflove (2002, 2004) and Otsuyama *et al.* (2003) have developed two- and three-dimensional FDTD models of impulsive ELF propagation around the entire surface of the earth. Periodic boundary conditions are used in conjunction with a latitude-longitude grid that wraps around the complete earth-sphere. These models have been verified by numerical studies of frequency-dependent propagation attenuation with distance, antipodal propagation, and the Schumann resonance. Figure 9.14 visualizes the results of one such model (Simpson and Taflove [2004]) which illustrates the propagation completely around the Earth of an ELF electromagnetic pulse generated by a vertical lightning stroke off the coast of South America. In this model, all features of the lithosphere and ionosphere located within ±100 km of sea level are modeled with a resolution of approximately 40 × 40 × 5 km.

9.7.2 High-Speed Electronics

High-speed electronic circuits have been traditionally grouped into two classes: **analog microwave circuits** and **digital logic circuits**.

(1) Microwave circuits typically process band-pass signals at frequencies above 3 GHz. Common circuit features include microstrip transmission lines, directional couplers, circulators, filters, matching networks, and individual transistors. Circuit operation is fundamentally based on electromagnetic wave phenomena.

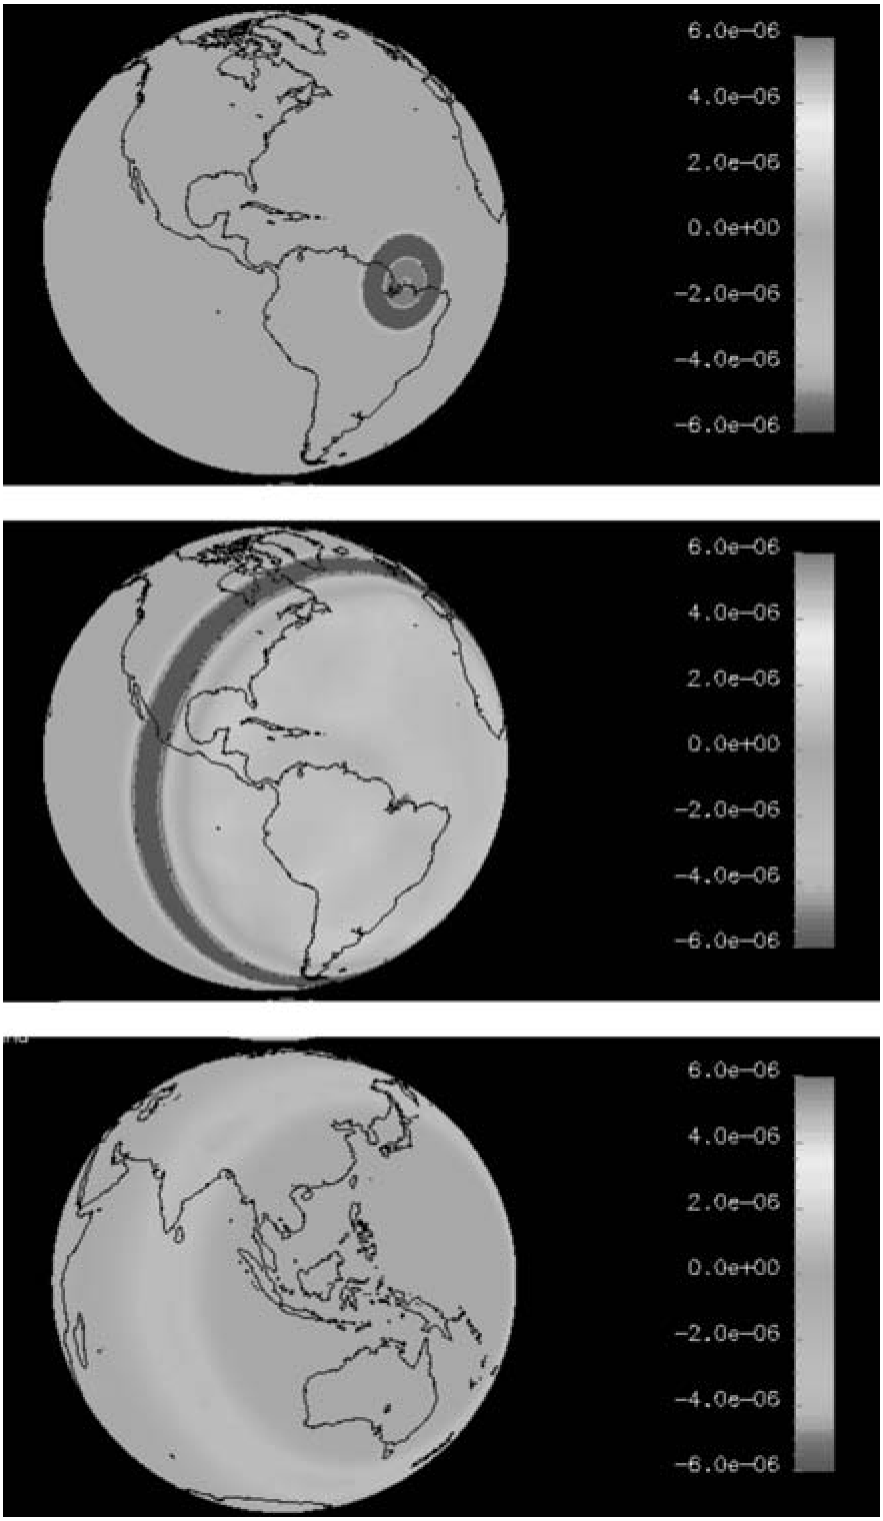


FIGURE 9.14 Snapshot Visualizations of the FDTD-Computed Global Propagation of an ELF Electromagnetic Pulse Generated by a Lightning Strike Off the Coast of South America (Simpson and Taflove [2004]). All features of the lithosphere and atmosphere located within ±100 km of sea level are modeled in three dimensions with a resolution of approximately 40 × 40 × 5 km.

(2) Digital circuits typically process low-pass pulses having clock rates below 3 GHz. Typical circuits include densely packed, multiple planes of metal traces providing flow paths for the signals, dc power feeds, and ground returns. Via pins provide electrical connections between the planes. Circuit operation is nominally *not* based on electromagnetic wave effects.

The distinction between the design of these two classes, however, is blurring. Microwave circuits are becoming very complex systems comprised of densely packed elements. On the digital-circuit side, the rise of everyday clock speeds to 3 GHz implies low-pass signal bandwidths above 10 GHz, which are well into the microwave range. Electromagnetic wave effects that, until now, were in the domain of the microwave engineer are becoming a limiting factor in digital-circuit operation. For example, hard-won experience has shown that high-speed digital signals can spuriously:

- Distort as they propagate along the metal circuit paths
- Couple (cross talk) from one circuit path to another
- Radiate and create interference to other circuits and systems

An example of electromagnetic field effects in a digital circuit is shown in Figure 9.15, which illustrates the results of applying FDTD modeling to calculate the coupling and cross talk of a high-speed logic pulse entering and leaving a microchip embedded in a conventional dual in-line integrated-circuit package. The fields associated with the logic pulse are not confined to the metal circuit paths and, in fact, smear out and couple to all adjacent circuit paths.

9.7.3 Microwave Penetration and Coupling

Computational electromagnetics has played an important role in helping to assess and mitigate the effects of high-level electromagnetic wave coupling into sensitive electrical and electronic equipment. The primary sources of such waves include **lightning, nuclear electromagnetic pulse** (NEMP), and **high-power microwaves** (HPM).

NEMP can burn out electrical and electronic equipment on the earth's surface located many hundreds of miles away from the detonation of a nuclear bomb above the earth's atmosphere. Equipment failures on this geographical scale could leave a nation largely defenseless against subsequent attack. HPM neutralize electronics in the same manner as NEMP but can be applied on a more selective basis for either tactical or strategic applications. For both NEMP and HPM, computational solutions of Maxwell's equations have been used to understand the complex electromagnetic wave penetration and coupling mechanisms into potential targets and create means to mitigate these mechanisms. FDTD is particularly useful for these purposes since it can model extremely complicated three-dimensional structures in a straightforward manner. Figure 9.16 illustrates the results of

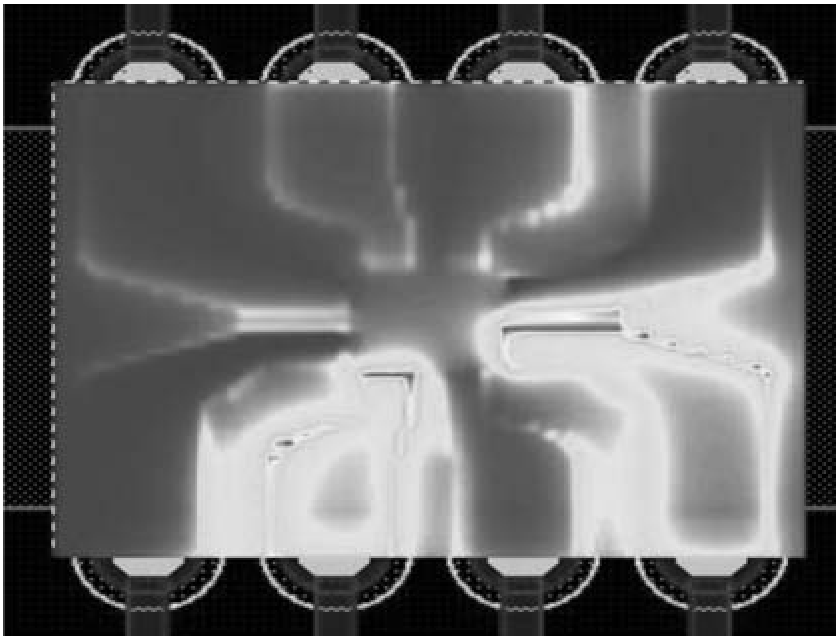

FIGURE 9.15 Snapshot Visualization of FDTD-Computed Coupling and Crosstalk of a High-Speed Logic Pulse. The pulse is entering and leaving a microchip embedded in a conventional dual in-line integrated-circuit package. Courtesy of Prof. M. Picket-May, University of Colorado-Boulder.

applying FDTD modeling to calculate the interaction of a 10-GHz radar beam with a missile radome containing a horn antenna.

9.7.4 Ultrawideband Microwave Imaging for Early Stage Breast Cancer Detection

Recently, several researchers have conducted theoretical investigations of the use of ultrawideband microwave pulses for early stage breast cancer detection. In principle, this technique could detect smaller tumors over larger regions of the breast, a detection that is not currently possible using X-ray mammography. This technique would also help prevent a patient's exposure to potentially hazardous ionizing radiation. In this proposed technique, an array of small antennas would be placed on the surface of the breast to emit and then receive a short electromagnetic pulse lasting less than 100 ps. Signal-processing techniques would then be applied to the received pulses at each antenna element to form the breast image. In work to date, FDTD modeling has provided simulated test data and allowed optimization of the imaging algorithms. As shown in Figure 9.17, these simulations indicate promise for imaging small, deeply embedded malignant tumors in the presence of the background clutter due to complicated surrounding normal tissues.

9.7.5 Photonic Integrated Circuits

Microcavity ring and disk resonators are proposed components for filtering, routing, switching, modulation, and multiplexing/demultiplexing tasks in ultrahigh-speed photonic integrated circuits. Figure 9.18 is a scanning electron microscope image of a portion of a prototype photonic circuit comprised of 5.0-μm diameter aluminum gallium arsenide (AlGaAs) microcavity disk resonators coupled to 0.3-μm wide optical waveguides across air gaps spanning 0.1 to 0.3 μm.

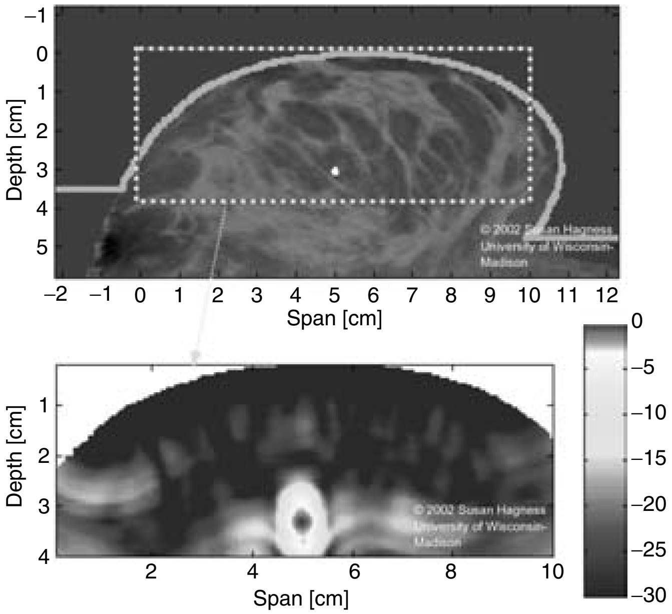

FIGURE 9.17 Top: MRI-derived Breast Model. This image shows the location of a 2-mm diameter malignant breast tumor at a depth of 3 cm. Bottom: image reconstructed from backscattered waveforms obtained by FDTD modeling. The scale is in decibels. Note that the tumor signature is 15–30 dB (30 to 1,000 times) stronger than the backscattering clutter due to the surrounding normal tissues. Courtesy of Bond *et al.* (2003).

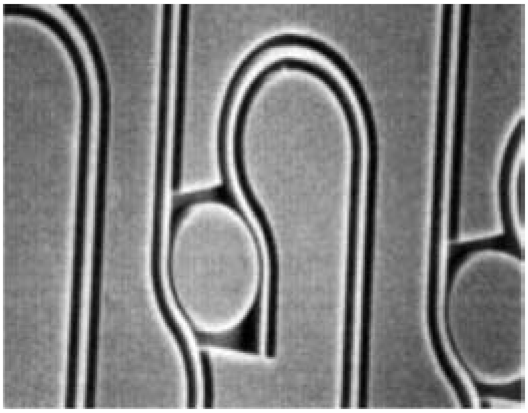

FIGURE 9.18 Scanning Electron Microscope Image of a Prototype Photonic Integrated Circuit. The photonic circuit is comprised of 5.0-μm diameter AlGaAs microcavity disk resonators coupled to 0.3-μm-wide AlGaAs optical waveguides across air gaps spanning as little as 0.1 μm. Courtesy of Prof. S.-T. Ho, Northwestern University.

By computationally solving Maxwell's equations, the coupling, transmission, and resonance behavior of the micro-optical structures in Figure 9.18 can be determined. This permits effective engineering design. For example, Figure 9.19 shows visualizations of the FDTD-calculated sinusoidal steady-state optical electric field distributions for a typical microdisk in Figure 9.18. In the upper left panel, the optical excitation is at a nonresonant frequency, 193.4 THz (an optical wavelength, λ, of 1.55 μm). Here, 99.98% of the rightward-directed power in the incident signal remains in the lower waveguide. In the upper right panel, the excitation is at the resonant frequency of the first-order radial whispering-gallery mode of the microdisk, 189.2 THz ($\lambda = 1.585$ μm). Here, there is a large field enhancement in the microdisk, and 99.79% of the incident power switches to the upper waveguide in the reverse (leftward) direction. This yields the action of a passive, wavelength-selective switch.

The lower left and lower right panels of Figure 9.19 are visualizations at, respectively, the resonant frequencies of the second- and third-order whispering-gallery modes: 191.3 THz

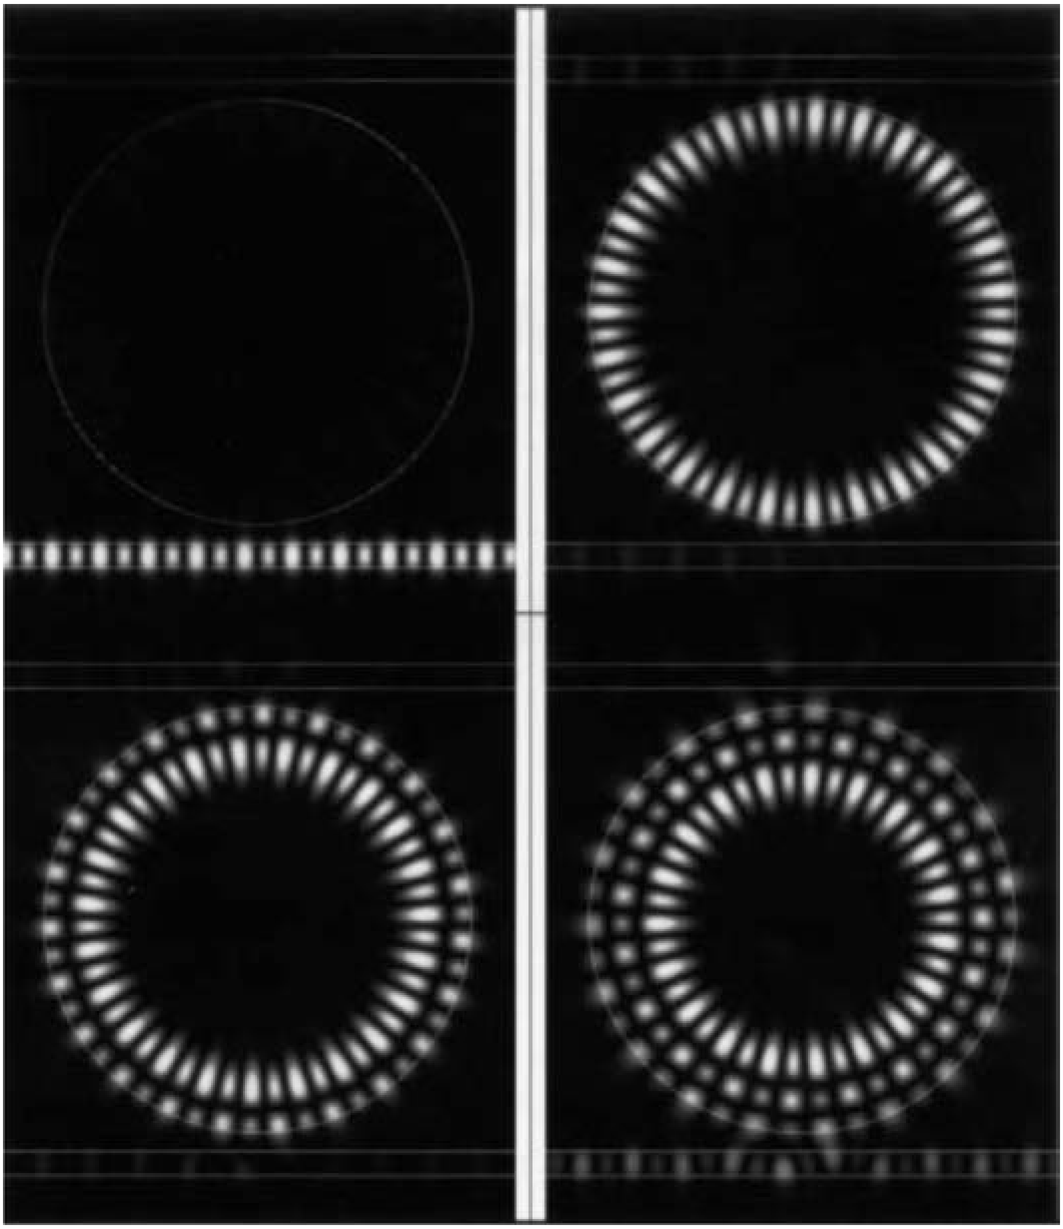

FIGURE 9.19 Visualizations Illustrating the FDTD-Calculated Sinusoidal Steady-State Optical Electric Field Distributions in a 5.0-μm Diameter GaAlAs Microdisk Resonator. The resonator is coupled to straight 0.3-μm wide GaAlAs optical waveguides for single-frequency excitations propagating to the right in the lower waveguide. Upper left: Off-resonance signal; Upper right: On-resonance signal, first-order radial mode; Lower left: Second-order radial-mode resonance; Lower right: Third-order radial mode resonance. Courtesy of Hagness *et al.* (1997).

($\lambda = 1.567\,\mu\text{m}$) and 187.8 THz ($\lambda = 1.596\,\mu\text{m}$). A goal of current design efforts is to suppress such higher order modes to allow the use of microdisks as passive wavelength-division multiplexing devices having low cross talk across a wide spectrum or as active single-mode laser sources.

9.7.6 Light Switching: Light in Femtoseconds

Recent optical systems can generate laser pulses down to 6 fs in duration. From a technology standpoint, it is clear that controlling or processing these short pulses involves understanding the nature of their interactions with materials over enormous bandwidths and very likely in beam-intensity regimes where material nonlinearity plays an important role. A key factor here is material dispersion, having two components: (1) **linear dispersion** (i.e., the variation of the material's index of refraction with frequency at low optical power levels) and (2) **nonlinear dispersion** (i.e., the variation of the frequency-dependent refractive index with optical power).

Advances in FDTD computational techniques for solving Maxwell's equations have provided the basis for modeling both linear and nonlinear dispersions over ultrawide bandwidths. An example of the possibilities for such modeling is shown in Figure 9.20, which is a sequence of snapshot visualizations of the dynamics of a potential femtosecond all-optical switch. This switch uses the collision and subsequent "bouncing" of pulsed optical spatial **solitons**, which are pulsed beams of laser light that are prevented from spreading in their transverse directions by the optical focusing effect of the nonlinear material in which they propagate.

Referring to the top panel of Figure 9.20, this switch would inject an in-phase, 100-fs pulsed signal and control solitons

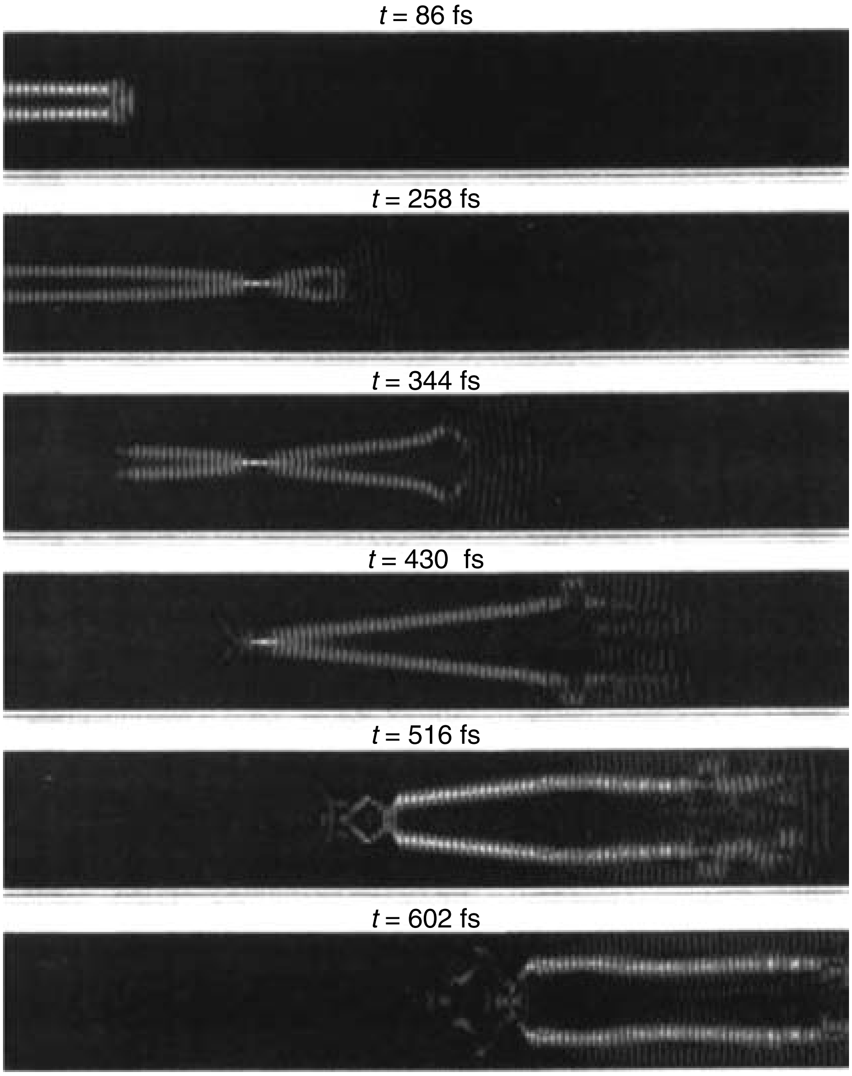

FIGURE 9.20 Sequential Snapshot Visualizations of the FDTD-Computed Electric Field of Equal-Amplitude, In-Phase, 100-fs Optical Spatial Solitons Copropagating in Glass. The optical pulses propagate from left to right at the speed of light in glass. Courtesy of Joseph and Taflove (1994).

into ordinary glass (a Kerr-type nonlinear material) from a pair of optical waveguides on the left side. Each pulsed beam has a 0.65-μm transverse width, while the beam-to-beam spacing is in the order of 1 μm. In the absence of the control soliton, the signal soliton would propagate to the right at the speed of light in glass with zero deflection and then be collected by a receiving waveguide. However, as shown in the remaining panels of this figure, a copropagating control soliton would first merge with and then laterally deflect the signal soliton to an alternate collecting waveguide. (Curiously, the location of the two beams' merger point would remain stationary in space while the beams would propagate at light-speed through this point.) Overall, the optical pulse dynamics shown in Figure 9.20 could provide the action of an all-optical "AND" gate working on a time scale about 1/10,000th that of existing electronic digital logic.

Application of FDTD solutions of Maxwell's equations to problems such as the one illustrated in this figure shows great promise in allowing the detailed study of a variety of novel nonlinear optical wave species that may one day be used to implement all-optical switching circuits (light switching light), attaining speeds 10,000 times faster than those of the best semiconductor circuits today. The implications may be profound for the realization of "optonics," a proposed successor technology to electronics that would integrate optical-fiber interconnects and optical microchips into systems of unimaginable information-processing capability.

9.8 Summary and Conclusions

This chapter reviewed key elements of the theoretical foundation and numerical implementation of finite-difference time-domain (FDTD) solutions of Maxwell's equations. The chapter included:

- Introduction and background
- Review of Maxwell's equations
- The Yee algorithm
- Theory of numerical dispersion
- Theory of numerical stability
- Perfectly matched layer (PML) absorbing boundary conditions
- Examples of FDTD modeling applications

With literally hundreds of papers on FDTD methods and applications published each year, it is clear that FDTD is one of the most powerful and widely used numerical modeling approaches for electromagnetic wave interaction problems. With expanding developer and user communities in an increasing number of disciplines in science and engineering, FDTD technology is continually evolving in terms of its theoretical basis, numerical implementation, and technological applications, which now span the spectral range from ELF to daylight.

Radar and Inverse Scattering

Hsueh-Jyh Li and
Yean-Woei Kiang
*Department of Electrical Engineering,
National Taiwan University,
Taipei, Taiwan*

10.1 Introduction

Radar is constructed from the words **radio detection and ranging**. The early purpose of a radar was to detect the presence of a target and measure its range by transmitting radio waves. Modern radars not only detect target and measure distances, but they also have the capability of locating, imaging, and identifying targets. A typical radar consists of a transmitter, an antenna, a receiver, a signal processor, and a display.

There are different types of radars. According to the physical relationship between the transmitting and receiving antennas, they can be classified into **monostatic radars** and **bistatic radars**. The monostatic radar has a common antenna used for both transmitting and receiving, while the bistatic radar has transmitting and receiving antennas separated by a considerable distance. According to the waveforms transmitted, radars can be classified into **continuous wave** (CW) radars or **pulsed** radars. A CW radar's transmitter operates continuously.

A pulsed radar transmits a relatively short burst of pulses, and after each pulse, the receiver is turned on to receive the echo. According to the primary missions, radars can be classified into **search radars** and **tracking radars**. Search radars continuously scan a volume of space without dwelling at any location. Their primary missions are detecting targets and determining a target's range and direction. Tracking radars dwell on individual targets and track their motion in range, azimuth, elevation, and/or Doppler.

10.2 Parameters of a Pulsed Radar

The most popular type of radar is the **pulsed radar**. The waveform of a pulsed radar is usually represented by the **pulse duration** τ, the **pulse repetition interval** (PRI) T, or the **pulse repetition frequency** (PRF) f_p. PRI is the time interval between two adjacent pulses. PRF is the rate that pulses repeat per second and is equal to the inverse of PRI. The fraction of the total time that the transmitter is on is called the **duty cycle** d_c. For a fixed PRI, duty cycle is given by:

$$d_c = \tau T. \qquad (10.1)$$

Target range is the distance between the target and the radar. It can be determined by measuring the time required by the pulse to travel to the target and return. The target range is given by:

$$R = c\tau_d/2, \qquad (10.2)$$

where c is the speed of light, τ_d is the time delay, and the factor 2 accounts for the round-trip.

If the time delay is smaller than the PRI, the range determined by equation 10.2 is unambiguous. If the PRF is too high or the PRI is too short, the echo pulses from the target might arrive after the transmission of the next pulse, and then the range measured might be ambiguous. The maximum unambiguous range is given by:

$$R_{\text{unamb}} = cT/2 = c/(2f_p), \qquad (10.3)$$

where T is the PRI and where f_p is the PRF.

10.3 Radar Equation

A **radar equation** relates the range of a radar to the characteristics of the transmitter, receiver, antenna, target, and distance. Consider a monostatic radar. Let P_t be the transmitted power, G the antenna gain, R the distance of the target. Then, the power density at the target is given by:

$$P_d = \frac{P_t G}{4\pi R^2}. \qquad (10.4)$$

Assume the target receives the incident power with an area σ, called the **radar cross section** (RCS), and radiates isotropically. Hence, the power density at the radar is given by:

$$P_d' = \frac{P_d \sigma}{4\pi R^2} = \frac{P_t G_t \sigma}{(4\pi R^2)^2}. \qquad (10.5)$$

Assume the radar antenna has an effective area A_e, which is related to the antenna gain by $A_e = G_r \lambda^2/4\pi$. Then, the power received by the radar is as written here:

$$P_r = P_d A_e = \frac{P_t \cdot G_t \sigma G_r \lambda^2}{(4\pi R^2)^2 \cdot 4\pi} = \frac{P_t G^2 \sigma \lambda^2}{(4\pi)^3 R^4}, \qquad (10.6)$$

where the same antenna has been used both for transmitting and receiving. Let $S_{\min}$ be the minimum detectable signal, and let the maximum range that a target can be detected for a given RCS σ be the following:

$$R_{\max} = \left[\frac{P_t G^2 \sigma \lambda^2}{(4\pi)^3 S_{\min}}\right]^{1/4}. \qquad (10.7)$$

10.4 Radar Cross Section

The **radar cross section** (RCS) of a target is the equivalent area seen by a radar. It is the fictitious area intercepting that amount of power which, when scattered equally in all directions, produces an echo at the radar equal to that from the target. Mathematically, it is written as:

$$\sigma = \lim_{R\to\infty} 4\pi R^2 \frac{|E_s|^2}{|E_i|^2}, \qquad (10.8)$$

where:

- R = distance between radar and target
- E_s = scattered field strength at radar
- E_i = incident field strength at target

10.4.1 RCS of Simple Objects

In theory, the RCS of a target can be determined by solving Maxwell's equations with proper boundary conditions. Only objects with simple geometries, however, can be determined in this way. The RCS of a simple conducting sphere as a function of the normalized circumference ($2\pi a/\lambda$, where a is the radius of the sphere and λ is the wavelength) is shown in Figure 10.1. The RCS of this figure can be divided into the **Rayleigh region**, the **Mie** or the **resonance region**, and the **optical region**. In the Rayleigh region, where the size of the sphere is small compared with the wavelength, the RCS varies with λ^4. In the optical region, where the dimensions of the sphere are

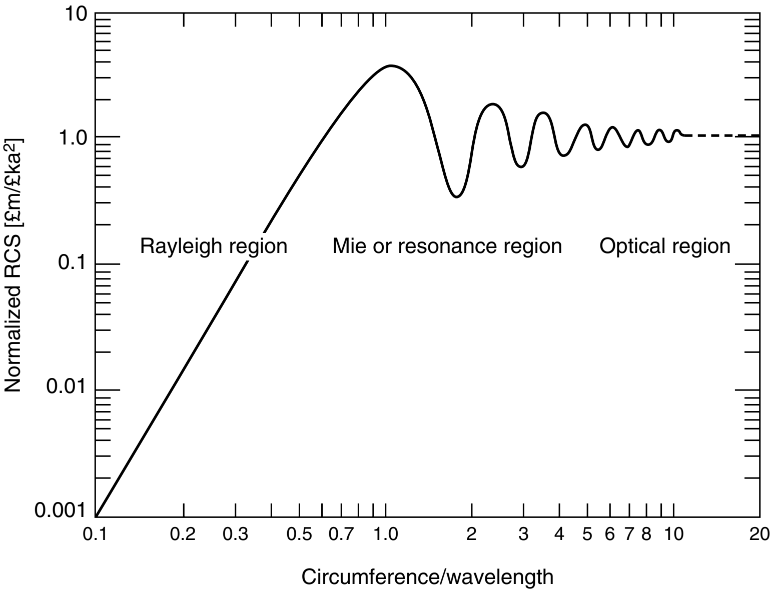

FIGURE 10.1 The RCS of a Conducting Sphere as a Function of the Normalized Circumference

large compared with the wavelength, the RCS approaches a constant value πa^2. In the Mie or resonance region, which is between the optical and the Rayleigh region, the RCS is oscillatory with frequency.

The RCS of a target depends on the aspect angle, frequency, and polarization. It is not directly related to the physical area. When the object dimension is much greater than the wavelength, the RCS of a conducting plate with a physical area A observed at the normal direction can be approximated by the product of the effective gain of the plate and the physical area. The product is given by:

$$\sigma = G_e \cdot A = \frac{4\pi A}{\lambda^2} \cdot A = \frac{4\pi A^2}{\lambda^2}. \qquad (10.9)$$

As an example, if the conducting plate has an area of $1\,\text{m}^2$, and the wavelength is 1 cm, then the RCS at the normal direction is $12,560\,\text{m}^2$, which is a hundred thousand times the physical area!

The approximate formulas for the RCS of some simple objects are shown in Table 10.1.

The RCS of a complex target that is large compared to a wavelength is highly dependent on the aspect angle. A small

TABLE 10.1 Approximate Formulas for the RCS of Some Simple Objects

Object	Aspect	RCS	Symbol
Sphere	Any	πa^2	a: Radius

Paraboloidal	Axial	πa^2	a: Apex radius of curvature
Cylinder	Normal to axis	$\frac{2\pi a L^2}{\lambda}$	a: Radius L: Length
Large flat plate	Normal	$\frac{4\pi A^2}{\lambda^2}$	A: Plate area
Square plate	Angle to normal	$\frac{4\pi a^4}{\lambda^2}\left[\frac{\sin(ka\sin\theta)}{ka\sin\theta}\right]$	a: Length of side
Circular plate	Angle θ to normal	$\frac{\pi a^2}{\tan^2\theta}J_1^2(2ka\sin\theta)$	a: Radius of plate J_1 (): Bessel function of the first order
Dihedral	Maximum direction	$\frac{8\pi a^2 b^2}{\lambda^2}$	a,b: Length of side
Trihedral	Maximum direction	$\frac{4\pi a^4}{3\lambda^2}$	a: Edge length
Square trihedral	Maximum direction	$\frac{12\pi a^4}{\lambda^2}$	a: Edge length

change in the aspect angle can cause the RCS to fluctuate several tens of decibels.

10.4.2 RCS Enhancement and Reduction

In some civilian applications, such as navigation, it is desirable to enhance the radar echo of the object so that it can be easily detected or tracked. The metal corner reflectors are usually used for this purpose because their RCSs have large values over a wide angular coverage. On the contrary, for electronic warfare and electronic countermeasure, it is desirable to reduce the RCS of military targets so that they will not be detected by the radar. There are several ways to reduce the RCS of a target: **shaping, absorbing,** and **cancelling**. Shaping includes specific design configuration, such as placing engine intakes where they can be shielded by other parts of the object. The purpose of the radar absorber is to absorb incident energy and thereby reduce the energy scattered back to the radar. Cancellation methods require loading the object with suitable impedance to cancel the returns from other parts of the body. Cancellation methods are too complicated to implement and are seldom used.

10.5 Radar Transmitters

The function of the **radar transmitter** is to generate an electromagnetic signal to illuminate the target. The transmitters can be classified into the oscillators and power amplifiers. The power amplifiers can be divided into three groups: the **linear beam O-type**, the **cross-field M-type**, and the **solid-state type** amplifiers. The O-type power amplifiers are characterized by high gain, high power capability, low noise, and large size. Typical O-type tubes include klystrons, travelling wave tubes, and twystrons. The cross-field M-type amplifiers are characterized by low gain, moderate to high power capability, moderate noise, wide bandwidth, and small size. Typical M-type tubes include cross-field amplifiers and magnetrons. The solid-state transmitters have lower voltage requirements and poor operation at higher frequency bands. Solid-state devices for amplifiers include bipolar junction transistors, field effect transistors, transferred-electron devices, and avalanche transit-time devices.

Two types of radar transmitters exist: **coherent** and **incoherent**. Coherent transmitters produce a signal whose phase is known prior to transmission. Coherent-on-receive and incoherent transmitters produce a signal whose phase is unknown prior to the start of the transmit output.

10.6 Radar Receivers and Displays

The function of the radar receiver is to detect desired echo signals in the presence of noise, interference, or clutter. In general, a radar receiver has four functional blocks: the **amplification block**, the **band-select filter block**, the **matched filter block**, and the **demodulation block**. The amplification block increases the amplitude of the incoming signal to levels usable in the post stages—band-select filter block, the matched filter block, and the demodulation block. The band-select filter block rejects out-of–band interference. The matched filter block shapes the signals and noise to gain the maximum signal-to-noise ratio. The demodulation function block removes the carrier and translates the signal to its information frequencies or baseband.

The **superheterodyne** is the most popular receiver type. In a superheterodyne receiver, the signals are offset downward by a local oscillator. Amplification and filtering take place at a lower frequency or intermediate frequency. This type of receiver has the advantage of good sensitivity, high gain selectivity, and reliability.

10.6.1 Receiver Noise

Noise is the chief limiting factor of the sensitivity of a receiver. If the receiver itself were perfect and did not generate any excess noise, there would still exist noise generated by the thermal motion of the conduction electrons. This noise is called **thermal noise**. The thermal noise power is proportional to the temperature T (degrees Kelvin) and the receiver bandwidth B_n (hertz) and is given by:

$$P_n = kTB_n. \tag{10.10}$$

Where k is Boltzmann's constant $= 1.38 \times 10^{-23}$ J/deg. The B_n is the equivalent noise bandwidth defined as the width of a rectangular filter whose peak response equals that of the actual filter and whose area equals that under the actual filter. Mathematically, B_n is given by:

$$B_n = \frac{\int_{-\infty}^{\infty} |H(f)|^2 df}{|H(f_0)|^2}, \tag{10.11}$$

where $H(f)$ is the frequency response of the filter and where $H(f_0)$ is the peak response of the filter.

10.6.2 Noise Figure and Temperature

For a practical receiver, the noise power is often greater than the thermal noise power. The total noise power at the receiver output may be considered to be equal to the thermal noise power multiplied by a factor called the **noise figure**. The noise figure is a measure of the degradation of signal-to-noise-ratio as the signal passes through the receiver. It measures how much noise is added by the receiver and can be expressed by:

$$F_n = \frac{(S/N)_i}{(S/N)_o}, \tag{10.12}$$

where $(S/N)_i$ is the signal-to-noise-ratio at the input to the receiver and where $(S/N)_o$ is the signal-to-noise-ratio at the output to the receiver.

If there are N amplifiers in cascade, the equivalent noise figure is given by:

$$F_e = F_1 + \frac{F_2 - 1}{G_1} + \frac{F_3 - 1}{G_1 G_2} + \cdots \frac{F_N - 1}{G_1 G_2 \ldots G_{N-1}}, \qquad (10.13)$$

where F_i and G_i are the noise figure and the gain of the ith stage amplifier, respectively.

The **noise temperature** is the noise introduced by an amplifier that may be expressed as an effective temperature:

$$T_e = (F_n - 1)T_0, \qquad (10.14)$$

where T_0 is the room temperature.

10.6.3 Mixers

The function of a **mixer** is to convert RF energy to intermediate frequency (IF) energy with minimum loss and without spurious responses. The inputs to the mixer are the signal at the radio frequency and the sinusoid from a local oscillator (LO). The output is the signal at the intermediate frequency. Mixing is the process of multiplying the RF signal by the local oscillator and then low-pass filtering the product.

The conversion process of a mixer will cause a loss known as **conversion loss**, which is defined as:

$$Lc = \frac{\text{available RF power}}{\text{available IF power}}. \qquad (10.15)$$

The available power means that power can be obtained when the impedences are matched. Conversion loss is a measure of the efficiency of the mixer in converting RF signal power into IF.

Balanced mixer

Noise that accompanies the LO signal can appear at the IF. A method of eliminating LO noise is via the **balanced mixer**. A balanced mixer uses a four-port hybrid junction as shown in Figure 10.2. The LO and RF signals are applied to the two ports. Diode mixers are in each of the remaining two ports. At one diode, the sum of the RF and LO signals appears, and at the other diode is the difference of the two signals. The two diode mixers should have the same characteristics and be well matched. The IF signal is the subtraction of the two diode outputs. Because the LO noise at the two diode mixers are in phase, it will be canceled at the output.

10.6.4 IF Amplifiers

Most gain and filtering are obtained in the IF amplifier. Typical IF amplifiers have gains of up to 120 dB. The design of the IF filters involves the matched filter and the Doppler shift.

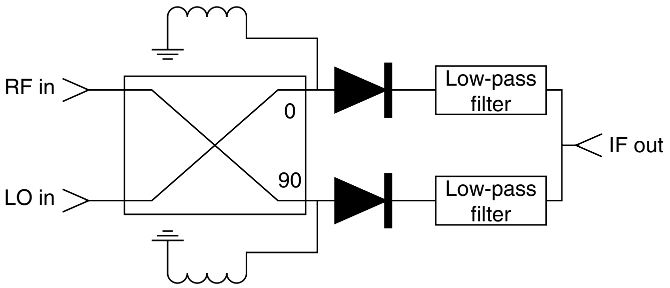

FIGURE 10.2 A Balanced Mixer Using a Four-Port Hybrid Junction

The purpose of a **matched filter** is to maximize the signal-to-noise ratio. If the noise is a white noise, the matched filter's characteristics are given by:

$$H(f) = G_0 S^*(f) \exp(-j2\pi f t_1), \qquad (10.16)$$

where *H(f)* is the transfer function of the matched filter, G_0 is a constant, $S^*(f)$ is the complex conjugate of the spectrum of the received signal, and t_1 is the time of maximum response of the filter.

Most IF amplifiers have high gains and **gain control**. The automatic gain control (AGC) is to hold the amplitude at the output of the receiver constant. Multichannel tracking receivers should have the same gain control voltage applied to all receivers, and they must maintain the same gain over their gain control range (90 dB or more). Maintaining identical gains in multiple channels over wide gain-control excursions is called **gain tracking**.

The amplitude of radar signals has a very wide dynamic range. To avoid the saturation of the amplifier output, the **log receiver** is usually used. In a log receiver, the amplitude of the output is proportional to the logarithm of the amplitude of the input. It can compress the output dynamic range so that weak signals can be enhanced and observed.

10.6.5 Displays

The function of the **display** is to visually present the information contained in the radar echo signal to the operator so that he or she can easily interpret and take action. There are various types of displays. Some of the more usual displays adapted from the IEEE standard definitions are listed below:

- An **A-scope** is a deflection-modulated display in which the vertical deflection is proportional to target echo strength, and the horizontal coordinate is proportional to the range.
- A **B-scope** is an intensity-modulated rectangular display with an azimuth angle indicated by the horizontal coordinate and range by the vertical coordinate.
- A **C-scope** is an intensity-modulated rectangular display with an azimuth angle indicated by the horizontal coordinate and elevation angle by the vertical coordinate.

- A **plan position indicator (PPI) or P-scope** is an intensity-modulated circular display where echo signals are shown in plan position with range and azimuth angle displayed in polar coordinates.
- A **range-height indicator** (RHI) is an intensity—modulated display with height as the vertical axis and range as the horizontal axis.
- A **duplexer** is a device that allows the transmitter and the receiver to share the same antenna. On transmission, it protects the receiver from burnout; on reception, it directs the echo signal to the receiver. The duplexer must provide a very large isolation (greater than 60 dB) between the transmitter and receiver with a very small loss of the desired signal. Most radar duplexers are in one of the two types: **circulator** and **TR tube**.

10.7 Radar Antennas

The basic role of the **radar antenna** is to act as a transducer between the free space and the electromagnetic wave sources or receivers. During transmission, it is used to concentrate the radiated energy into a shaped beam or in a desired direction. During reception, it is used to collect the echo signal and deliver it to the receiver.

Most radar systems employ a single antenna for both transmitting and receiving. If the antenna has identical performance parameters (such as impedance, pattern, and gain) for both functions, it is called **reciprocal**.

Directivity of an antenna is defined as the ratio of the maximum radiation power intensity to the average intensity and is expressed by:

$$\begin{aligned} G_D &= \frac{\text{maximum radiation intensity}}{\text{average radiation intensity}} \\ &= \frac{\text{maximum power per steradian}}{\text{total power radiated}/4\pi} \end{aligned} \qquad (10.17)$$

Gain of an antenna involves antenna losses and is defined in terms of power accepted by the antenna at its input port. The relation between gain and directivity is written as:

$$G = \eta G_D, \qquad (10.18)$$

where η is called the efficiency factor, which counts for antenna losses, such as impedance mismatch loss or ohmic loss. An approximate relationship between directivity and the antenna half-power beamwidths can be expressed by:

$$G_D = \frac{40,000}{B_{az} \cdot B_{el}}, \qquad (10.19)$$

where B_{az} and B_{el} are the azimuth and elevation half-power beamwidths in degrees, respectively.

The **effective aperture** A_e of an antenna is the portion of its total projected area that effectively captures the electromagnetic waves. It is related to the physical aperture by:

$$A_e = \eta_A A, \qquad (10.20)$$

where η_A is called the aperture efficiency. A_e is related to the antenna gain by:

$$G = \frac{4\pi A_e}{\lambda^2}, \qquad (10.21)$$

where λ is the operating wavelength. One can estimate the antenna gain if the physical area, the efficiency, and the operating frequency are known.

Radar antennas can be classified into two broad categories: Aperture antennas and array antennas.

10.7.1 Aperture Antennas

Cosecant-Squared and Cassegrain Antennas

The **cosecant-squared antenna** is a popular type of aperture antenna. In the cosecant-squared antenna pattern, the gain as a function of elevation angle θ is given by:

$$G(\theta) = G(\theta_0) \cdot \frac{\csc^2 \theta}{\csc^2 \theta_0} \quad \text{for } \theta_0 < \theta < \theta_m, \qquad (10.22)$$

where θ_0 and θ_m are the angular limits that the beam follows in a csc^2 shape. The cosecant-squared antenna has the important property of the echo power received from a target of constant RCS at a constant altitude being independent of the target range.

The **cassegrain antenna** is the most common antenna using multiple reflectors. In the cassegrain antenna, the feed, placed at or near the paraboloid main reflector, illuminates the hyperboloidal subreflector, which in turn illuminates the paraboloidal main reflector.

Aperture blockage and **spillover** are two main problems of multiple reflectors. An obstacle, such as a feed or feed support, in front of a reflector is called aperture blockage. Aperture blockage degrades the antenna performance by lowering the gain, increasing the side lobes, and filling in the nulls. If the feed beamwidth is excessive and illuminates over the reflector aperture, it is called spillover. Spillover will cause an undesired antenna response in the direction of the spillover.

Antennas for ground-based or airplane radars are usually covered by a **radome** for protection. A radome is a dielectric shield covering to protect an antenna operated under severe weather conditions. Radomes must be mechanically strong and not interfere with the normal operation of the antenna.

10.7.2 Array Antennas

An **array antenna** is a directive antenna made of individual elements. Its radiation pattern can be adjusted by controlling the amplitude and phase of the currents at the individual elements. By changing the relative phase shift between elements, the beam of an antenna array can be scanned. The beam of an array antenna can be steered by properly varying the phase of the signals applied to each element.

Consider a uniformly spaced array with a number of elements N and spacing d. Assume the progressive phase shift between elements is ϕ. The radiation pattern of the array can be expressed by:

$$G(\theta) = \frac{\sin^2[N/2(kd \sin\theta - \phi)]}{N^2 \sin^2[1/2(kd \sin\theta - \phi)]}. \tag{10.23}$$

The direction of the main beam will be at angle θ_0 when the progressive phase shift ϕ is equal to $kd \sin\theta_0$. The following is a list of different arrays.

- **Frequency-scan array:** If the adjacent antenna elements are connected by a transmission line with length ℓ, the progressive phase shift will be $k\ell = 2\pi\ell/\lambda$. By changing the frequency, the progressive phase shift will be varied, and the main beam of the array can be controlled by changing the operating frequency. This type of array is called the frequency-scan array. If the beam is to point in a direction θ_0, then the phase difference ϕ should be:

$$\phi = kd \sin\theta_0 + 2m\pi = 2\pi\, \ell/\lambda, \tag{10.24}$$

  where m is an integer.
- **Beamforming:** If the array is only used for reception, the antenna pattern can be digitally "beamformed." The output from each array element may be amplified and sampled. The sampled signals are then transferred to a computer for processing. The beam pattern can be formed digitally by applying suitable beamforming algorithms.
- **Multiple beam array:** In principle, an N-element array can generate N-independent beams. Multiple beams can be simultaneously obtained by attaching additional phase shifters to each element. The advantage of using multiple beams is that they allow parallel operation and allow a higher data rate than can be achieved from a single beam. A popular multiple beam array is the **Butler beamforming array**. It uses a lossless network consisting of 3-dB 90 hybrids along with fixed-phase shifters to form N contiguous beams from an N-element array, where N is some power of 2. The number of 3-dB hybrids required for an N element is equal to $(N/2)\log_2 N$, and the number of fixed phase shifters is $(N/2)(\log_2 N - 1)$.
- **Adaptive array:** An adaptive array adjusts the weights (amplitude and phase) of elements to achieve some desired performance, such as maximizing the received signal to interference plus noise ratio. Interference or jamming can be greatly reduced by forming a beam pattern with nulls pointing to the jammers. Adaptive arrays require some a priori knowledge of the desired signal, such as the direction, waveform, or statistical properties to train the weights.
- **Coherent side lobe canceller:** The coherent side lobe canceller uses a small number of auxiliary elements to adaptively place nulls in the directions of jammers. The auxiliary elements have a side lobe structure matched to that of the main antenna, but the antenna's main lobe is much smaller. The response of the main and auxiliary antennas are subtracted, thus cancelling the response of the radar antenna's side lobes but not the main lobe.

10.8 Clutter

Clutter is the unwanted signal echo from such sources as the sea, land, and atmosphere. It is real echo signal rather than random noise. The ground effects on radar signals can be divided into forward scattering and backscattering. A smooth surface provides strong forward scattering but weak backscattering, whereas a rough surface enables poor forward scattering but good backscattering.

The distinction between rough and smooth surfaces can be determined by the **Rayleigh criterion**. The critical height h_c of surface irregularities for a given angle of incidence θ_i can be defined as:

$$h_c = \frac{\lambda}{8 \sin\theta_i}. \tag{10.25}$$

A surface is considered smooth or rough if its irregularity height is less than or greater than h_c. At a small incident angle θ_i, a surface with large irregularities can still be viewed as a smooth surface.

A flat surface can be assumed to have a reflection coefficient. For rough surfaces, the flat surface reflection coefficient should be multiplied by a **roughness loss factor** to account for the diminished reflected field. The roughness loss factor ρ_s is given by:

$$\rho_s = \exp\left[-\left(\frac{\pi\sigma_h \sin\theta_i}{\lambda}\right)^2\right], \tag{10.26}$$

where σ_h is the standard deviation of the surface height about the mean surface height, and θ_i is the incident angle.

The RCS of an extended clutter surface is usually expressed by a parameter called the **normalized RCS**, which is the RCS per unit area. It is a dimensionless quantity and is strongly dependent on the incident angle, the surface material, and roughness. To find the total RCS of a ground surface illuminated by a pulse, integration should be performed on all the area elements that return to the radar at the same instant. The area that should be integrated is determined by the radar–surface geometry, the antenna's illuminating pattern, and the pulse duration.

Consider an airborne pulse radar pointing its antenna toward the ground or sea surface at a depression angle. If the area illuminated by the pulse is smaller than the area covered by the antenna beamwidth, then the illumination is called **pulse width-limited illumination**. If the area covered by the antenna beamwidth is smaller than that covered by the pulse, the illumination is called **beamwidth-limited illumination**. With pulse width-limited illumination, the received clutter power is inversely proportional to R^3, whereas with beamwidth-limited illumination, the received clutter power is inversely proportional to R^2.

10.9 Radar Detection

Detection is the process of deciding whether a target is present. The received field consists of a signal, interference, and noise. After the processing unit, the receiver output is compared with a predetermined threshold. If the receiver output is greater than the threshold, a detection is declared. Otherwise, no detection occurs. There are four possible states:

1. No target is present, and the receiver output is smaller than the threshold.
2. The target is present, and the receiver output crosses the threshold.
3. The target is present, but the receiver output is smaller than the threshold.
4. No target is present, but the receiver output crosses the threshold.

The first two states are called **correct decision**, and the last two states are called **detection errors**. The third case is called **missing**, and the fourth case is called **false alarm**.

Because noise is a random process and the target signal may fluctuate, detection performance is treated by probability. The following quantities are important in radar detection:

- **Probability of detection:** The $\mathbf{P_d}$ probability that the receiver output exceeds the threshold and the target is present.
- **Probability of missing $\boldsymbol{P_m}$:** The probability that the received voltage is below the threshold but the target is present. $P_m = 1 - P_d$.
- **Probability of false alarm $\boldsymbol{P_f}$:** The probability that the received voltage exceeds the threshold but the target is not present.

In radar detection, the threshold is usually determined by the allowable probability of false alarm. The probability of detection for a sine wave in white Gaussian noise as a function of the signal-to-noise ratio and the probability of false alarm are shown in Figure 10.3.

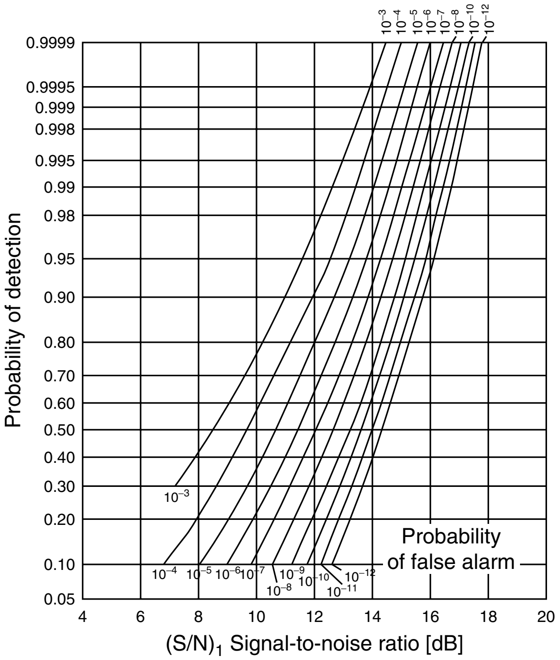

FIGURE 10.3 The Probability of Detection in White Gaussian Noise and the Probability of False Alarm. The probability is shown as a function of the signal-to-noise ratio.

10.9.1 Pulse Integration

Radar detection can be based on a single pulse echo. It can also be based on the integration of many pulses returned from a particular target. Integration can be accomplished either before or after the detector. Integration before the detector is called **predetection integration** or **coherent integration** because both amplitude and phase of each pulse echo can be preserved in the integration. Integration after the detector is called **postdetection** or **incoherent integration**, indicating the phase is not preserved after detector.

If n pulses (all having the same signal-to-noise ratio and phase) were coherently integrated, the resultant signal-to-noise ratio would be n times that of a single pulse. If the same pulses are incoherently integrated, the resultant signal-to-noise ratio would be less than n times that of a single pulse.

Let $(S/N)_1$ be the value of signal-to-noise ratio of a single pulse required to produce given probability of detection, and let $(S/N)_n$ be the value of signal-to-noise ratio per pulse required to produce the same probability of detection when n pulses are integrated. The integration improvement factor is defined as the ratio of $(S/N)_1$ to $(S/N)_n$, which is the improvement in the signal-to-noise ratio when n pulses are postdetection integrated.

10.9.2 RCS Fluctuation

The radar cross section of a complex target is highly dependent on the aspect angle. The echo signal from a target in motion usually fluctuates with time. Swerling (1960) has postulated four fluctuation models:

- **Case 1**: Scan-to-scan fluctuation exists, and the **probability density function** (pdf) for the cross section is given by:

$$P(\sigma) = \frac{1}{\sigma_{av}} \exp\left(-\sigma/\sigma_{av}\right), \tag{10.27}$$

  where σ_{av} is the average cross section over all target fluctuation.
- **Case 2**: Pulse-to-pulse fluctuation exists, and the pdf is the same as case 1.
- **Case 3**: Scan-to-scan fluctuation exists, and the pdf for the cross section is given by:

$$P(\sigma) = \frac{4\sigma}{\sigma_{av}^2} \exp\left(-2\sigma/\sigma_{av}\right). \tag{10.28}$$

- **Case 4**: Pulse-to-pulse fluctuation exists, and the pdf is the same as case 3.

The pdf assumed in equation 10.27 applies to complex targets consisting of many independent scatterers of equal RCS, and the pdf assumed in equation 10.28 applies to targets consisting of a dominant reflector and many small scatterers. Pulse-to-pulse fluctuation corresponds to fast fluctuation, and scan-to-scan fluctuation corresponds to slow fluctuation.

The detection of radar signals depends on the distribution of noise and interference. The white Gaussian noise has a flat spectrum and has a Gaussian distribution of noise voltage with pdf given by:

$$P(v) = \frac{1}{\sqrt{2\pi\psi_0}} \exp\left(-v^2/2\psi_0\right), \tag{10.29}$$

where ψ_0 is the variance of the noise, and the mean value of the noise is taken to be zero.

If the Gaussian noise is passed through a narrow band IF filter, the probability density function of the noise voltage output is the following:

$$P(R) = \frac{R}{\psi_0} \exp\left(-R^2/2\psi_0\right), \tag{10.30}$$

if a sine wave signal of amplitude A along with noise is at the input to the IF filter. The probability density function of the envelope detector output is known as the Rician distribution and is given by:

$$P(R) = \frac{R}{\psi_0} \exp\left(-\frac{R^2 + A^2}{2\psi_0}\right) I_0\left(\frac{RA}{\psi_0}\right), \tag{10.31}$$

where $I_0(x)$ is the modified Bessel function of zero order.

With white Gaussian noise, given a threshold V_T, the probability of false alarm is as follows:

$$\begin{aligned} P_f = P_{rob}(V_T < R < \infty) &= \int_{V_T}^{\infty} \frac{R}{\psi_0} \exp\left(-\frac{R^2}{2\psi_0}\right) dR \\ &= \exp\left(-\frac{V_T^2}{2\psi_0}\right) \end{aligned} \tag{10.32}$$

The probability of detection is as written here:

$$P_d = \int_{V_T}^{\infty} \frac{R}{\psi_0} \exp\left(-\frac{R^2 + A^2}{2\psi_0}\right) I_0\left(\frac{RA}{\psi_0}\right) dR \tag{10.33}$$

Constant False Alarm Rate

The threshold for detection is usually determined to achieve a desired false alarm rate. The false alarm rate is quite sensitive to the threshold level. A **constant false alarm rate** (CFAR) can be obtained by adjusting the threshold in accordance with the measured background. There are different schemes for obtaining CFAR. The cell-average CFAR uses a tapped delay line to sample the range cells to either side of the test cell. The number of taps used in the cell-average CFAR might vary from 16 to 20. Clutter-map CFAR is to divide the radar's space into range and azimuth bins. Over several scans, a moving average of the clutter residue in each range-azimuth cell is calculated and is used to determine the threshold level. In the guard-band CFAR scheme, the interference level is determined by examining the frequency bands adjacent to the band containing the signal. The threshold is determined by this interference level. This type of CFAR is effective against wideband interference but not effective against clutter. The limiting CFAR scheme is used when the bandwidth of the interference is much greater than that of the target echo signal, such as with wideband noise jamming and with impulse jamming. In this scheme, except the wideband interference, signal plus high amplitude impulse interface is amplified and then pass through a limiter. After limiting, the signal and the interference have the same amplitude. Because the interference has much wider spectral bandwidth in the frequency domain, the power distributed to the signal band is much smaller than the signal. After passing through a band pass filter matched to the signal, the signal amplitude is thus much greater than the interference amplitude.

10.10 Continuous Wave Radars

10.10.1 Continuous Wave Radar

For a continuous wave (CW) **radar**, the transmitter is operated continuously rather than pulsed. A CW radar can obtain the target speed by measuring the Doppler frequency. Consider a CW radar with frequency f_0 and a target with a relative velocity v_r with respect to the radar. The Doppler shift of the received signal is given by:

$$f_d = 2v_r/\lambda = 2v_r f_0/c. \tag{10.34}$$

In the IF stage, the CW Doppler radar has a Doppler filter bank, which is a bank of narrow band filters centered at different frequencies. The center frequencies of the filters are staggered to cover the entire range of Doppler frequencies. The Doppler frequency is determined by the filter that has the largest output.

10.10.2 Frequency-Modulated CW Radar

The CW radar can measure the Doppler frequency of the target, but it cannot measure the target range. The **frequency-modulated CW radar** (FM–CW) can measure both the range and Doppler frequency of the target. In the FM–CW radar, the transmitted frequency changed as a function of time in a known manner.

Figure 10.4(A) shows the principle of triangular FM–CW ranging on a single target with no Doppler shift. The range information is contained in the frequency difference between the signal echo and the radar's present transmitting frequency. If there is no Doppler frequency, the difference frequency is a measure of the target range, which is given by:

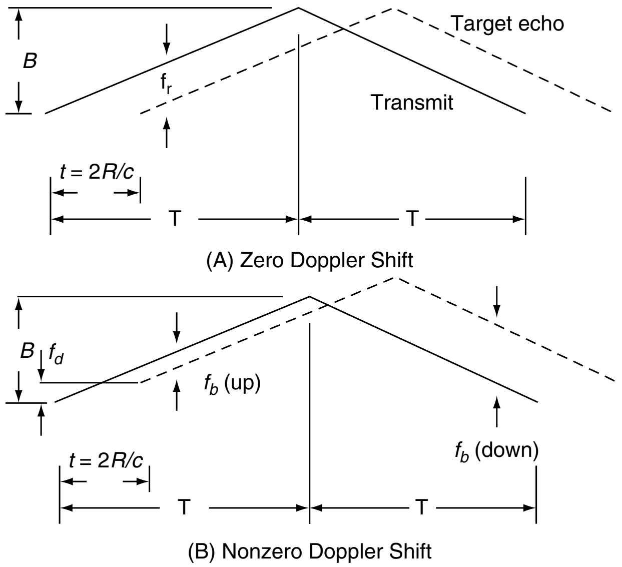
$$R = \frac{cTf_r}{2B}, \tag{10.35}$$

where B is the bandwidth of the transmitted signal, T is the period of the modulation wave, f_r is the frequency difference between the signal echo and the present transmitting signal, and c is the light speed.

If there is a Doppler shift, there is a received frequency–time relationship, as shown in Figure 10.4(B). There are two difference frequencies: the upper beat frequency, $f_b(\text{up})$, and the down beat frequency, $f_b(\text{down})$. The range frequency f_r and the Doppler frequency f_d can be extracted by:

$$\begin{aligned} f_r &= \frac{1}{2}[f_b(\text{up}) + f_b(\text{down})]. \\ f_d &= \frac{1}{2}[f_b(\text{down}) - f_b(\text{up})]. \end{aligned} \tag{10.36}$$

FM–CW radars can be used in airborne applications. For example, an FM–CW altimeter can be placed in the aircraft to measure height above the surface of the earth. A Doppler navigation radar can measure the vector velocity relative to the frame of reference of the antenna assembly. A Doppler navigation radar having forward and rearward beams is called a **Janus system**. With the Janus system, the angular displacement of the aircraft heading and the speed along the ground track can be measured.



(A) Zero Doppler Shift

(B) Nonzero Doppler Shift

FIGURE 10.4 Principle of Triangular FM–CW Ranging on a Single Target with Different Doppler Shifts

10.11 Moving Target Indicator and Pulse Doppler Radars

10.11.1 Moving Target Indicator Radar

In some radar applications, moving targets' signals are embedded in strong stationary clutter. Moving targets will produce a Doppler frequency shift, while the stationary clutter has very small spectral spreading around zero frequency. The **moving target indicator** (MTI) radar is a pulsed radar that uses the Doppler frequency shift as a means for discriminating moving targets from stationary clutter.

Delay-Line Canceller

A basic MTI single **delay-line canceller filter** is shown in Figure 10.5(A). The delay line has a time delay equal to the pulse repetition interval. The received signal and the reference signal are fed to a mixer called the phase detector, whose output is proportional to the phase difference of the two input signals.

The canceller output in the time domain is as follows:

$$y(t) = x(t) - x(t - T). \tag{10.37}$$

In the frequency domain, the output is shown by:

$$Y(\omega) = X(\omega)[1 - \exp(-j\omega T)]. \tag{10.38}$$

The transfer function of the filter is as follows:

$$\begin{aligned} H(\omega) &= \frac{Y(\omega)}{X(\omega)} = [1 - \exp(-j\omega T)] \\ &= 2j \sin\frac{\omega T}{2} \exp(-j\omega T/2), \end{aligned} \tag{10.39}$$

(B) A Double Canceller

(C) Frequency Responses of a Single Canceller (Solid Line) and a Double Canceller (Dashed Line)

FIGURE 10.5 Delay-Line Canceller Filter

and

$$|H(\omega)| = 2\left|\sin\frac{\omega T}{2}\right|. \qquad (10.40)$$

Two single cancellers can be cascaded to become a double canceller as shown in Figure 10.5(B). The transfer function of the double canceller is written as:

$$|H(\omega)| = 4\sin^3\frac{\omega T}{2}. \qquad (10.41)$$

The frequency responses of a single canceller and a double canceller are shown in Figure 10.5(C).

Blind Speeds

It is noted that in Figure 10.5(C), the frequency responses have nulls at multiples of the repetition frequency f_R. This indicates that Doppler frequencies equal to multiples of f_R will subject to total attenuation. Returns from targets with corresponding velocities will be highly attenuated and cannot be detected by the radar. These velocities are called **blind speeds**. The blind speed problem can be alleviated by the staggered PRF technique, which modulates the interpulse period with more than one PRF and uses the corresponding delays in the canceller filter. With the staggered PRF, the first null response or the blind speed will be increased.

Consider a double canceller with stagger pulse repetition intervals, aT and $(2-a)T$, which has an average delay T. Define the stagger ratio as $a/(2-a)$. If $a = (m-1)/m$, the stagger ratio $= (m-1)/(m+1)$, where m is a large and even integer; then, the first blind Doppler frequency will be at $f_{\text{blind}} = m/2T$.

Several figures of merit can be used to compare performance between various MTI filters. Some definitions are given here:

- **Clutter attenuation (CA):** The ratio of the clutter power at the filter *input* to the clutter power at the filter *output*
- **MTI improvement factor:** The *output* target-to-clutter ratio divided by the *input* target-to-clutter ratio
- **Subclutter visibility (SCV):** The ratio between the *input clutter power* and the *input target power* that yields equal powers at the output of the canceller filter

If $S_c(\omega)$ is the clutter power spectral density, and $|H(\omega)|$ is the magnitude of the filter response, the clutter attenuation is given by:

$$CA = \frac{\int_{-\infty}^{\infty} S_c(\omega)\,d\omega}{\int_{-\infty}^{\infty} S_c(\omega)|H(\omega)|^2\,d\omega}. \tag{10.42}$$

The filter attenuates the clutter, and it may also attenuate the signal. Assume that all Doppler frequencies are equally likely between 0 and the highest Doppler angular frequency $\omega_M = 4\pi V_m/\lambda$, where V_m is the highest target velocity. Define the average power gain as:

$$\overline{G} = \frac{1}{\omega_M}\int_0^{\omega_M} |H(\omega)|^2\,d\omega. \tag{10.43}$$

Then the output target power $P_{T\text{out}}$ is equal to $\overline{G}P_T$, where P_T is the input target power. By the definition of clutter attenuation, the output clutter power P_{cout} is equal to P_c/CA, where P_c is the input clutter power. The improvement factor I is related to $\overline{G}$ and CA by:

$$I = \frac{P_{T\text{out}}/P_{\text{cout}}}{P_T/P_c} = CA \cdot \overline{G}. \tag{10.44}$$

The expressions of CA, I, $\overline{G}$, and SCV depend on the target spectrum, the clutter spectrum, and the types of canceller filters. Assume that the clutter spectrum is normally distributed around zero Doppler with a variance of σ_ω^2, and assume that the Doppler spectrum is uniformly distributed between 0 and $1/T$. For a single canceller, we then have:

$$\begin{aligned} CA &\cong \frac{1}{2\left[1-\exp\left(-(\mathbf{T}\sigma_\omega)^2/2\right)\right]} \cong \frac{1}{(T\sigma_\omega)^2} \quad \textit{if } T\sigma_\omega \ll 1. \\ \overline{G} &= 2. \\ I &\cong CA \cdot \overline{G} = \frac{1}{\left[1-\exp\left(-(\mathbf{T}\sigma_\omega)^2/2\right]\right.} \cong \frac{2}{(T\sigma_\omega)} \quad \textit{if } T\sigma_\omega \ll 1. \end{aligned} \tag{10.45}$$

For a double canceller, the corresponding parameters are the following:

$$\begin{aligned} CA &\cong \frac{1}{6\left[1-4/3\exp\left[-(T\sigma_\omega)^2/2\right]+\frac{1}{3}\exp\left[-(2T\sigma_\omega)^2/2\right]\right]} \\ &\cong \frac{1}{3(T\sigma_\omega)^4} \quad \text{for } T\sigma_\omega \ll 1. \\ \overline{G} &= 6. \\ I &= CA \cdot \overline{G} \\ &\cong \frac{2}{(T\sigma_\omega)^4} \quad \text{for } T\sigma_\omega \ll 1. \end{aligned} \tag{10.46}$$

10.11.2 Pulse Doppler Radar

A **pulse Doppler radar** uses the Doppler shift to discriminate moving targets from stationary clutter. A low PRF radar has a long unambiguous range but results in blind speeds. On the contrary, a high PRF radar can avoid blind speeds but experiences ambiguity in range. MTI usually refers to a radar in which the PRF is low enough to avoid ambiguity in range but results in blind speeds. The pulse Doppler radar operates with high PRF to avoid blind speeds but at the expense of range ambiguity.

The pulse Doppler radar usually uses filter banks, which are implemented with a discrete Fourier transform rather than delay cancellers to remove the clutter. The improvement factor is a function of the size of the Fourier transform and the window function used.

10.12 Tracking Radar

Tracking refers to a radar following the position of one or multiple targets in space. Before the tracking process, the radar has to detect targets and find their range, angular location, and sometimes velocity. The requirements on the accuracy of angle measurement for a tracking radar are more strict than those for a search radar.

The principle of tracking radar is to use the error signal to adjust the antenna's pointing direction. The difference between the target direction and the reference direction, usually the axis of the antenna, is defined as the **angular error**. The tracking radar attempts to position the antenna with zero angular error (i.e., to locate the target along the reference direction).

Tracking radars are classified by how the tracking errors are developed. The principal tracking schemes include **lobe switching**, **conical scan** and **monopulse tracking**.

- **Lobe switching:** In the **lobe switching** mode, the antenna beam is switched alternately between two positions. The difference in amplitude between the voltages obtained in the two positions is a measure of the angular displacement of the target from the switching axis. The sign of the difference determines the direction that the antenna must be moved. When the switching axis is in the direction of the target, the voltages in the two positions are equal. Another two additional positions can be used to determine the direction of the target in the orthogonal plane.
- **Conical scan:** In the **conical scan** mode, an offset antenna beam is rotated continuously about an axis. The angle between the axis of rotation and the axis of the beam is called the **squint angle**. The echo from a target at the rotation axis will be constant all along the rotation period, while the echo from a target off the rotation axis will be sinusoidally modulated at the rotation frequency. The amplitude of the modulation indicates how far the

target is located off the axis. The phase of the modulation gives information about the direction of the target.

- **Monopulse system:** In the lobe switching and conical scan, tracking radars require several pulses to extract the error signal. During this interval, if the pulse echoes contain additional modulation components, such as fluctuating RCS, the tracking accuracy will be degraded. In fact, the angle of arrival of the target echo can be determined with a single pulse by measuring the relative phase or relative amplitude of the received echo pulse. Because information of the angular error is obtained on the basis of a single pulse, the system is called a **monopulse system**.

The monopulse system employs two overlapping antenna patterns to form the **sum pattern** and the **difference pattern**. The sum pattern is used for transmission, and both the sum pattern and difference pattern are used for reception. The sum pattern provides target detection and range measurement. The difference pattern provides the magnitude of the angular error. The monopulse antenna should have a sum pattern with high gain in the foresight and have a difference pattern with a large value of slope at the crossover of the offset beams.

10.12.1 Glint Error

Amplitude fluctuation, **angle fluctuation**, **receiver thermal noise**, and **servo-noise** limit the tracking accuracy. Amplitude fluctuation of an echo signal is an important limitation factor to the lobe switching and conical scan radars but not an important factor to the monopulse radar. In a tracking radar, the apparent angle of arrival (AOA) of a target is at the direction of the antenna with zero error signal. The apparent AOA may not be confined to the physical extent of the target and may be off the target. Changes in the target aspect with respect to the radar may cause the apparent AOA to wander from one direction to another direction. This random wandering of the apparent AOA is called angle fluctuation or **target glint**. The glint phenomenon is more pronounced when a relatively large target is at short range, which may make the radar unable to track the target and may be the chief factor limiting tracking accuracy. The angular error due to glint varies inversely with distance. Different carrier frequencies may produce different glint errors. The glint error can be reduced by averaging the independent measurements obtained with frequency agility over a bandwidth greater than $c/2D$, where D is the target depth. The qualitative angular error as a function of range is shown in Figure 10.6. The thermal noise term is inversely proportional to R^2, the glint error is inversely proportional to R, and the servo-noise is independent of range.

10.12.2 Track-While-Scan Radar

The track of a target or tracks of multiple targets can be determined with a surveillance radar. As the surveillance radar passes each target, its position is reported to the radar processor. After consecutive scans and reports, the targets' positions can be smoothed, and their future locations can be predicted. A surveillance radar that develops tracks on targets is sometimes called a **track-while-scan** (TWS) **radar**. In a modern radar, the target detection and tracking can be automatically processed by a data processor called **automatic detection and tracking** (ADS). An ADS system can perform the functions of target detection, track initiation, track association, track update, track smoothing, and track termination.

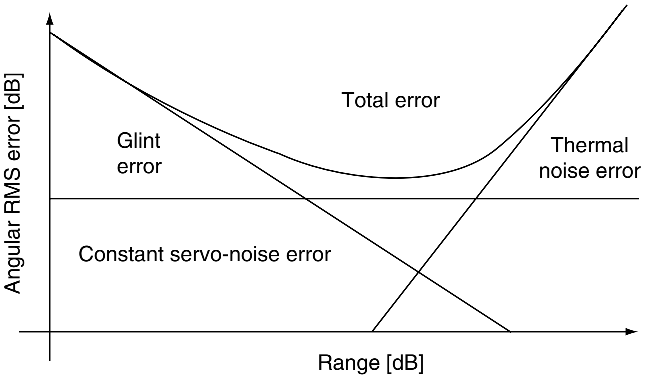

FIGURE 10.6 The Qualitative Angular Error as a Function of Range

10.13 High-Resolution Radar

A low-resolution radar views a target as a single point. Therefore, most targets to the low-resolution radar are point targets with different RCS or echo powers. When a high-resolution radar views the same target, it sees many scattering points and information about the targets, such as sizes, features, or images, that can be extracted from the received echoes.

10.13.1 Resolution

Targets can be resolved in range, azimuth cross-range, elevation cross-range, and Doppler. Resolution represents the smallest separation between two quantities that the radar can distinguish. Range resolution is a function of the transmitted waveform and is inversely proportional to the signal bandwidth. The resolution can be expressed by:

$$\Delta R \cong c/(2B), \tag{10.47}$$

where c is the speed of light and where B is the bandwidth. The factor 2 accounts for the round-trip. The cross-range resolution is proportional to the antenna 3-dB beamwidth $\Delta\theta$ and range R and can be expressed by:

$$\Delta X \cong R \cdot \Delta\theta. \tag{10.48}$$

The Doppler resolution is inversely proportional to the time T_D for collecting the target signal and can be expressed by:

$$\Delta f_D \cong 1/T_D \qquad (10.49)$$

10.13.2 Pulse Compression

To obtain a high-range resolution, the pulse is usually compressed. Pulse compression is the process of transmitting a wide pulse to achieve large radiated energy and processing it to a narrow pulse to obtain fine-range resolution. The transmitted pulse is called the **expanded pulse**, and the processed pulse is called the **compressed pulse**. The received signal is processed by passing it through a matched filter. The ratio of the transmitted pulse width to the compressed (or processed) pulse width is called the **pulse compression ratio**.

There are two primary classes of pulse compression: **analog** and **digital**. For analog compression, the transmitted waveform is a **linear FM pulse**. For digital compression, the transmitted waveform is a **phase-coded pulse**.

- **FM pulse compression:** In the linear FM pulse compression, the transmitted waveform consists of a rectangular pulse of constant amplitude. The frequency increases linearly over the duration of the pulse. On reception, the echo is passed through a pulse compression filter, or a matched filter. The output is the autocorrelation of the modulated pulse. The peak power of the correlator output is increased by the pulse compression ratio.
- **Phase-coded pulse compression:** In the phase-coded pulse compression, a long pulse with duration T_p is divided into N subpulses, called chips, of width T_c. The phase of each subpulse is chosen to be either 0 or π radian. The output of the matched filter has a spike of width T_c with an amplitude N times greater than that of the long pulse. The pulse compression ratio is $T_p/T_c = N$.

Two popular code sequences are used for the phase-coded pulse compression: the **Barker code** and the **pseudorandom code**. A binary phase-coded sequence that results in equal side lobes after passing through the matched filter is called a Barker code. The longest Barker code is of length 13. Pseudorandom codes are generated using shift registers with feedback and a modulo-two adder. An n-stage shift register has a total of 2^n different possible states. When the output sequence is of period $2^n - 1$ (the state of all zeros is excluded), it is called a maximal length sequence or a pseudonoise (PN) sequence.

Ambiguity Function

The ambiguity function is the two-dimensional (2-D) autocorrelation of waveform in time and frequency. It can be described as:

$$X(t, f) = \int_{-\infty}^{\infty} \mu(\tau)\mu^*(t+\tau)e^{j2\pi f\tau}d\tau, \qquad (10.50)$$

where $X(t, f)$ is the 2-D ambiguity function in time and frequency, and $\mu(\tau)$ is the waveform described in the time domain.

The diagram that represents the ambiguity function is called the ambiguity diagram. It indicates the limitations and utility of particular classes of waveforms and gives a general guideline for the selection of suitable waveforms for various applications.

10.14 High Cross-Range Resolution Radar

The cross-range resolution of a conventional radar is proportional to the product of the 3-dB antenna beamwidth and range. Consider a conventional imaging radar having an antenna with 2 m in length and transmitting linear FM pulses with a bandwidth of 10 MHz. Assume the radar is operated at 2 GHz; then, the 3-dB beamwidth is $\Delta\theta \approx \lambda/2L \cong 0.0375$ rad. If the range from the radar to the ground surface is 20 km, the cross-range resolution will be $\Delta x = R \times \Delta\theta = 20000 \times 0.0375 = 750$ m, much greater than the range resolution, which is equal to $\Delta R \cong c/2B = 15$ m. The cross-range resolution can be greatly improved by using the synthetic aperture technique.

10.14.1 Synthetic Aperture Radar

Synthetic aperture radar (SAR) is a radar carried by a moving vehicle that provides a high-resolution image in both range and cross-range. The fine range is obtained by transmitting waveforms with wide bandwidth, and the cross-range resolution is enhanced by moving the antenna to synthesize a large effective length.

Consider a side-looking SAR geometry as shown in Figure 10.7. The effective length of the synthetic antenna L_{eff} is the distance the radar moves while a scatterer remains in the beam. The beamwidths for a real array with length ℓ and a synthetic

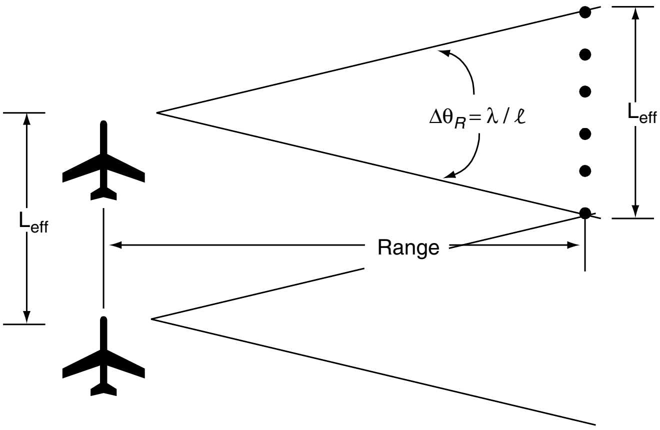

FIGURE 10.7 A Side-Looking SAR Geometry

array having an effective length L_{eff} are shown via these equations, respectively:

$$\Delta\theta_R = \lambda/\ell. \tag{10.51}$$

$$\Delta\theta_S = \lambda/2L_{eff}. \tag{10.52}$$

It is noted that there is a factor 2 in the denominator of equation 10.52. The effective synthetic length is related to the real array length by:

$$L_{eff} = R \cdot \Delta\theta_R = R\lambda/\ell,$$

where R is the range between the scatterer and the radar. The cross-range resolution of SAR at range R is as written here:

$$\Delta X_s = R \cdot \Delta\theta_S = R \cdot \lambda/2L_{eff} = \frac{\ell}{2} \tag{10.53}$$

The cross-range resolution is independent of range and wavelength, and the resolution is better with smaller real antenna length.

Unfocused and Focused SAR

The ranges between the scatterer and the antenna at different flying positions along the synthetic length are not a constant. The range when the antenna is at both ends is greater than the range when the antenna is at the normal to the flight path. When the range difference for the antenna at different positions exceeds a range resolution cell, it is called **range walk**. A range walk will cause the reconstructed image to be unfocused or obscure. To avoid the range walk, the maximum synthetic length should be limited to a length that allows the scatterers to always be in the far-field of the synthetic antenna. The synthetic length should be:

$$L_{eff}^2 < \lambda R/2.$$

The SAR constrained by the range walk is called the **unfocused SAR**. The best resolution for an unfocused SAR is the following:

$$\Delta X = R \cdot \frac{\lambda}{2L_{eff}} \cong (\lambda R/2)^{1/2}. \tag{10.54}$$

A focused SAR refers to data received that are phase-compensated so the range walks are effectively removed. After focusing, the cross-range resolution of equation 10.53 can be obtained.

Motion Compensation

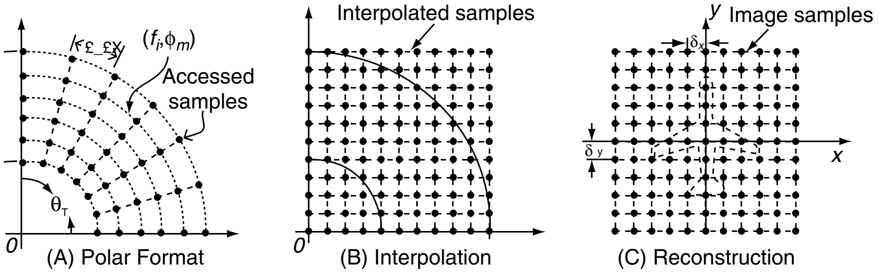
In generating the synthetic aperture, the signal processing assumes that the radar flies along a straight line at constant speed. Practically, the vehicle carrying the antenna may be subjected to deviation from linear motion. Motion compensation is to compensate the phase of the received signal for the displacement of real antenna motion from the position of the ideal SAR being generated.

10.14.2 Inverse Synthetic Aperture Radar

In SAR, the synthetic aperture is obtained by the motion of radar antenna. For inverse synthetic aperture radar (ISAR), the radar is stationary, and the aperture is synthesized by the motion of the object. A basic type of ISAR is the synthetic aperture with rotating objects.

ISAR Imaging of Rotating Objects

The procedure of ISAR imaging of rotating objects is as follows: The object to be imaged is mounted on a rotation pedestal. At each aspect, wideband complex frequency responses (amplitude and phase) or high-resolution range profiles of the backscattered fields are measured and recorded. The object is then rotated by a small angle, and another set of frequency responses or range profiles are taken. This process is repeated until data are gathered for a specified total rotation angle. If the measured quantities are the frequency responses, the data collected are arranged in a polar format as shown in Figure 10.8(A), where the radial line represents the frequency and where the azimuth represents the rotation angle. The point $(f_i, \phi_m,)$ represents the data measured at frequency f_i and



(A) Polar Format (B) Interpolation (C) Reconstruction in Different Arrangements

FIGURE 10.8 The Data Collected by Rotation Object Imaging in Different Arrangements

aspect ϕ_m. The image can be reconstructed by taking a 2-D Fourier transform over the collected frequency responses. To use the efficient 2-D fast Fourier transform (FFT), the data sampled in polar grid format should be converted to data sampled in rectangular grid format through an interpolation process as shown in Figure 10.8(B). The image is then processed by taking the 2-D FFT on the interpolated samples as shown in Figure 10.8(C). If the data measured are the complex range profiles for each aspect angle, we can convert the complex range profile into the complex frequency response through a 1-D FFT and arrange the frequency response data in polar format. The image can be reconstructed by the same procedure shown in Figure 10.8. The cross-range resolution ΔX of rotating object imaging is related to the total rotation angle ϕ_T and wavelength λ by:

$$\Delta X = \frac{\lambda}{4\sin(\phi_T/2)}. \qquad (10.55)$$

If the total rotation angle is small, equation 10.55 can be simplified to $\Delta X \cong \lambda/2\phi_T$. The sampling criterion for the angular rotation is to satisfy the Nyquist criterion and avoid the aliasing effect. If the maximum extent of the object is $D_{\max}$, the angular increment $\delta\phi$ should be:

$$\delta\phi < \frac{\lambda}{2D_{\max}} \qquad (10.56)$$

10.15 Inverse Scattering

10.15.1 Definition and Applications

The inverse scattering problem is to reconstruct or recover some physical and/or geometric properties of an object from the measured scattered field under the illumination of an incident wave. The reconstructed information of interest includes, for instance, the dielectric constant distribution and the shape or structure. The interrogating or probing radiation can be an electromagnetic wave (e.g., microwave, optical wave, and X-ray), an acoustic wave, or some other waves. The problem of inverse scattering is important when details about the structure and composition of an object are required but can not be ascertained from measurements made *in situ.*

Due to its noninvasiveness, inverse scattering has wide applications in nondestructive evaluation, medical imaging, remote sensing, seismic exploration, target identification, geophysics, optics, atmospheric sciences, and other such fields.

10.15.2 Properties of the Inverse Scattering Problem

From a mathematical point of view, the existence, uniqueness, and stability of the solution are important concerns of the inverse scattering problem. Several conditions have been suggested to ensure the existence and uniqueness of the solution. It is quite difficult, however, to deal with the instability, which is inherent to the problem. The ill-posed problem, which means that a small error on the data (i.e., the measured scattered field) may cause a large error on the solution (i.e., the reconstructed result), usually makes the inverse scattering problem rather intractable. This phenomenon is even more significant from the viewpoint of applied science or engineering where the incompleteness of measured data and the noise contamination are not uncommon. In addition, it can be shown that the measured data depend nonlinearly on the property function of the object. This nonlinearity also increases the complexity of the inverse scattering problem.

Categories of Electromagnetic Inverse Scattering Problems

Here, the concern is with electromagnetic inverse scattering or electromagnetic imaging problem for which the electromagnetic wave is used as a probing tool. From different aspects, we can classify the electromagnetic inverse scattering problems in various ways. According to the physical properties of the material, the object may be a conductor (for which the information to be reconstructed is the shape function) or a dielectric (for which the dielectric constant distribution and hence also the shape function are to be reconstructed). Moreover, the dielectric object can be homogeneous or inhomogeneous, and different inversion algorithms may apply. According to the environment in which the object is embedded, there may be whole-space problem or half-space problem. The latter is more difficult than the former due to the complexity of Green's function and the geometric limitation on the data measurement for the buried object. According to the dimensionality, the inverse scattering problem may be of one, two, or three dimensions. The one-dimensional problems, which are related to the remote sensing of layered media, have been intensively investigated. There still remain difficulties, however, in the two- or three-dimensional case.

10.15.3 Integral Equation Formulations: Three-Dimensional Case

This discussion now presents some rigorous integral equation formulations for inverse scattering of a conductor as well as a dielectric in the general three-dimensional case. Consider an object occupying the volume V bounded by the surface S with unit outer normal $\hat{n}$, as shown in Figure 10.9.

This object of interest is embedded in a homogeneous background with dielectric constant ε_{rb}. When an incident time-harmonic electromagnetic wave with electric field $\vec{E}^i(\vec{r})$ and angular frequency ω impinges on the object, one can measure the scattered field $\vec{E}^s(\vec{r})$ outside it. The purpose of inverse scattering is to reconstruct the shape of the object (for a conductor) or the dielectric constant distribution $\varepsilon_r(\vec{r})$ of the object (for a dielectric) based on the measured scattered field.

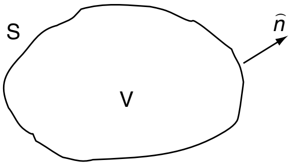


FIGURE 10.9 Object Embedded in a Homogeneous Background

Starting with Maxwell's equations as well as appropriate boundary conditions and using the Green's function technique, one can derive the following integral equations relating the scattered field to the property function of the object:

For a conductor:

$$\begin{cases} \vec{E}^s(\vec{r}) = j\omega\mu \int\int_S \bar{\bar{G}}(\vec{r},\vec{r}')\cdot\vec{J}_s(\vec{r}')dS', \quad \text{some } \vec{r} \notin V. \\ -\hat{n}\times\vec{E}^i(\vec{r}_0) = j\omega\mu\hat{n}\times\int\int_S \bar{\bar{G}}(\vec{r}_0,\vec{r}')\cdot\vec{J}_s(\vec{r}')dS', \quad \vec{r}_0 \in S. \end{cases} \tag{10.57}$$

For a dielectric:

$$\begin{cases} \vec{E}^s(\vec{r}) = -k^2 \int\int\limits_v\int \bar{\bar{G}}(\vec{r},\vec{r}')\cdot\left[\frac{\varepsilon_r(\vec{r})}{\varepsilon_{rb}}-1\right]\cdot\vec{E}(\vec{r}')dV', \quad \text{some } \vec{r}\notin V. \\ \vec{E}(\vec{r}_0) = \vec{E}^i(\vec{r}_0) - k^2\int\int\limits_v\int \bar{\bar{G}}(\vec{r}_0,\vec{r}')\cdot\left[\frac{\varepsilon_r(\vec{r}')}{\varepsilon_{rb}}-1\right]\cdot\vec{E}(\vec{r}')dV', \quad \vec{r}_0 \in V. \end{cases} \tag{10.58}$$

In equations 10.57 and 10.58 $\vec{J}_s$ is the induced surface current density on the conductor, $\bar{\bar{G}}$ is the dyadic Green's function, $\vec{E}$ denotes the total electric field in the dielectric object, μ is the permeability (a constant), and k is the wave number of the background medium. For the conductor case, the induced surface current density $\vec{J}_s$ is related to shape function through the second part of equation 10.57. Then, from the first part of equation 10.57, it is apparent that the unknown shape function is nonlinearly related to the known (measured) scattered field. In a similar manner, the total field $\vec{E}$ in the dielectric object is related to the dielectric constant distribution ε_r through the second part of equation 10.58. Therefore, the first part of equation 10.58 implies that the unknown dielectric constant distribution depends nonlinearly on the known (measured) scattered field. In other words, the inverse scattering problem is a nonlinear ill-posed problem and various numerical techniques have been developed to tackle it. Note also that for the cases of lower dimensionality or under some circumstances, integral equations 10.57 and 10.58 can be simplified or transformed into other equivalent forms.

10.15.4 Methods for Solving the Inverse Scattering Problem

A variety of inversion algorithms have been proposed to solve the aforementioned inverse scattering problems under various conditions. The numerical techniques can be roughly classified into two general categories: the **approximate approach** and the **rigorous method**. The former is usually based on the linearized model in which the scattered field is approximated as a linear function of the object function. That is, the theoretical formulation is approximated at the beginning, and hence, the problem can be simplified and easily treated. On the other hand, the rigorous approach deals directly with the nonlinear problem based on the rigorous formulation. It is almost impossible to have a closed-form or exact solution, however, and some numerical techniques, including how to discretize the problem, are still needed to obtain a reconstructed result.

Approximate Approaches

Bojarski's Identity

Based on the physical optics (PO) approximation, Bojarski proposed in 1967 the so-called Bojarski's identity that can be used to determine the shape function of a conducting object from the measured back-scattered far-field over all frequencies and all aspect angles. This approach is illustrated in the following. Consider a conductor of volume V bounded by the surface S. When this conductor is illuminated by an electromagnetic plane wave $\vec{E}^i_o e^{-j\vec{k}^i\cdot\vec{r}}$, the back-scattered far-field can be expressed as:

$$\vec{E}^s \approx -\frac{e^{-jkR}}{\sqrt{2\pi}R}\vec{E}^i_0\cdot\rho(\vec{K}), \tag{10.59}$$

with

$$\rho(\vec{K}) = \frac{-j}{2\sqrt{\pi}}\int\int_{\vec{K}\cdot\hat{n}>0} e^{j\vec{k}\cdot\vec{r}'}(\vec{K}\cdot\hat{n})dS'. \tag{10.60}$$

In these equations, $\vec{K}$ is $-2\vec{k}^i$, R is the distance from the reference point on the object, and $\vec{K}\cdot\hat{n}>0$ refers to the illuminated part of the surface. Now consider the scattered field when illuminated from the opposite direction ($\vec{K}\to-\vec{K}$). Take the complex conjugate and obtain:

$$\rho^*(-\vec{K}) = \frac{-j}{2\sqrt{\pi}}\int\int_{\vec{K}\cdot\hat{n}<0} e^{j\vec{k}\cdot\vec{r}'}(\vec{K}\cdot\hat{n})dS'. \tag{10.61}$$

If the conducting object is convex, then:

$$\rho(\vec{K})+\rho^*(-\vec{K}) = \frac{-j}{2\sqrt{\pi}}\oint\!\!\oint_S e^{j\vec{k}\cdot\vec{r}'}(\vec{K}\cdot\hat{n})dS' = \frac{K^2}{2\sqrt{\pi}}\int\int\int_V e^{j\vec{k}\cdot\vec{r}'}dV'. \tag{10.62}$$

Here, the divergence theorem has been used. The complex scattering amplitude $\Gamma(\vec{K})$ and the characteristic function $\gamma(\vec{r}')$ of the object can be defined as:

$$\Gamma(\vec{K}) = \frac{2\sqrt{\pi}}{K^2}[\rho(\vec{K})+\rho^*(-\vec{K})]. \tag{10.63}$$

$$\gamma(\vec{r}') = \begin{cases} 1 & \text{inside } V \\ 0 & \text{outside } V \end{cases}. \tag{10.64}$$

The result is the following three-dimensional Fourier transform relationship:

$$\Gamma(\vec{K}) = \iiint \gamma(\vec{r}') e^{j\vec{k}\cdot\vec{r}'} dV'. \tag{10.65}$$

Taking the inverse Fourier transform, yields:

$$\gamma(\vec{r}) = \frac{1}{(2\pi)^3} \iiint \Gamma(\vec{K}) e^{j\vec{k}\cdot\vec{r}} d\vec{K}. \tag{10.66}$$

Equation 10.66 is Bojarski's identity and shows that the object shape can be reconstructed by measuring the backscattered far-field over all $\vec{K}$. Since the PO approximation is valid only at high frequencies and for smooth convex conducting surfaces, Bojarski's identity has its own theoretical limitation. Another practical difficulty is that the measured far-field data should be complete over "all" frequencies and "all" aspect angles. However, this difficulty is common to almost all the inversion algorithms. In spite of these difficulties, Bojarski's identity is useful for reconstructing the shape of a large, smooth convex conductor for which the multiple scattering effect can be neglected. Moreover, the algorithm is also efficient in computation because it makes use of the **fast Fourier transform** (FFT).

Diffraction Tomography

The X-ray **computerized tomography** (CT) has been widely used for medical imaging and diagnosis since the 1970s. The basic idea of it is that the total attenuation of the X-ray traversing the object along some direction is related to the integrated absorption by the object along that direction. Hence, the attenuation distribution of the transmitted X-ray forms a Radon transform of the absorption distribution of the object. The projection–slice theorem is used to collect the data in the Fourier domain, and then the inverse Fourier transform is performed (by FFT) to reconstruct the absorption distribution of the object. Now, if the electromagnetic wave is used to reconstruct dielectric constant distribution of the object in a similar manner, the diffraction effect due to finite wavelength should be taken into account. It is quite complicated to do in general. For a weakly inhomogeneous object, however, it is possible to formulate the diffraction tomography in a manner similar to CT, and the general solution can be obtained. To be specific, here the dielectric object of interest is assumed to be weakly inhomogeneous such that the total field $\vec{E}$ in the first part of equation 10.58 can be approximated by the incident field $\vec{E}^i$. This is usually referred to as the **Born approximation**. Consider a two-dimensional dielectric object illuminated by a plane wave incident from the direction $\hat{\imath}$, as shown in Figure 10.10.

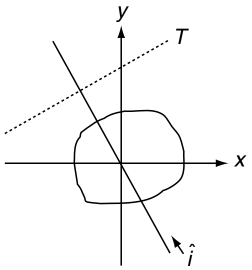

FIGURE 10.10 A 2-D Dielectric Illuminated by a Wave

The forward scattered field measured along the line T perpendicular to $\hat{\imath}$ can be expressed as the integral of the product of the Green's function, incident field and the dielectric constant of the object. Taking the one-dimensional Fourier transform of the scattered field along the line perpendicular to $\hat{\imath}$, one sees that the transformed field is related to the values of the two-dimensional Fourier transform of the dielectric constant contrast evaluated on a semicircle. The orientation of the semicircle depends on the incident direction $\hat{\imath}$, and its radius is frequency-dependent. Note that this semicircle corresponds to the slice for the conventional X-ray CT. If we change the direction of the incident wave (and hence the corresponding direction of receiving line) over all aspect angles and/or vary the frequency of the incident wave, sufficient transformed data will be available in the two-dimensional spatial frequency domain. After proper interpolation of the data to fit the rectangular coordinates, one can take the two-dimensional inverse Fourier transform (by FFT) to obtain the reconstructed dielectric constant distribution. This is the basic principle of the forward-type diffraction tomography. For the reflection-type, one can measure the back scattered field along the line perpendicular to $\hat{\imath}$ and perform similar processes (except that the transformed data are now on another semicircle away from the origin). This discussion is based on the Born approximation that holds only for the case of very weak inhomogeneity of the dielectric object. However, one can enlarge the range of inhomogeneity a little further such that the Rytov approximation is valid. By properly defining the measured quantity (taking the logarithm of the total field divided by the incident field), it can be shown that all the aforementioned processes are still valid. Therefore, the diffraction tomography can be applied to a larger range of inhomogeneity of the dielectric object as long as the Rytov approximation is satisfied. Note that the idea of diffraction tomography can also be applied to inverse scattering of the conducting object. Under the physical optics approximation, the scattered field can be approximately expressed as a linear function of a properly defined shape function of the object. Therefore, the one-dimensional Fourier transform of the scattered field will be related to the values of the two-dimensional Fourier transform of the shape function evaluated on a semicircle. This is indeed the basic scheme of the diffraction tomography. However, the shape function defined here is not rigorous since it depends on the incident wave vector. Note that this type of diffraction tomography is applicable only to the large, smooth convex conductor because of the limitation on the PO approximation. Compared to the inversion algorithm of Bojarski's identity for which the far-field measured data are required, the measurement for the diffraction tomography can be made in the near zone. This may be convenient in practical applications.

Rigorous Approaches

Iterative Methods

As mentioned previously, the inverse scattering problem is in general a nonlinear problem in the sense that the unknown object function is nonlinearly related to the measured scattered field. To solve it rigorously, iterative techniques are usually applied. Although various algorithms have been proposed, they are based on the same principle—taking the variation of the nonlinear equation and solving the resulting linearized problem at each iterative step to update the solution. For illustration, consider a dielectric object of dielectric constant distribution $\varepsilon_r(\vec{r})$ illuminated by the incident field $\vec{E}^i(\vec{r})$. The scattered field $\vec{E}^s(\vec{r})$ is related to the dielectric constant $\varepsilon_r(\vec{r})$ through equation 10.58. First discretize the object into N small cells and assume that the dielectric constant and electric field are constants in each cell. By the moment method, transform the integral equation 10.58 into the following algebraic matrix equation:

$$[G_2][\tau]([I]-[G_1][\tau])^{-1}[E^i]=[E^s]. \tag{10.67}$$

Here, matrix $[G_2]$ corresponds to the Green's function relating an interior point in the object to an exterior point outside the object, $[G_1]$ corresponds to the Green's function associated with two interior points, $[\tau]$ is a diagonal matrix with elements being the contrast of the object's dielectric constant with respect to the surroundings, $[E^i]$ lists the incident field in N cells, $[E^s]$ lists the measured scattered field outside the object, and $[I]$ is an identity matrix. The nonlinear relation between $[\tau]$ and $[E^s]$ is apparent in equation 10.67. For solving this nonlinear algebraic equation, first take the variation or differential of equation 10.67 to yield:

$$[G_2]([I]-[\tau][G_1])^{-1}[\delta\tau]([I]-[G_1][\tau])^{-1}[E^i]=[\delta E^s], \tag{10.68}$$

which describes a variation $[\delta E^s]$ due to a variation $[\delta\tau]$. The linear relation between $[\delta E^s]$ and $[\delta\tau]$ in equation 10.68 can also be rewritten in the following familiar form:

$$[A_\tau][x]=[b], \tag{10.69}$$

where matrix $[A_\tau]$ depends on the contrast $[\tau]$ of the dielectric constant and is related to matrices $[G_2]([I]-[\tau][G_1])^{-1}$ and $([I]-[G_1][\tau])^{-1}[E^i]$. All the unknowns in $[\delta\tau]$ are listed in the column matrix $[x]$, and the column matrix $[b]$ contains the elements in $[\delta E^s]$. Note that equation 10.69 is the basic equation used at each iterative step. The whole iteration scheme proceeds by first choosing an initial guess $[\tau_{(0)}]$ of the true contrast of the dielectric constant $[\tau_{\text{true}}]$. The resulting scattered field $[E^s_{(0)}$ due to $[\tau_{(0)}]$ can be calculated by equation 10.67, and the difference in scattered field $[\delta E^s_{(0)}]$ between the measured value and the calculated one is evaluated. To the first-order approximation, $[\delta\tau_{(0)}]$ obtained from solving equation 10.69 is used to update the initial guess to $[\tau_{(1)}]=[\tau_{(0)}]+[\delta\tau_{(0)}]$. This new $[\tau_{(1)}]$ is then taken as the initial guess at the second step, and a similar procedure is repeated to obtain further updated $[\tau_{(2)}]$. In other words, the above procedure is repeatedly executed, using $[\tau]$ updated at the previous step, until the variation $[\delta\tau]$ between consecutive steps is smaller than some prescribed value. This illustrates the basic principle of the iterative methods. Based on the idea of iteration, other algorithms have been created, such as the Newton-Kantorovitch technique, Born iterative method, and distorted Born iterative method.

Other Methods

Note that after discretization, the inverse scattering problem can be cast into a multivariable nonlinear problem. There exist, of course, miscellaneous methods for solving this problem. Apart from those mentioned previously, other available methods include genetic algorithm and simulated annealing.

Regularization

Inverse scattering is an ill-posed problem in the sense that its solution is unstable with respect to the perturbation of the measured data. Explicit evidence is the occurrence of inverting an ill-conditioned matrix during the inversion process. For example, matrix $[A_\tau]$ in equation 10.69 is usually of high condition-number inducing errors at each iterative step. To address the ill-posed problem the regularization process is usually used. The basic idea of regularization is to compute a meaningful "smooth" solution or to filter out the high-frequency components associated with the small singular values. If the inverse scattering problem is so formulated that the convolution or Fourier transform is involved, the regularization is realized by introducing a low-pass filter during the deconvolution or inverse Fourier transform process. If the matrix inversion is involved in the inverse scattering problem, one can take the pseudoinverse transformation or, equivalently, singular value decomposition method to regularize the problem. In this approach, the effect of singular values smaller than some threshold is neglected to obtain the well-behaved solution. Another equivalent technique, known as **Tikhonov method**, has also been proposed. It incorporates a properly chosen well-posed problem into the original ill-posed one to increase the stability of the resulting solution. All of the discussions in this chapter are from the mathematical point of view. In practice, one can incorporate prior knowledge or some constraints in the reconstruction operation to limit the range of possible solutions. In addition, more measured data at multiple frequencies and/or from multiview illumination will be helpful for the stabilization of the solution.

11.1 Introduction

In this chapter, a variety of topics concerning communication systems at microwave- and millimeter-wave frequencies are discussed.

Section 11.2, Device Technology and Concepts, begins with a discussion on noise at these frequencies. Because wireless applications are the primary drive for development of these frequency bands, understanding the basic concepts of noise at these frequencies becomes of fundamental importance in understanding the sensitivity of high-frequency components, such as low-noise amplifiers and mixers. The section continues with an introduction to the most common microwave devices, including bipolar transistors, field-effect transistors, high electron mobility transistors, and two-terminal microwave devices. Noise mechanisms and most common applications as well as their most common small-signal models are discussed. Heterojunction bipolar transistors are briefly mentioned in the section on bipolar transistors.

In Section 11.3, Active Microwave Circuits, issues relevant to the design of the most common types of active microwave circuits are discussed. The section first presents the design of microwave amplifiers using an *S*-parameter approach. Next, microwave oscillator design is briefly outlined. The stability conditions for both one- and two-port microwave oscillators are presented. The section concludes with a discussion on microwave detectors and mixers. Detectors are often used in control circuitry. Mixers are used in up-conversion and down-conversion circuitry of wireless systems. Fundamental operation of mixing phenomena is described and figures of merits for mixers are defined.

Section 11.4, Planar Antennas, presents a unique and practical class of antennas for application at microwave- and millimeter-wave frequencies. These antennas, often referred to as printed antennas, are completely compatible with many types of high-frequency transmission lines and can be constructed directly on a printed circuit board. Their low cost, ease of fabrication, and control over their radiation properties makes these antennas very useful in commercial wireless systems at these frequencies. Four types of planar antennas are discussed, including the patch antenna, slot antenna, the tapered slot antenna (TSA), and the newly developed quasi-Yagiantenna. The section concludes with an antenna selection guide, containing geometry and radiation characteristics of a wide variety of planar antennas in one compact table for easy reference.

Last, this chapter briefly discusses active integrated antennas (AIAs). In this approach, the compatibility of planar antennas with popular microwave frequency transmission lines and active devices is exploited by directly integrating the active circuitry with the antenna platform. This results in a compact and highly functional system with many interesting characteristics.

11.2 Device Technology and Concepts

This section deals with fundamental basics of active microwave circuits: **noise in a microwave system** and **noise in active microwave devices**. As this section first explains, at microwave frequencies, noise is dominated by thermal and shot noise, not $1/f$ noise. Then, the bipolar transistor, heterojunction bipolar transistor, field effects transistor, high electron mobility transistor, and two-terminal microwave devices are discussed. Excellent references on these topics can be found in Fukui (1981) and Yngresson (1991).

11.2.1 Noise in a Microwave System

In a microwave system, a small signal can be measured even when no applied signal is present. This is due to noise that can come from several sources. The sensitivity of receiver components, such as the low noise amplifier (LNA) and mixer, is fundamentally limited by the noise figures of their components and background noise. For these reasons, noise is of fundamental importance in many active microwave frequency designs and will be covered briefly in this section. Dominant mechanisms are typically thermal noise and shot noise at microwave frequencies. If a microwave device is used to directly convert a signal to baseband, $1/f$ noise may become an important noise factor as well since $1/f$ noise determines oscillator phase noise.

Thermal (Johnson) noise is one of the dominant types of noise present in microwave circuits, and it is caused by the random fluctuations of the electrons due to thermal agitation. At microwave frequencies and for a temperature, T, close to room temperature, an expression for the rms voltage produced by a resistor of value R is the following:

$$v_n = \sqrt{4kTRB}. \tag{11.1}$$

Note that k is Boltzmann's constant ($1.374 \times 10^{-23}\,\mathrm{J/^\circ K}$), and B is the bandwidth that the noise is measured over. Therefore, the thermal noise depends on bandwidth and not on the center frequency. For this reason, it is also referred to as **white noise**.

Shot noise is noise due to electron and hole fluctuations in any device with an average dc current flow. **Flicker noise** ($1/f$ *noise*) is noise due to a variety of sources that exhibits a $1/f^{\alpha}$ dependence, where α is close to one. At microwave frequencies, the contribution of flicker noise is usually negligible with respect to other noise mechanisms. Its contribution can be significant for some microwave devices operated below 50 MHz.

Typically, flicker noise will be dominant at lower frequencies until the **corner frequency** is reached, above which thermal noise dominates. For particular devices, shot noise will also have a contributive effect. As with thermal noise, however, shot noise is also approximately independent of frequency. Therefore, from a macroscopic point of view, both of these mechanisms can be lumped together when characterizing a device or component in terms of its noise characteristics. The question then becomes how to best describe a noise source. The simplest way is to consider a simple resistor. As shown in Figure 11.1, this may be a **noisy resistor** or a **noiseless resistor**.

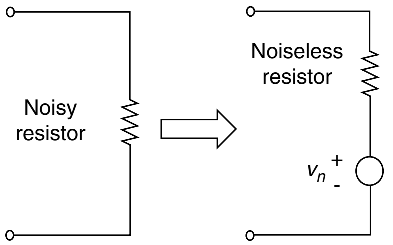

FIGURE 11.1 Model of a Noisy Resistor

The noise power available from an arbitrary 1-port network with an input impedance $Z(f) = R(f) + jX(f)$ can be expressed in terms of a noise temperature. If the available noise power, P_a, is constant over the frequency range of interest, then a noise temperature can be defined as:

$$T_s = \frac{P_a}{kB}. \tag{11.2}$$

Note that this is not the physical temperature at which the network is measured but the temperature required for a resistor to give the proper available noise power. This can be determined by measurements with a calibrated noise source.

Noise of two-port networks, such as from mixers or amplifiers, is also of interest in receiver design. For a noisy two-port network with known gain G_a when both ports are terminated in a simultaneous conjugate match, the available noise power at the output will be given by:

$$P_{no} = P_{ni}G_a + P_{ne} = kT_sBG_a + P_{ne}. \tag{11.3}$$

The first variable represents the noise amplified (or attenuated) by the network. The second, P_{ne}, represents the excess noise generated by the network itself. In addition, if the input noise temperature, T_s, is held at 0° Kelvin, the output noise power will consist of only P_{ne}. The noisy two-port can be replaced by a noiseless two-port giving the same noise power output. This is done by defining an effective noise temperature of the two-port network itself, T_e:

$$T_e = \frac{P_{ne}}{kBG_a}. \tag{11.4}$$

The total noise power output of the equivalent noiseless two-port is then:

$$P_{no} = kT_s\left[1 + \frac{T_e}{T_s}\right]BG_a. \tag{11.5}$$

In equation 11.5, the calculation in brackets is of particular interest. By simple manipulation, it can be shown that this part of the calculation is equivalent to the signal-to-noise ratio (SNR) at the input to that at the output. This term is defined to be the **actual noise figure** of the two-port:

$$F_a = 1 + \frac{T_e}{T_s} = \frac{SNR_i}{SNR_o}. \qquad (11.6)$$

By convention, the noise figure is often cited for a two-port network. The noise figure, F, is defined to be the actual noise, F_a, with T_s held at room temperature ($T_s = 290°K$).

Often, two-port networks will be cascaded in a receiver. For instance, several LNAs may be required to boost a received signal to a sufficient level that it can be down-converted. In this case, the designer may be interested in the overall effect of cascading each two-port network. The total effective noise temperature and noise figure of n cascaded two-ports can be found using:

$$F = F_1 + \frac{F_2 - 1}{G_{a1}} + \cdots + \frac{F_n - 1}{G_{a1}G_{a2}\cdots G_{a(n-1)}}. \qquad (11.7)$$

$$T_e = T_{e1} + \frac{T_{e2}}{G_{a1}} + \cdots + \frac{T_{en}}{G_{a1}G_{a2}\cdots G_{a(n-1)}}. \qquad (11.8)$$

Bipolar Junction Transistor

Typically made from silicon in the NPN configuration, the microwave bipolar junction transistor (BJT) is historically the dominant device below 4 GHz but does find some application above this frequency. Currently, silicon CMOS devices are increasingly competitive at these frequencies for many applications.

Conceptually, operation of the microwave BJT is similar to its lower frequency counterparts, but it requires scaled-down base widths (commonly 0.1 μm). While the gate voltage controls the FET, the base current controls the BJT. A cross-sectional view of an idealized BJT with an interdigital design is shown in Figure 11.2.

Several commonly referred to characteristics for BJT transistors are useful for choosing a device. The first of these is f_T: the gain-bandwidth frequency. This is the frequency for which the **short-circuit current gain** of the device is unitary (0 dB). The second is $f_{\max}$, the maximum frequency of oscillation, or the maximum frequency that the device can produce negative resistance. Typically, the parameter h_{fe}, the low frequency short-circuit current gain, is not used with microwave frequency devices. The meaning of these parameters is illustrated in Figure 11.3. Note that gain rolls off at the rate of −6dB/Octave.

A standard hybrid-π model for the BJT transistor is shown in Figure 11.4. At microwave frequencies, the resistance of $r_{b'c}$ is typically much larger than the reactance of $C_{b'c}$, which it is in parallel with, allowing it to be replaced with an open circuit. The resistance r_{ce} may also be large enough with respect to $C_{b'e}$ and $r_{b'e}$ so that it may be omitted as well, resulting in a simpler model at microwave frequencies. Extrinsic components of the package, however, are also important at microwave frequencies. A typical equivalent model of the package is shown to the right of the intrinsic BJT model.

Due to their low cost and reliable performance, Si BJTs are found in many applications below 4 GHz. Packaged low-power (general purpose), medium-power, and low-noise BJTs are available from many manufacturers. Power versions are also available. Figures of merit for microwave BJTs are f_T and $f_{\max}$. In terms of the equivalent circuit model, these are given by:

$$f_T = \frac{g_m}{2\pi Cb'e}. \qquad (11.9)$$

$$f_{\max} = \sqrt{\frac{f_T}{8\pi rb'eCb'c}}. \qquad (11.10)$$

Noise mechanisms in microwave BJTs are thermal noise caused by thermal agitation of the carriers in the ohmic resistance of the emitter and base, collector, and shot noise caused

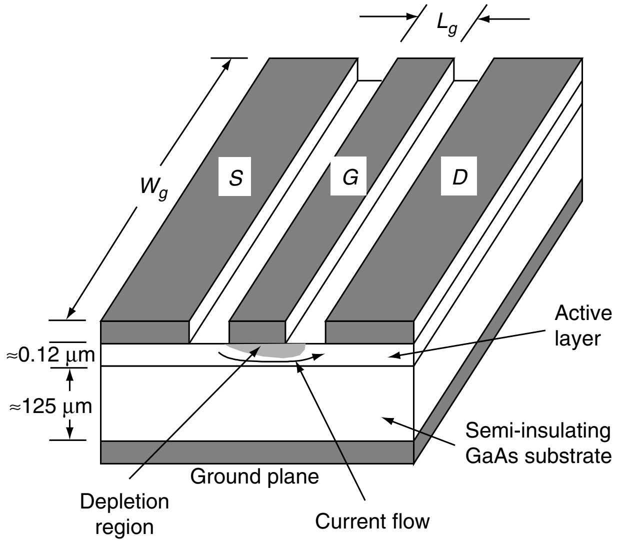

FIGURE 11.5 Physical Structure of Idealized GaAs MOSFET

by fluctuation in the electron and hole currents due to biasing conditions.

Inclusion of a heterojunction in the BJT has been demonstrated to yield a device with superior microwave properties, including higher gains and superior noise figure. The device is commonly referred to as the heterojunction bipolar transistor (HBT). Unlike conventional microwave frequency BJT transistors that are Si-based, the HBT typically uses GaAs technology with a significantly higher velocity of electrons in the *n*-doped GaAs. Commercial development of the HBT is not nearly as mature as competing technologies, such as development of the HEMT. It is therefore expected that significant improvements will be made in these devices, which already show respectable performance. SiGe HBT transistors have also been successfully developed.

Metal-Oxide-Semiconductor Field Effect Transistor (MOSFET)

The MOSFET, typically made of gallium arsenide (GaAs FET) because of its high electron mobility, is the most common device used for amplification (low noise and power) in the regions between 4 to 60 GHz. It is also commonly used in oscillators, mixers, and switches. Due to the excellent noise properties of the MOSFET, it is often used for sensitive receivers below 4 GHz. GaAs FETs typically exhibit higher power gain, lower noise figure, and higher output capabilities than Si BJTs above 4 GHz. The idealized geometry of a GaAs FET is shown in Figure 11.5. Note that the depletion region below the gate controls the amount of current flowing between the source and drain. With zero applied bias, the depletion region will consist of only the built-in potential of the Schottky barrier. As the gate potential is made negative relative to the source, the depth of the depletion region increases, with the effect of increasing channel resistance and reducing current. Pinch-off occurs when the depletion region reaches the semi-insulating GaAs substrate.

The GaAs FET is the primary building block of monolithic microwave-integrated circuits (MMICs). Generally, smaller gate length (L_g) corresponds to higher f_{max}. Longer gate width (W_g) corresponds to higher output power. A gate

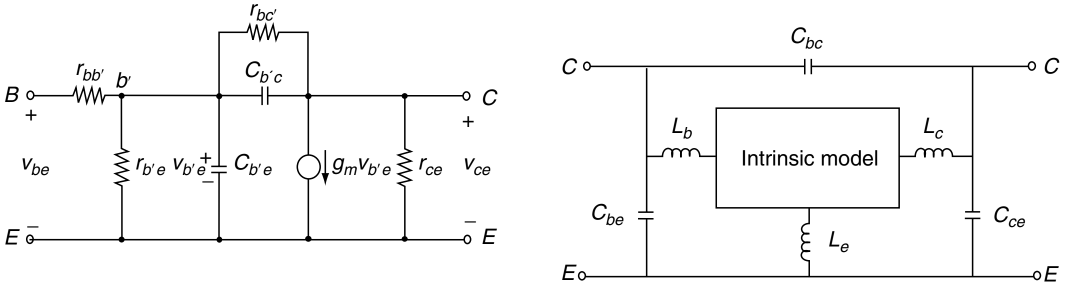

FIGURE 11.4 Hybrid-π Model for the BJT Transistor. Note that simplifications to this model can often be made at microwave frequencies. The BJT (intrinsic) model (right) is incorporated into an equivalent circuit model for packaging parasitics.

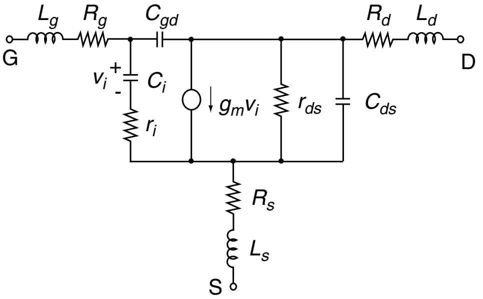

C_i:	Gate-to-source capacitance	(0.3 pF)
r_i:	Gate-to-source channel resistance	(2.5 Ω)
C_{gd}:	Gate-to-drain capacitance	(0.02 pF)

L_d:	Drain parasitic inductance	(0.1–0.9 nH)

FIGURE 11.6 Equivalent Common-Source Model of Typical MOSFET. This model includes packaging effects.

width that is too long, however, can result in degraded performance. This is often overcome by using an interdigitated design with additional "fingers." Conceptually, this is like connecting several lower power devices in parallel.

A small signal equivalent model, including external parasitics, for the MOSFET transistor in common-source mode is shown in Figure 11.6. Each component is defined to the right of the equivalent circuit, with typical values for a GaAs MOSFET with a gate length of 1 μm and a gate width of 250 μm given in parentheses. There are many minor variations of this model. Often, the drain-to-source resistance, r_{ds}, is omitted. In addition, when the gate-to-drain feedback capacitance is small enough to be neglected, it is replaced with an open circuit, resulting in the simplified unilateral model for a common-source GaAs FET.

In terms of the equivalent model, the frequencies f_T and $f_{\max}$ are given by:

$$f_T = \frac{g_m}{2\pi C_i}. \tag{11.11}$$

$$f_{\max} = \frac{f_T}{2}\sqrt{\frac{r_{ds}}{r_i}}. \tag{11.12}$$

Intrinsic noise sources in a GaAs FET are thermal channel noise and noise at the gate induced by the channel noise voltage. Flicker noise is insignificant above 50 MHz. Extrinsic noise sources in the equivalent model are R_g and R_s as well as the gate bonding pad resistance.

High Electron Mobility Transistor

Also known as a modulation-doped field effect transistor (MODFET), the high electron mobility transistor (HEMT) structure is similar to that of a typical MOSFET, with the difference being the inclusion of a heterojunction formed by growing an additional layer of AlGaAs under the gate contact, as shown in Figure 11.7. This results in very high electron mobilities and consequently much higher f_T and $f_{\max}$ for a given feature size. HEMT devices typically exhibit much better noise performance than MESFET devices and are used well into the millimeter-wave frequency range.

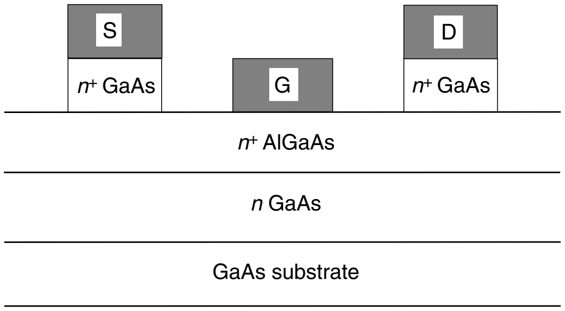

FIGURE 11.7 Cross Section of Typical HEMT Transistor

Two-Terminal Devices

While microwave and millimeter-wave transistor technology has matured considerably in last decade, many applications still rely on two-terminal devices for a number of reasons, including frequency limitations of transistors and noise or niche applications, such as P-i-N diodes in switching circuitry. Microwave and millimeter-wave diodes are still commonly used in oscillators and mixer circuitry. Two of the most commonly used two-terminal devices at these frequencies are the **transferred electron device** (TED), which relies on the Gunn effect, and the **impact ionization transit-time** (IMPATT) diode. Both of these devices may be used in reflection-type oscillators and amplifiers. Schottky diodes are used well into the millimeter-wave region and beyond.

The TED consists of a bulk semiconductor, typically GaAs, that demonstrates the Gunn effect. Contacts are attached at each terminal. Under specific biasing conditions, a region of negative differential resistance (NDR) is formed in a region of the device. If the electric field jumps above the threshold value, additional carries (both positive and negative) will be generated, forming a dipole domain. This domain will propagate to the terminal of the device, where a current spike will be observed. At this point, the field again passes threshold and a new domain is formed that will again propagate to the terminals. The result is a periodic spike in the terminal current. The period of the spike is $f = L/v_d$, where L is the length of the device and v_d is the velocity of the domain in the material.

The IMPATT diode relies on avalanche breakdown in the device to generate an external current. The nonlinear device provides negative resistance that is a function of the amplitude of the RF current flowing through the device. At higher RF current amplitude, the negative resistance is depleted, which is essential for stable operation as an oscillator.

Although IMPATT and TED are the most common two-terminal microwave- and millimeter-wave devices, a variety of other devices also exist, depending on the application. However, the trend of increasing monolithic integration (which uses three-terminal devices) in microwave- and millimeter-wave is reducing the prevalence of these devices.

11.3 Active Microwave Circuits

Design for microwave- and millimeter-wave frequency circuits are fundamentally different from the approach used at lower frequencies. Since measurements at these frequencies most naturally consist of *S*-parameter measurements, components are most commonly characterized by their *S*-parameter response. Design techniques also naturally reflect this. This section briefly outlines microwave amplifier design, oscillator design, and detectors and mixers. Because these circuits are most commonly used in communications with tight EMI and linearity constraints, issues such as intermodulation distortion, harmonic generation, saturation, and nonlinear models are briefly discussed in applicable contexts. An excellent reference on microwave amplifier design is Gonzalez (1996). A good reference dealing with many practical aspects of nonlinear circuits Maas (1998).

11.3.1 Amplifiers

Amplification is one of the primary functions in an active microwave circuit. Historically, microwave tubes or diodes in a negative resistance configuration were used to achieve gain. Currently, transistors (usually GaAs FETs) are almost universally used for this purpose. Design of microwave transistor amplifiers takes two specific paths: small signal amplifiers, such as the low noise amplifiers (LNA), use small signal *S*-parameters for an adequate design, whereas large signal amplifiers, such as power amplifiers, rely on more advanced techniques including load-pull and nonlinear modeling for an adequate design. This section discusses the basics of transistor amplifier design in terms of *S*-parameters. The basic concepts will be the same for both small-signal and large-signal amplifier design. However, large-signal amplifier design requires that large-signal *S*-parameters be available.

Historically, amplifiers have been designed with a graphical approach using Smith charts and simultaneously plotting circles for the parameters of interest, such as gain, stability, voltage standing wave ratio (VSWR), or noise figure at a particular frequency. A treatment of this technique is not possible in this chapter due to space limitations. Most modern microwave design CAD tools have built these functions into their interface, and the user requires only a physical understanding of the technique rather than a detailed knowledge of the equations for generating the circles that are involved. This discussion, hence, focuses on presenting the most important parameters used for microwave amplifiers.

Figures of merit for an amplifier depend on a particular application. Gain and stability are important for all amplifiers. Another figure of merit is noise figure (NF), which is of primary importance for a low-noise amplifier in a typical amplifier. In a power amplifier, efficiency may be of primary concern if the system has a limited supply of dc power, such as in satellite transmitters or handheld phones. The first topic of discussion is general amplifier concepts. Issues relevant to LNA and PA design will be discussed separately.

A general block diagram of a transistor amplifier is shown in Figure 11.8. It consists of three blocks with associated gains: input matching (G_s), output matching (G_L), and transistor *S*-parameters (G_0). Using transmission line theory, it can be easily shown that the reflection coefficients on the input and output sides of the transistors are given as:

$$\Gamma_{\text{in}} = S_{11} + \frac{S_{12}S_{21}\Gamma_L}{1 - S_{22}\Gamma_L}. \tag{11.13}$$

$$\Gamma_{\text{out}} = S_{22} + \frac{S_{12}S_{21}\Gamma_S}{1 - S_{11}\Gamma_S}. \tag{11.14}$$

One important case is the **unilateral transistor**, which occurs if $S_{12} = 0$ or is small enough to be neglected. In this case, the effective gain factors for each component in terms of these reflection coefficients are as follows:

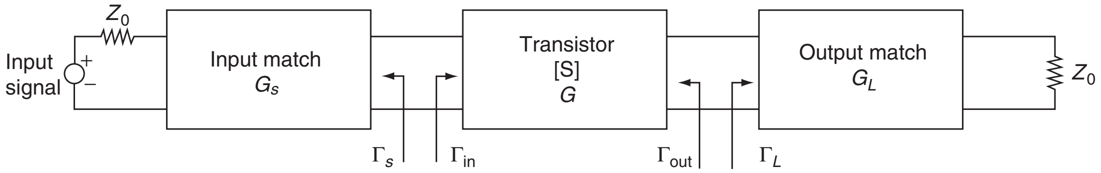

FIGURE 11.8 Block Diagram of a Transistor Amplifier

$$G_s = \frac{1-|\Gamma_s|^2}{|1-\Gamma_{\text{in}}\Gamma_s|^2}. \tag{11.15}$$

$$G_0 = |S_{21}|^2. \tag{11.16}$$

$$G_L = \frac{1-|\Gamma_L|^2}{|1-S_{22}\Gamma_L|^2}. \tag{11.17}$$

One of the most useful figures for an amplifier is the **transducer gain**, which is the ratio of the power delivered to the load to the power delivered by the source and depends on the input and output match. In terms of the gain coefficients, the transducer gain is $G_T = G_S G_0 G_L$. In terms of reflection coefficients, the transducer gain is given as:

$$G_T = \frac{1-|\Gamma_s|^2}{|1-\Gamma_{\text{in}}\Gamma_s|^2}|S_{21}|^2\frac{1-|\Gamma_L|^2}{|1-S_{22}\Gamma_L|^2}. \tag{11.18}$$

Note that maximum gain occurs when both the input and output provide conjugate matches (i.e., $\Gamma_s = S_{11}{}^*$ and $\Gamma_L = S_{22}{}^*$). Moreover, the amplifier must be operated in a stable configuration to ensure that it will not oscillate. Oscillation may occur if the input or output port impedance has a negative real part, leading to $|\Gamma_{\text{in}}|$ or $|\Gamma_{\text{out}}|$ greater than the value of 1. Since Γ_{in} and Γ_{out} rely on Γ_L and Γ_S, stability can be ensured by proper matching conditions with possibly reduced gain. Two types of stability are typically defined: **unconditionally stable** and **conditionally stable**. An unconditionally stable network must have both $|\Gamma_{\text{in}}| < 1$ and $|\Gamma_{\text{out}}| < 1$ for *all* passive source and load terminations. A conditionally stable network will have both $|\Gamma_{\text{in}}| < 1$ and $|\Gamma_{\text{out}}| < 1$ for a range of passive source and load terminations. Note that in a unilateral device, it is sufficient that $|S_{11}| < 1$ and $|S_{22}| < 1$ for the device to be unconditionally stable. In addition, the maximum stable gain of a transistor is $G_{MSG} = |S_{21}|/|S_{12}|$. This is an important parameter when choosing a transistor. A convenient way of expressing the necessary and sufficient conditions for unconditional stability in terms of the S-parameters is through these equations:

$$|\Delta| = |S_{11}S_{22} - S_{12}S_{21}| < 1. \tag{11.19}$$

$$K = \frac{1-|S_{11}|^2-|S_{22}|^2+|\Delta|^2}{2|S_{12}S_{21}|} > 1. \tag{11.20}$$

Low-Noise Amplifier

A low-noise amplifier (LNA) is commonly found in all receivers. Its role is to boost the received signal a sufficient level above the noise floor so that it can be used for additional processing. The noise figure of the LNA therefore directly limits the sensitivity of the receiver. Minimum noise performance, F_{min}, occurs with a source termination with reflection coefficient Γ_{opt}. The noise figure of a two-port amplifier is given as:

$$F = F_{\text{min}} + \frac{4r_n|\Gamma_s - \Gamma_{opt}|^2}{\{1-|\Gamma_s|^2)|1+\Gamma_{opt}|^2}. \tag{11.21}$$

Note that r$_n$ is the equivalent normalized noise resistance of the two-port, $r_n = R_n/Z_0$. Moreover, r_n, F_{min}, and Γ_{opt} are known as noise parameters and given by the transistor manufacturer. They can also be determined experimentally.

Design of an LNA typically consists of trade-off between noise figure and gain while designing at the required stability. This can often be a difficult task. One technique to make a potentially unstable transistor an unconditionally stable transistor is to use resistive loading or feedback at the expense of reduced power gain and degraded noise figure.

Power Amplifier

Although the primary concern in an LNA is noise figure, **power amplifiers** (PA) have linearity and often efficiency requirements. Among other places, power amplifiers are found in all transmitters and are a significant user of dc power.

Since small-signal S-parameters are almost always operated in large-signal mode, they are typically not sufficient to ensure an accurate design. Other techniques include load-pull to determine optimal terminations or large-signal models, which are often available from the manufacturer or built into popular microwave CAD tools. The most common figure of merit for a microwave power transistor is the 1-dB **compression point**, a measure of the power-handling capabilities of the transistor. This is defined as the power where the saturation of the transistor reduces the power gain of the transistor by 1 dB from the small-signal power gain. This is graphically illustrated in Figure 11.9. The dynamic range is the range of linear performance that the amplifier provides measured from the minimal detectable output signal at the noise power level to the 1-dB compression point, $P_{1\text{ dB}}$.

Typically, power amplifiers are operated in the nonlinear regime, producing significant harmonics. These undesired har-

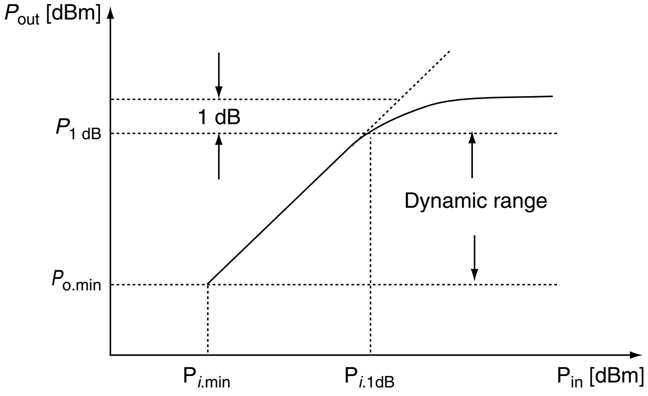

FIGURE 11.9 Graphical Illustration of the 1-dB Compression Point of a Microwave Amplifier

monics must be either "tuned" or filtered at the output. In the case of harmonic tuning, a resonant circuit at harmonic frequencies is formed at the output from either transmission line stubs or chip capacitors, where the capacitors possess a self-resonance near the harmonic frequencies. The power in the harmonics is then reflected back to the device with an appropriate phase to add to the fundamental power, therefore increasing efficiency. In practice, it is difficult to tune more than the first two or three harmonics. Additional filtering will often be required at the output.

Another concern in a microwave power amplifier is **intermodulation distortion**, which occurs when more than one input signal is injected into the amplifier. In particular, if two sinusoidal signals are simultaneously injected, the output will contain additional frequency components known as **intermodulation products** at *dc*, f_1, f_2, $2f_1$, $2f_2$, $3f_1$, $3f_2$, $f_1 \pm f_2$, $2f_1 \pm f_2$, and $f_1 \pm 2f_2$. Higher products may also be observable, depending on the amplifier. The frequencies $f_1 \pm f_2$ are known as second-order intermodulation products, and $2f_1 \pm f_2$ and $f_1 \pm 2f_2$ are third-order intermodulation products. The frequency of the third-order intermodulation products may be quite close to the input signal f_1 and f_2 and, therefore, fall into the bandwidth of the amplifier, causing distortion at the output. Of particular interest is the third-order intercept point, P_{IP3}. This is the point where the output power of P_f1 and P_{2f1-f2} intercepts extrapolated from linear operation of the amplifier. This quantity is useful for estimating third-order intermodulation products for different input power levels. A typical PA will exhibit P_{IP3} about 10 dB higher than the 1-dB compression point.

Because power amplifiers are often operated with a limited power supply, such as in portable handsets or satellite communications, efficiency can be an extremely important figure of merit. Due to limited gain in high-power microwave devices, power-added efficiency (PAE) is the most important type of efficiency and is given by:

$$PAE = \frac{P_{\text{out}} - P_{\text{in}}}{P_{DC}} \times 100\,\%. \tag{11.22}$$

11.3.2 Oscillators

The desired output of an **oscillator** is a stable, single frequency tone. Microwave frequency oscillators typically use loop-feedback or reflection-type feedback for stabilization. Microwave frequency oscillators may use any device that exhibits negative resistance when configured properly. Within their operating frequency range, bipolar junction transistor (BJT) devices as well as FET and HEMT devices are often used. At millimeter-wave frequencies, Gunn diodes or IMPATT diodes are often used. Accurate prediction of the output power and precise frequency of oscillation requires a nonlinear model of the device used in the oscillator. Use of high-*Q* resonators, however, allows reliable prediction of oscillation frequency even when small signal *S*-parameters are used. In practice, dielectric resonators (DR) are often used because of their high-*Q* value and stability. This section briefly outlines a few of the fundamentals of microwave oscillators.

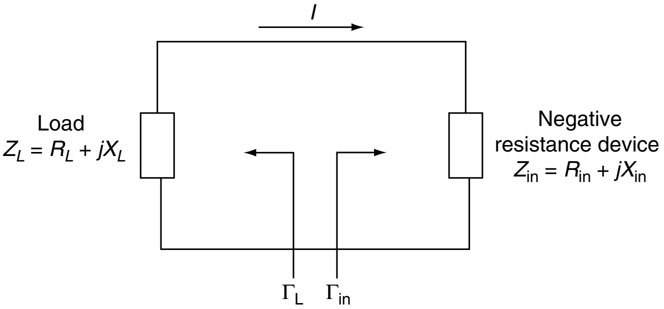

FIGURE 11.10 One-Port Negative Resistance Oscillator

Oscillator circuits that are 1-port use diodes, commonly the Gunn diode, to provide negative resistance for oscillation. A typical circuit for a 1-port negative resistance oscillator is shown in Figure 11.10. The frequency-dependant input impedance of the active device is $Z_{\text{in}}(\omega)$, with real and imaginary components $R_{\text{in}}(\omega)$ and $X_{\text{in}}(\omega)$. Note that Z_{in} is also typically a function of the bias voltage and current. Applying Kirchhoff's voltage law gives:

$$(Z_L + Z_{\text{in}})I = 0. \tag{11.23}$$

For nonzero *I*, this implies that oscillation can occur at any frequency if the following is true:

$$R_L + R_{\text{in}} = 0. \tag{11.24}$$

$$X_L + X_{\text{in}} = 0. \tag{11.25}$$

For a passive load, it is apparent that the device must provide negative resistance. For single-frequency operation, it is necessary to design the circuit so that the previous condition is met at only one frequency. Also note that because the impedance of the negative resistance device is affected by its operating mode, oscillation almost invariably undergoes some frequency shift. Moreover, conditions are (11.24) and (11.25) necessary for oscillation but do not guarantee stable steady-state oscillation. It can be shown that stable oscillation will occur if the following is satisfied:

$$\frac{\partial R_{\text{in}}}{\partial I}\frac{\partial}{\partial \omega}(X_L + X_{\text{in}}) - \frac{\partial X_{\text{in}}}{\partial I}\frac{\partial}{\partial \omega}R_{\text{in}} > 0. \tag{11.26}$$

The first factor, $\partial R_{\text{in}}/\partial I$, is positive for a typical device. The condition can then be satisfied if $\partial(X_L + X_{\text{in}})/\partial\omega \gg 0$. A high-*Q* circuit, such as a dielectric resonator, will ensure this.

Transistors are used in a two-port oscillator configuration, as shown in Figure 11.11. The circuit is designed so that the

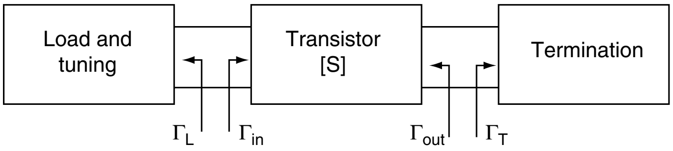

FIGURE 11.11 Two-Port Transistor Oscillator

transistor provides negative impedance at one port. Terminating one port of the transistor with impedance chosen to make the device unstable can cause this impedance. Then, to initiate oscillation, the load is chosen so that $R_L + R_{\text{in}} < 0$ and $X_L = -X_{\text{in}}$. Note that this concerns refer the small-signal impedance of the device. In practice, the value $R_L = -R_{\text{in}}/3$ is often used. When oscillation is initiated, the negative impedance provided by the device will decrease until a steady-state is reached when the large signal S-parameters are such that $\Gamma_L \Gamma_{\text{in}} = 1, 0$. As with the 1-port oscillator, high-Q resonators are often used to ensure stable oscillation and minimize phase noise.

11.3.3 Detectors and Mixers

Detectors and mixers use the nonlinear property of devices to achieve frequency conversion. Either diodes or transistors can be used for this purpose. A **detector** produces a dc signal whose amplitude varies in proportion to the amplitude of an applied RF signal. They are often used in power sensors and test equipment. A detector can also be used to demodulate information on a modulated RF signal. Mixers are used for both up-conversion in transmitters and down-conversion in receivers. A **mixer** is a circuit with two input ports for the RF and local oscillator (LO) signals and an output port for the intermediate frequency (IF) signal.

The basic concept of mixing and rectification is easily observed by considering a diode with the following I–V dependence:

$$i(V) = I_s[\exp(V\alpha) - 1]. \tag{11.27}$$

Note that $\alpha = q/nkT$, with q the charge of an electron, n as the ideality factor, I_s the saturation current, and k as Boltzmann's constant. Assume that V contains a dc voltage term, V_0, and a small signal ac signal, v, which may contain one or more frequency components. The current can be expanded in a Taylor series. Considering only the first three terms, the expansion becomes:

$$i = I_0\left(1 + \alpha v + \frac{\alpha^2 v^2}{2}\right). \tag{11.28}$$

If the diode is operated as a detector, the small signal ac signal, $v = A\cos(\omega t)$, may be inserted in the preceding equation:

$$\frac{i}{I_0} = 1 + \frac{\alpha^2 A^2}{4} + \alpha A \cos(\omega t) + \frac{\alpha^2 A^2}{4}\cos(\omega t) \tag{11.29}$$

Of particular interest for a detector is the small-signal current responsivity, β_0, defined to be the change in dc current due to application of the RF signal divided by time-average power. The change in dc current will be given by the second term on the right-hand side of the preceding equation ($\Delta i/I_0 = \alpha^2 A^2/4$). Since the change in current is proportional to the square of the amplitude of the input voltage, the small-signal operation is known as **square-law** detection. Taking the product of the diode current and voltage and integrating over one period, the small-signal current responsivity is simply:

$$\beta_0 = \alpha/2 \tag{11.30}$$

Operation of the detector is depicted in Figure 11.12. Note that at higher input levels, violating small-signal requirement conditions causes the device to saturate, and the three-term expansion of current is no longer sufficient to describe the behavior of the detector. When two signals are present, **mixing** occurs. This is most common in receivers, where the amplification is used to boost the signal at the intermediate frequency, thus increasing the sensitivity over direct detection schemes. With mixing, both an RF and a LO signal will be present. Expression of the small-signal ac is shown in this equation:

$$v = v_{RF}\cos(\omega_{RF} t) + v_{LO}\cos(\omega_{LO} t). \tag{11.31}$$

Note that, in general, *all* mixing products will be present in the spectrum of the output current (i.e., the current will contain components at $|m\omega_{RF} \pm n\omega_{LO}|$ with m and n integers ranging from zero to infinity. The first few mixing products are typically of primary interest. Using the three-term expansion of the output current, yields the following:

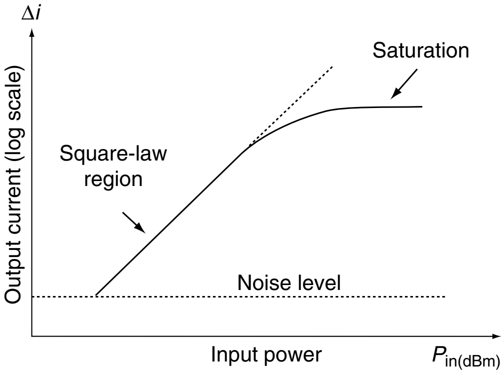

FIGURE 11.12 Square-Law Region for a Typical Diode Detector

$$
\begin{aligned}
\frac{i}{I_0} &= 1+\frac{\alpha^2}{4}\left(v_{RF}^2+v_{LO}^2\right)+\alpha v_{RF}\cos(\omega_{RF}t)+\alpha v_{LO}\cos(\omega_{LO}t)\\
&+\frac{\alpha^2}{4}v_{RF}\cos(2\omega_{RF}t)+\frac{\alpha^2}{4}v_{LO}\cos(2\omega_{LO}t)\\
&+\frac{\alpha^2}{2}v_{RF}v_{LO}\cos[(\omega_{RF}-\omega_{LO})t]+\frac{\alpha^2}{2}v_{RF}v_{LO}\cos[(\omega_{RF}+\omega_{LO})t].
\end{aligned}
\tag{11.32}
$$

The last two terms of the right-hand side of the preceding equation correspond to down-conversion and up-conversion, respectively. Moreover, the mixing products are also proportional to both RF and LO voltage. Mixing therefore exhibits linear behavior rather than the square-law behavior found with detection.

Specific issues with mixer design include matching for optimal performance, isolation, and rejection of image frequencies that can cause spurious responses near the desired intermediate frequency. A block diagram of a typical down-conversion mixer is shown in Figure 11.13. With applied RF and LO signals, the frequencies $f_{RF} \pm f_{LO}$ are present at the output of the mixer. Note that in practice, all mixing products will be present at the output. Then a low-pass filter is used to eliminate all but the desired intermediate frequency, $f_{RF} \pm f_{LO}$, for improved isolation. In addition to isolation, conversion loss is an important figure of merit for a mixer. In decibels, this is given as:

$$
CL = 10\log\left(\frac{P_{RF}}{P_{IF}}\right). \tag{11.33}
$$

Because FETs are commonly used in mixer circuits, this number can be positive, resulting in a mixer with gain. In fact, FET mixers with up to 10 dB of gain can be produced at X-band frequencies, with lower LO requirements than with diode mixers. Typically, this comes at the expense of degraded noise performance.

11.4 Planar Antenna Technology

Planar antennas are printed on a dielectric circuit board, typically with ground metallization on one side. These antennas are typically compatible with conventional planar transmission lines, such as microstrip, coplanar waveguide (CPW), and coplanar stripline (CPS), and may be integrated with other microwave circuitry. For this reason, planar antennas are often referred to as **integrated antennas**. These antennas are low profile and low cost. At microwave- and millimeter-wave frequencies, they are also typically quite compact. As the operating frequency of commercial wireless systems is consistently pushed higher, it becomes more feasible and economical to integrate the antenna and system on a single printed circuit board (PCB) or even on a die at millimeter-wave frequencies. In this section, four planar antennas are described, including the **microstrip patch antenna**, the **slot antenna**, the **tapered slot antenna** and the **quasi-Yagi antenna**. The section concludes with a brief discussion about the active integrated antenna approach.

11.4.1 Microstrip Patch Antenna

The patch antenna has several desirable qualities, including a broadside radiation pattern that allows it to be integrated into two-dimensional arrays. The antenna is also low profile and low cost, has good conformability, and has ease of manufacturing. It is readily integrated with microstrip or coaxial probe feeding. Multilayer schemes have been used for other types of feeding, including CPW and strip line. With microstrip feeding, it is also a relatively simple task to implement either linear or circular polarization excitation of the antenna.

The patch antenna, shown in Figure 11.14 with microstrip feeding, is one of the most widely used planar antennas. Feeding is extremely important with the patch antenna, and it contributes to bandwidth, crosspolarization levels, and

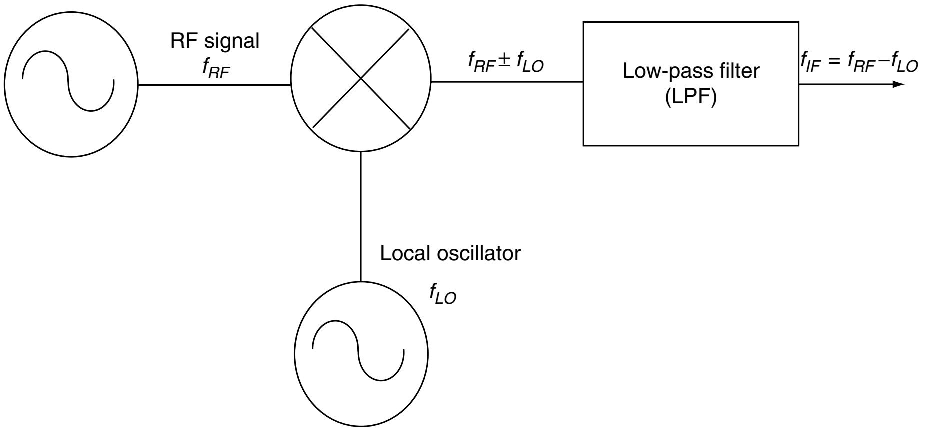

FIGURE 11.13 Block Diagram for a Down-Conversion Mixer Configuration

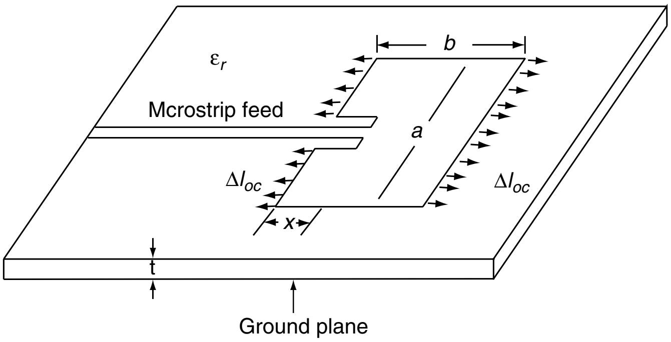

FIGURE 11.14 Top View of Microstrip-Fed Patch Antenna

ripple. Microstrip-fed patches have very narrow bandwidths, almost invariably less than 5%. Other feed mechanisms have been used to increased bandwidth, including proximity coupling and aperture coupling, both of which require multilayer fabrication. A review of this technology is discussed in Pozar (1992). Alternatively, matched bandwidth of the antenna can be increased by making the antenna substrate electrically thicker, effectively lowering the *Q*-factor of the antenna cavity for increased bandwidth. High levels of TM_0 surface waves, however, can result and therefore reduce the radiation efficiency as well as degrade the radiation pattern if the surface wave generates radiation (which can occur at the edge of finite ground antennas). The problem of electrically thick substrate is also a common one for high-frequency antennas on high-permittivity substrates, and high amounts of TM surface waves can result.

Returning to Figure 11.14, the microstrip feed is inset into the antenna a distance x to obtain an input match. The dimension b is chosen so that the cavity formed by the conductor on the top plane of the structure is resonant. This causes radiation at the two edges of the antenna, as shown by the fringing fields in the diagram. A simple and intuitive technique for modeling this antenna is the **transmission line model**. This model provides a reasonable estimate for the resonant frequency and a fairly accurate estimate of the input impedance close to resonance. Due to the narrow bandwidth of the patch antenna, it is typically not accurate enough to guarantee first-pass design success. The bandwidth, however, does provide a useful starting point as well as useful insight into the operation of the antenna.

A cross section of the patch antenna is shown in Figure 11.15. In this model, it is assumed that the patch antenna consists of a perfect magnetic conductor (PMC) walls on the sides of the patch antenna, giving rise to standing wave type modes inside the patch antenna cavity. The total length of the cavity is the length of the patch antenna (dimension b) and an effective length at each edge due to the microstrip open-end effect. The fundamental resonance of the cavity formed by the microstrip patch antenna will occur at the frequency where the total effective length of the patch antenna, $b + 2\Delta l_{oc}$, is equal to one-half a guided wavelength in the microstrip cavity. The equation representing this concept is as follows:

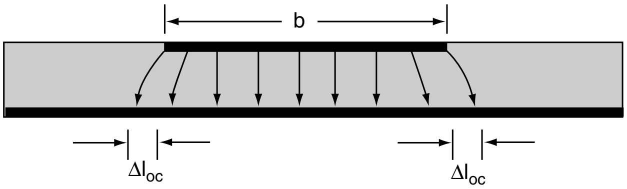

FIGURE 11.15 Cross Section of a Microstrip Patch Antenna

$$f_r = \frac{c}{2\sqrt{\varepsilon_{re}}}\frac{1}{b + 2\Delta l_{oc}}. \tag{11.34}$$

Note that c is the speed of light in a vacuum ($c = 3^*10^8$ m/s), and ε_{re} is the effective permittivity of the microstrip. In terms of the features in Figure 11.14, an approximate expression for the effective permittivity is as written here:

$$\varepsilon_{re} = \frac{\varepsilon_r + 1}{2} + \frac{\varepsilon_r - 1}{2}\left(1 + \frac{10t}{a}\right)^{-\frac{1}{2}}. \tag{11.35}$$

It is also necessary to have an estimate of the effective length due to the fringing effects. The following is a commonly used formula for the effective length of the fringing field:

$$\frac{\Delta l_{oc}}{t} = 0.412\frac{(\varepsilon_{re} + 0.3)(a/t + 0.264)}{(\varepsilon_{re} - 0.258)(a/t + 0.813)}. \tag{11.36}$$

By using these equations together, dimensions of the patch antenna can be chosen to achieve a particular resonant frequency. The accuracy of the model is typically a few percent. Because the bandwidth of a microstrip-fed patch is on the same order, this may not be accurate enough for first pass design.

It is also desirable to have an estimate of the input impedance of the antenna. The simplest way for estimating this is the transmission line model for the patch antenna. In this case, the antenna is modeled as two radiating slots of width Δl_{oc} and length a separated by a microstrip transmission line with dimensions corresponding to the dimensions of the patch antenna. Note that the feeding can be placed at one end of the antenna or at some point a distance x inside the patch, either by the use of an inset feed or a coaxial probe. The equivalent structure for interior feeding is shown in Figure 11.16. At resonance, the impedance of the radiating slot will be pure real. To first-order for $a \ll \lambda_0$ (which will be true on high-permittivity substrates), the radiation resistance of each slot may be approximated as:

$$R_a = \frac{90\lambda_0^2}{a^2}. \tag{11.37}$$

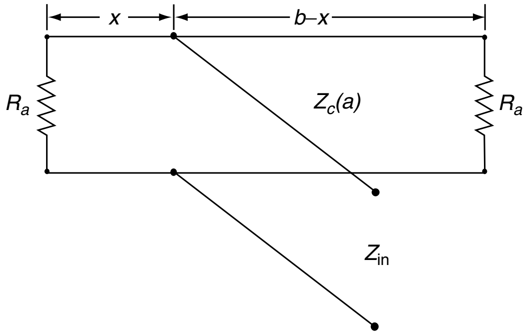

FIGURE 11.16 Transmission Line Model of a Patch Antenna. This model is used for determining the input impedance as a function of feed location.

Equation 11.37 provides a reasonable first-order estimate of the input impedance of the patch antenna near resonance. Note that there are many other simple models that also provide a first-order estimate of the input impedance. Often, the designer must either fabricate and perform measurements or obtain a full-wave solution to the structure using an electromagnetic (EM) simulator to achieve accurate design data for the antenna. This simple model, however, provides a useful starting place for the design.

Because the antenna's length determines the resonant frequency of the patch, higher antenna resonances will coincide with frequencies that are multiples of the fundamental resonance. If active circuitry, which may generate harmonic frequencies, is integrated with the patch antenna, harmonic radiation leading to co-site interference may occur. A circular geometry patch antenna may be used to reduce this problem. In this case, higher resonances of the antenna will be determined by circular harmonics (Bessel functions) and can be designed to occur away from circuit harmonics. A plot of the input impedance of one particular type of circular geometry patch, the circular segment patch antenna, is shown in Figure 11.17 along with its geometry. By looking at the frequency scale of the plot, it is apparent that higher resonances do not correspond to harmonic frequency of active devices that may be integrated with the antenna. Note that the input impedance was obtained by full-wave analysis. Measured radiation patterns of these types of antenna are comparable to that of a standard rectangular geometry patch antenna. In addition, circular geometry patch antennas are often more compact than rectangular geometry patch antennas. Note that the antenna is fabricated on a standard RT/Duroid of permittivity 2.33 and a thickness of 31 mils. A 120° sector of the antenna has been removed for optimal impedance. A microstrip feed is placed 30° from the edge of the voided sector. The radius of the antenna is 740 mils.

11.4.2 Slot Antenna

The **slot antenna**, consisting of a narrow slit in a ground plane, is a very versatile antenna. With modification, it is amenable to waveguide, coplanar waveguide (CPW), coaxial, slot line, or microstrip feeding schemes and has been used in all aspects of wireless and radar applications. The planar form of the slot antenna with CPW feeding is shown in Figure 11.18. Unlike the waveguide slot antenna that is excited from one side, the planar slot antenna demonstrates bidirectional radiation, which limits the application of this antenna. Alternatively, the slot may be either cavity- or reflector-backed to eliminate backside radiation at the cost of additional bulk and complexity.

As seen in Figure 11.18, CPW feeding is very natural to implement. Microstrip feeding may also be used, either by using vias to connect the microstrip transmission line or by electromagnetic coupling. With electromagnetic coupling, a quarter-wave open circuited microstrip transmission line is used to form a virtual short at the far side of the slot. If designed properly, all of the energy will couple to the slot antenna.

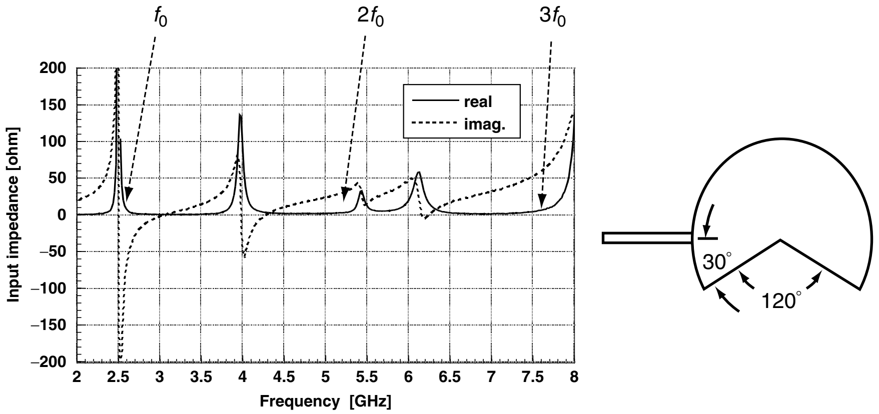

FIGURE 11.17 Input Impedance as a Function of Frequency for a Circular-Segment Patch Antenna (Right)

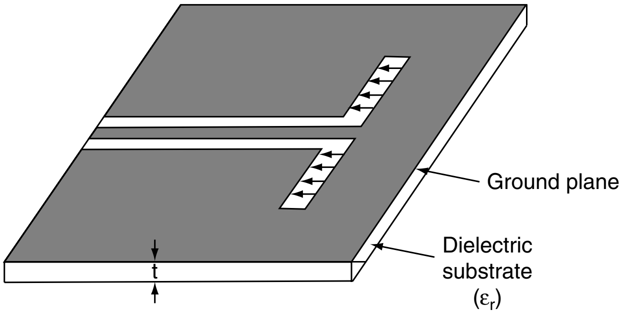

FIGURE 11.18 Geometry of a CPW-Fed Slot Antenna

The length and width of the slot, as well as material characteristics, determine the operating characteristics of the antenna. The planar slot antenna is typically operated at the first or second resonance. To estimate the proper length of the antenna, it is necessary to know the effective permittivity of the slot. For very thick dielectric substrates, the average of the dielectric permittivity and air is used (i.e., $\varepsilon_{eff} = (\varepsilon_r + 1)/2$). This may be inaccurate for thin substrates, however. In this case, it may be more suitable to use the effective permittivity of a slot line transmission line with proper width. The width of the antenna is often chosen as 10% of the length, allowing fairly large input return loss bandwidths.

The resonant half-wavelength slot antenna is desirable because of its compact size; however, it has large input impedance, typically larger than 300 Ω, which makes it difficult to match to. This can be circumvented by using an offset microstrip feed or the folded slot antenna, which stems directly from the folded dipole by Booker's relation. In this case, the slot is *folded* in upon itself. The overall length of the antenna remains approximately a half-wavelength, but increasing the number of folds reduces the radiation resistance. A folded slot with one fold will have one-quarter the radiation resistance of a standard slot antenna. The one-wavelength slot is also used with center-feeding because it is fairly simple to achieve an input match.

11.4.3 Tapered Slot Antenna

Like the slot antenna, the **tapered slot antenna** (TSA) is etched on a grounded dielectric slab. A TSA with a CPW feed via a CPW slot line transition is shown in Figure 11.19. This particular TSA with its exponential taper is known as a **Vivaldi antenna**. Other configurations of different taper profiles are also commonly used, including the linear taper (LTSA) and the constant width (CWSA). These antennas are completely planar, have an end-fire pattern, and can obtain high directivity and/or bandwidth. Proposed applications include millimeter-wave imaging, power combining, and use as an active integrated antenna element.

There are several important design concerns with TSAs. Radiation of a particular frequency will occur where the slot is a certain width. Slot width should reach at least one-half a wavelength for efficient radiation to occur. Therefore, maximum and minimum widths roughly determine the bandwidth of the structure. TSAs are usually built on thin, low-permittivity substrates if they are to achieve good radiation patterns and maintain good radiation efficiency that will be reduced by TM_0 surface wave losses. More about the tapered slot antenna may be found in Yngvesson *et al.* (1985, 1989).

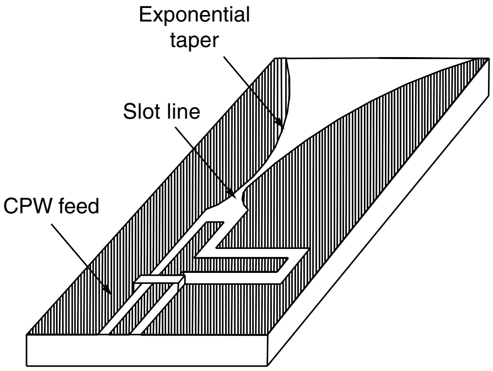

FIGURE 11.19 Tapered Slot Featuring CPW Feeding Via a CPW Slot Line Transition and Exponential Taper

11.4.4 Quasi-Yagi Antenna

Printed wire antennas are planar adaptations of wire antennas, such as dipole, loop, or spiral antennas. Due to a number of reasons, only limited success has been achieved at developing working versions of truly planar wire antennas. This is in part due to the popularity of microstrip and coplanar waveguide transmission lines at these frequencies, which are difficult to integrate with wire-based antennas. For instance, a printed microstrip dipole will have very small radiation resistance due to the shorting effect of the microstrip ground plane and consequently will have low efficiency when realistic estimates of losses are taken. This can be overcome by using an electrically thick substrate at the cost of increased losses due to substrate waves and increased weight and cost.

Alternatively, the microstrip ground plane can be modified to accommodate the printed wire antenna. Recently, a new type of microstrip-compatible planar end-fire antenna based on the well-known Yagi-Uda antenna has been developed. The layout and an X-band prototype of the quasi-Yagi antenna are shown in Figure 11.20. The antenna uses the truncated microstrip ground plane as the reflector and uses a microstrip-CPS transition as balanced feed on a single-layer high-dielectric substrate (Duroid, $\varepsilon_r = 10.2$). The X-band antenna shown in this figure uses a 0.635-mm thick Duroid.

The antenna radiates an end-fire beam, with a front-to-back ratio greater than 15 dB and a crosspolarization level below −12 dB across the entire frequency band. Figure 11.21 plots input return loss and radiation patterns for the antenna. Both

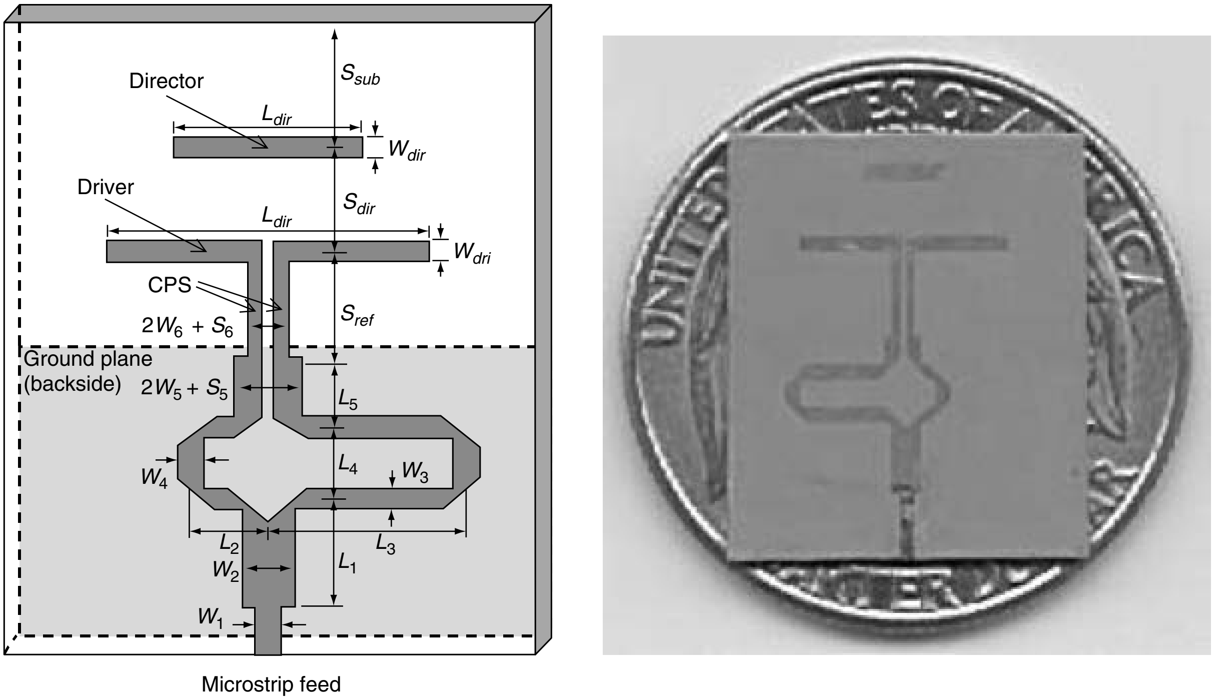

FIGURE 11.20 Layout of Quasi-Yagi Antenna (Left) and Photograph of X-Band Prototype (Right)

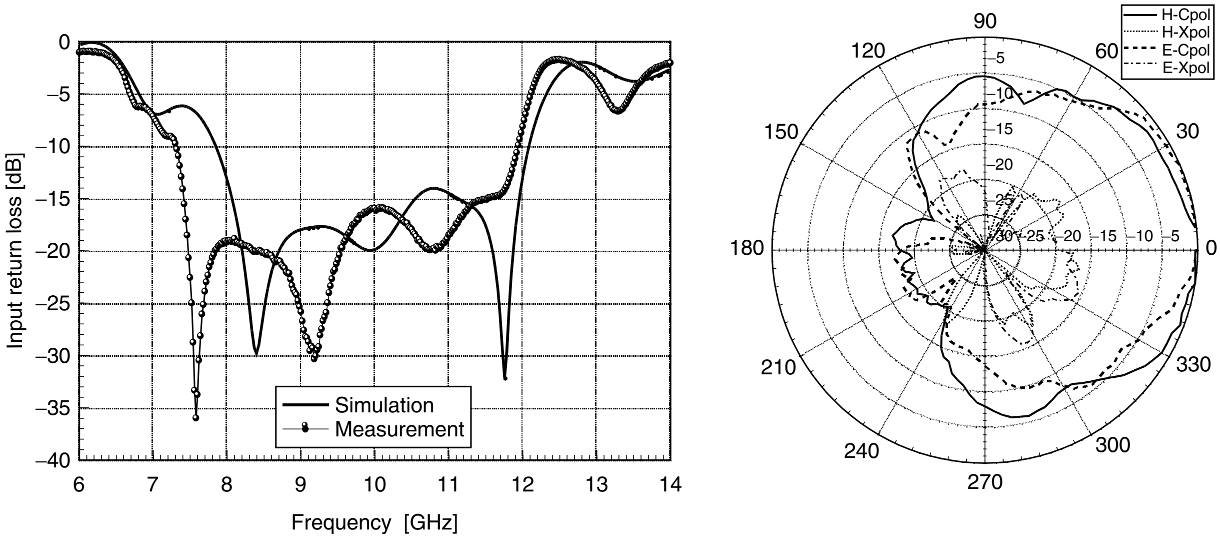

FIGURE 11.21 Input Return Loss (Left) and Measured Radiation Characteristics (Right) of X-Band Quasi-Yagi Antenna

finite-difference time-domain (FDTD) simulation and measurement results for the input return loss are shown. The simulated and measured bandwidths (VSWR < 2) are 43 and 48%, respectively, covering the entire X-band. The antenna is at least two orders smaller in volume than a standard horn antenna for the same frequency coverage. The quasi-Yagi antenna can be scaled linearly to any frequency band of interest while retaining the wideband characteristics. In fact, a *C*-band prototype simulated and fabricated on 1.27-mm thick Duroid ($\varepsilon_r = 10.2$) measured 50% frequency bandwidth (4.17 to 6.94 GHz). FDTD simulation for a millimeter-wave version indicates that a single quasi-Yagi antenna works from 41.6 to 70.1 GHz (51% bandwidth), which covers part of *Q*- and most of the *V*-band.

The quasi-Yagi antenna should prove to be an excellent array element and should find application in any architecture that

TABLE 11.1 Planar Antenna Selection Guide

		Pattern	Directivity	Polarization	Bandwidth	Comments
Patch		Broadside	Medium	Linear/circular	Narrow	Easiest design
Slot		Broadside	Low/medium	Linear	Medium	Bidirectional
Ring		Broadside	Medium	Linear/circular	Narrow	Feeding complicated
Spiral		Broadside	Medium	Linear/circular	Wide	Balun and absorber
Bow-tie		Broadside	Medium	Linear	Wide	Same as spiral
TSA (Vivaldi)		End-fire	Medium/high	Linear	Wide	Feed transition
LPDA		End-fire	Medium	Linear	Wide	Balun, Two-layer
Leaky-wave		Scannable	High	Linear	Medium	Beam-steering, beam-tilting
Quasi-Yagi		End-fire	Medium/high	Linear	Wide	Uniplanar, compact

has been proposed for tapered-slot antennas, such as imaging arrays and power combining. The quasi-Yagi antenna has several additional advantages over the tapered slot including narrower width, direct microstrip feeding, and the ability to design on a high-permittivity substrate. Moreover, radiation efficiency may be improved because of the truncated ground plane. This will eliminate losses due to TM_0 mode in the antenna region that may be a significant loss mechanism with the TSA antenna. More about the quasi-Yagi antenna may be found in Qian *et al.* (1998) and Deal *et al.* (1999).

11.4.5 Planar Antenna Selection Guide

Due to space limitations, this chapter has presented four types of planar antennas. A wide variety of other types of planar antennas also exist, with varying radiation characteristics and applications. For convenience, many of these antennas are included in Table 11.1.

11.5 Active Integrated Antennas

The compatibility of planar antennas with various types of printed circuit transmission lines allows the possibility of active circuitry and antenna being fabricated on a single printed circuit board, which allows for several attractive possibilities. First, minimizing losses between the antenna and receiver will increase sensitivity with no additional engineering of the receiver. In transmit mode systems, placing the power amplifier directly at the antenna minimizes output losses to realize high-efficiency performance by eliminating interconnects. This is possible if proper matching can be maintained. This approach is limited at lower frequency by the physical size of the planar antenna; typically, resonant-type antennas even on high-permittivity substrates will be a few fractions of a free space wavelength. However, at microwave- and millimeter-wave frequencies, smaller wavelength causes this approach to be attractive for an integrated system with maximum performance.

In this approach, the antenna often takes on additional functionality. For instance, the circular-segment antenna of Figure 11.17 has been used to perform harmonic tuning and filtering in addition to its role as radiator. This is possible because the higher resonances of the antenna do not correspond to harmonic frequencies of the amplifier because of its circular nature (Radisic *et al.*, 1997, 1998). Various other tasks have been assigned to the planar antenna, including using a two-port antenna for power combining (Deal *et al.*, 1998, 1999) and noise matching. Reviews of AIA technology can be found in Lin and Itoh (1994, 1998).

VI

ELECTRIC POWER SYSTEMS

Anjan Bose
College of Engineering and Architecture, Washington State University, Pullman, Washington, USA

The Importance of the Electric System

In the list of the greatest engineering achievement of the 20th century, the National Academy of Engineering ranked electrification at the very top. The availability of electricity for industrial, commercial, and domestic uses has affected human society more profoundly than any other technology in the history of mankind. From the modest start in 1882 of Edison's Pearl Street electric generating station in New York City that could provide electric lights in a few buildings in lower Manhattan, to the highly interconnected power grids of today that span continents to bring reliable and affordable electric power to most of human habitation, the development of the technology of electric power systems is a remarkable story of not only engineering innovation but also of business practices, governmental regulations, and societal changes.

This section covers, albeit briefly and in a sweeping overview, the electrical engineering aspects of the **electric power system**. The electric power system, often referred to as the electric power grid, is made up of electric generation, transmission, and distribution, all aspects of which are touched on in the following chapters. The generation of electricity requires the conversion of fossil (e.g., coal, oil, and gas), nuclear (e.g., fission), or renewable fuels (e.g., hydro, solar, wind, and fusion) into electricity, and the considerable engineering needed on mechanical, chemical, and nuclear aspects is an explanation that is outside the scope of this textbook. Similarly, the various use of electricity to produce light, heat, and mechanical work is also not covered here. The electrical portion of the power system, however, is covered in some detail.

Chapters 1 and 2 cover the general principles of three-phase alternating current systems and the various electrical components that make up the electric power system. Of these components, electric machines are covered in the next two chapters, with Chapter 3 covering power transformers and Chapter 4 covering rotating machines that generate electricity (generators) or use electricity to do mechanical work (motors). Chapters 5 and 6 cover high-voltage transmission and lower voltage distribution, respectively. The rest of the section is then devoted to system aspects, with Chapter 7 covering the analytical tools needed to study and design the power system and Chapter 8 explaining operation and control. Techniques and equipment to protect the power system against short circuits are covered in Chapter 9. The concluding Chapter 10 briefly covers power quality issues that have become more important today as electricity is used for more precise applications like the production of integrated circuit chips.

Three-Phase Alternating Current Systems

Anjan Bose
College of Engineering and Architecture, Washington State University, Pullman, Washington, USA

1.1 Introduction

Although the first electric power system, Edison's Pearl Street system, was based on direct current (dc), the advantages of alternating current (ac) systems were obvious by the turn of the 20th century. The voltage drop in an electrical circuit limited the distance from the source of electricity to where it was consumed. The Westinghouse transformer made it possible to boost and lower voltage levels in ac systems, making it possible early on to bring electricity into Buffalo, NY, and Portland, OR, from generators at waterfalls many miles away. Further, the Tesla induction motor replaced all steam-driven manufacturing machinery because it was more clean and flexible, thus ensuring the usage of ac as the preferred technology. Despite this, some pockets of dc power systems survived until after World War II.

The choice of a three-phase transmission and distribution system over a single-phase system also came very early because of the increased efficiency of transmitting power. Although the use of electricity at the consuming end is in one phase low voltage (except for very large industrial use), transmission and distribution are always done in a three-phase system. To understand the efficiency of transmitting power, consider the discussion following section.

1.2 Two-Wire and Three-Wire Systems: Current

For a two-wire, single-phase system, let the root-mean-square (rms) voltage between the wires be V, the rms current be I, and the phase angle between the voltage and current be ϕ. The power transmitted over this line is then given by:

$$P = VI\cos\phi. \tag{1.1}$$

In a three-wire, three-phase system, let the rms voltage between each wire and the ground (the ground is often a grounded wire, making it a four-wire system) be V', the current in each wire be I, and the phase angle between the two be ϕ. Because there are three phases, the total power transmitted is as follows:

$$P = 3V'I\cos\phi. \tag{1.2}$$

However, V' in equation 1.2 is the voltage of each wire to ground, whereas V in equation 1.1 is the voltage between the two wires. In the three-phase system, the voltage in each wire is 120° out of phase with each other. Thus, the voltage V between any two wires of the three-phase system is $\sqrt{3}V'$. Hence, $V' = V/\sqrt{3}$, and:

$$P = \sqrt{3}VI\cos\phi. \tag{1.3}$$

A three-wire, three-phase system can then transmit 73% more power than a two-wire, single-phase system by just the addition of one wire. A three-phase system also has some major advantages in the generation and use of electricity by rotating machines as will be explained later.

The three-phase ac systems have been adopted worldwide. The frequency of the ac and the voltage levels chosen around the world vary. The frequency of 60 Hz was adopted in North America (and a few other places), and 50 Hz is used in all other parts of the world. Because the frequency must be the same to interconnect power systems, only these two frequencies have become standards (exceptions to this are a few isolated systems like those used in rail transportation).

1.3 Voltages

Voltages, unlike current, can vary a lot, and transformers can always be used to match voltages. Moreover, several levels of voltages are used in one geographic area from the 110- or 220-V single phase inside a residence to maybe a 765-KV three phase for transmission, with five or six intermediate levels in between.

In general, generators will produce electricity at low voltages, up to about 20 KV for large generators, but this voltage will be boosted immediately outside the generating stations to high transmission level voltages by transformers. The advantages of transmitting power at higher voltages are very easy to see from equation 1.3. The same power transmitted at a higher voltage requires less current. Less current implies that the voltage drop IR and the power losses I^2R are both lower. Less current also means that the wire size needed will be smaller, which is a savings not just in the wire but in the whole transmission structure.

The siting of generators at hydro dams and mine mouths required the transmission of power over long distances to population centers, and the economies of scale encouraged larger power plants. The concentration of generation in a limited number of locations required that alternate transmission paths be available between the generator locations and the consumption areas. Thus, transmission developed as a meshed network of lines so that the loss of a line did not disrupt the flow of power to consumers.

The main difference between **transmission** and **distribution** used to be that transmission lines transferred larger amounts of power at higher voltages over longer distances, while distribution lines transferred smaller amounts of power at lower voltages locally. However, distribution lines are radial, and the major distinction between transmission lines and distribution lines today is that the transmission system is a meshed network, while the distribution system is radial. In terms of voltages, all lines over 100 KV are always meshed and part of the transmission system, and all voltages below 30 KV are always radial and are classified as distribution. The in-between voltage levels (e.g., 69 KV or 34.5 KV) are sometimes radial in sparsely populated rural areas while meshed in densely populated downtown urban areas; when they are in a mesh network, the term **subtransmission** is sometimes used for these voltage levels.

1.3.1 Industry Business Structure

The business structure for this industry for decades has been either a state-owned monopoly, a model used in most countries, or a state-regulated monopoly; the latter is a model used in the United States. Thus, the generation, transmission, and distribution in one contiguous geographic region would be owned by one corporation as a vertically integrated monopoly. Such a configuration is shown in Figure 1.1 with the generators (circles), transmission, and distribution shown in one corporate box. The transmission system of one corporation is often interconnected to the transmission of the neighboring corporations, thus creating the large electric power grid enabling the exchange of power between corporations.

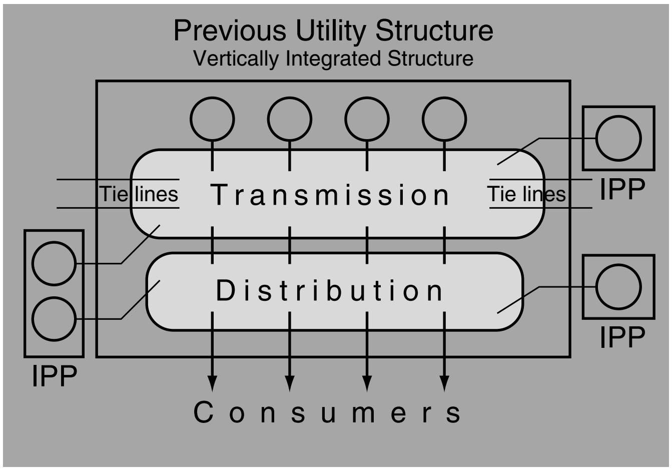

FIGURE 1.1 The Old Vertically Integrated Power Industry Structure

In some countries during the last couple of decades, to encourage more entrepreneurial building of generation plants, governments started to allow independent power producers (IPPs) to build generating plants that could be connected to the grid. Rules were set up to require the monopoly power companies to buy this generation from the IPPs at certain rates. These IPPs are shown in separate boxes in Figure 1.1.

In most countries, there is a move to "deregulate" the power industry by introducing competition in a region. The main restructuring has been the separation and privatization of the generation into separate companies that compete with each other to sell electricity to the distribution companies or directly to the customers. This breaking up of the vertically integrated corporation is shown by the many boxes in Figure 1.2. The transmission system, being the main pathway for the generation

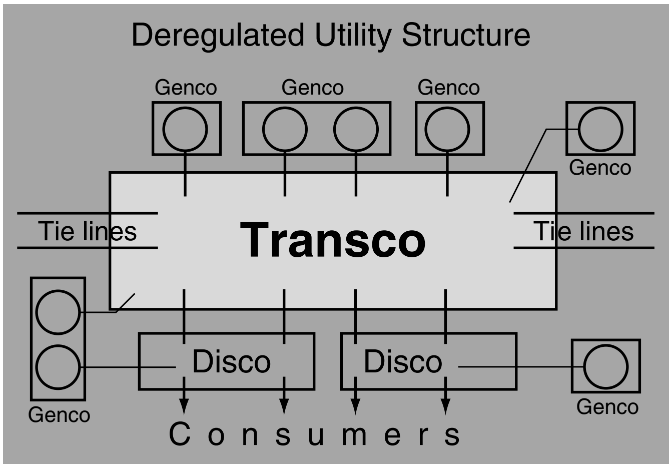

FIGURE 1.2 The New Deregulated Power Industry Structure

to reach the customers, remains under strict regulation with the main rule being the nondiscriminatory availability of electricity to all sellers and buyers of electric power. In most cases, the distribution companies are also regulated to ensure that the retail customer is not affected by big swings in electricity prices.

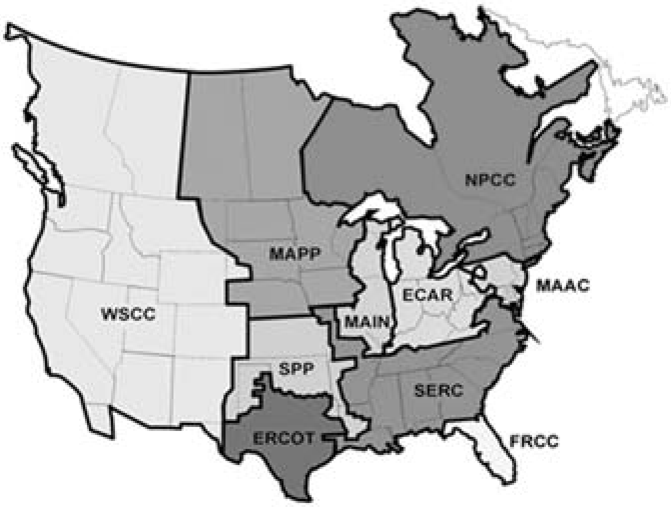

FIGURE 1.3 The Reliability Regions of the North American Power Grid

The breakup of the old vertically integrated monopolies has resulted in more corporate entities that are involved. In addition, new companies providing new services, like brokering power sales, have also entered the picture. Active markets in wholesale power are operating.

The technical operation of the power grid, however, has not changed much. The interconnected transmission network is still the same. Some of these interconnected transmission networks are very large, spanning vast geographical areas. The North American power grid is shown in Figure 1.3 and divided up into **reliability regions** that plan and operate the regional portion of the grid in a coordinated fashion. The Western region (WSCC) and Texas (ERCOT) are only connected to the rest of the grid with dc ties instead of ac. The Eastern Interconnection is synchronously connected through the ac transmission and is the largest synchronously connected power grid in the world with 687 GW of installed generation and 128,000 miles of transmission.

The West European Power Grid is shown in Figure 1.4. The separate regions are again connected with dc ties. The largest synchronously operating grid is that of continental Europe recently enlarged by the interconnecting of some of the Eastern European countries that disconnected from the old Soviet grid to interconnect with the West. The installed generation capacity is 512 GW with 125,000 miles of transmission.

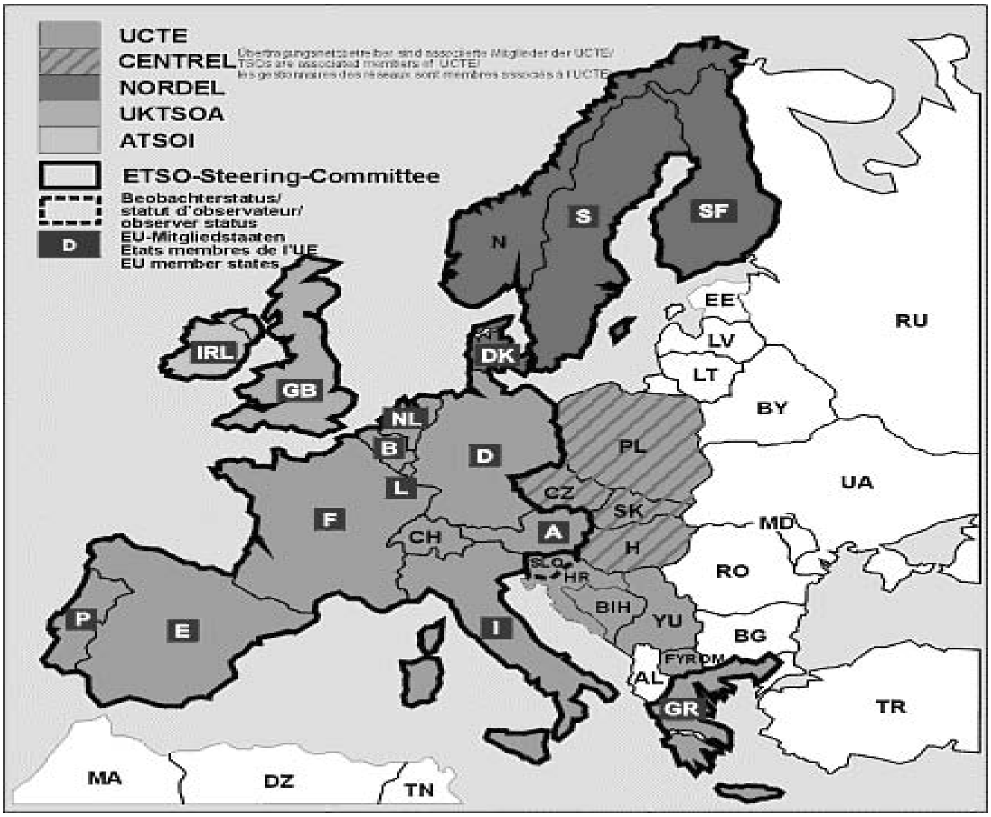

FIGURE 1.4 The West European Power Grid

Electric Power System Components

Anjan Bose
College of Engineering and Architecture, Washington State University, Pullman, Washington, USA

2.1 Introduction

The **electric power system**, in very general terms, is made up of generators, transformers, transmission and distribution lines, and loads. Although these are called components in this chapter, each of these is a complex system on its own and has many components. All of these are three-phase, 60-Hz components except for the smallest loads, such as residences, where the three phases are split into single-phase, low-voltage supply.

2.2 Generators and Transformers

Almost all **generators** turn mechanical power into electrical power through a 60-Hz synchronously rotating machine. The only exceptions are the new generators that convert solar, wind, or chemical power into electrical energy, but the amount of generation available in these modes is yet a small fraction; however, any nonsynchronous generator has to be connected to the grid through interfacing equipment that converts to 60 Hz.

For a synchronous machine driven by a turbine, the turbine is controlled by a governor that regulates its speed to maintain 60 Hz while generating the power required. The electrical generator has a voltage regulator and exciter that control its output voltage. The synchronous generator is covered in more detail in Chapter 4, Electric Machines.

The main purpose of a **transformer** is to transform one ac voltage level to another by a fixed ratio. A transformer has no moving parts except that some have the capability of changing the transformation ratio by small percentages through moving taps; this enables better control of the output voltage. Transformers can be single-phase or three-phase, and three single-phase transformers can sometimes be used instead of one three-phase transformer. Although one three-phase transformer is cheaper than three one-phase transformers for the same purpose, if a spare is needed for reliability purposes, two three-phase transformers are more expensive than four one-phase transformers!

A special type of transformer is the **phase-shifting transformer**. This type of transformer may or may not transform the voltage magnitude, but it does change the phase relationship between the output and input voltages. The power transfer through the transformer can be controlled by changing this phase angle. Details on transformers are provided in Chapter 3, Power Transformers.

2.2.1 Transmission and Distribution

The main difference between **transmission** and **distribution** lines is the voltage level. They always have three wires for the three phases insulated for the voltage level and can be with or without a fourth grounded (uninsulated) wire. They can be strung overhead on wooden or steel towers, or they can be laid underground in conduits. **Overhead lines** are bare and are hung from a string of insulators that can insulate the high voltage from the tower. **Underground cables** have to be covered in insulation throughout.

The design and installation of overhead lines and underground cables require very specialized engineering that gets quite complex for higher and higher voltages. For high-voltage overhead lines, the design of the wires, towers, and insulators and their installation over hundreds of miles of different terrain require the resolution of electrical, mechanical, material, and civil engineering issues. Similarly, for high-voltage cables, a different set of equally complex issues arise in design, especially in the insulation that may even require pressurized oil; installation underground in crowded downtown areas or under water has its own challenges. Transmission is covered in Chapter 5 and distribution in Chapter 6.

Transmission that is dc is not covered in this section although its usage is increasing around the world. The main use of dc transmission is to interconnect two separate areas where some power transfer is desirable but a synchronous (ac) connection is not. The main features of such an interconnection are the ac–dc conversion and the dc–ac inversion that allows the connection of two ac systems with a dc line. The design of the line itself—two wires with or without a ground wire—is not particularly different from ac transmission. In some cases, where the geographic distance between the two separate ac areas is small, the interconnection may not even require a dc transmission line but only back to back ac–dc and dc–ac converters.

The locations where transmission and distribution lines are connected through switches (circuit breakers) and transformers are known as **switchyards** or **substations**. The design of these substations becomes more complex with higher voltages and the numbers of lines and transformers. In less crowded areas these substations can take up many acres of open space, but it becomes more difficult to fit equipment into limited urban spaces. In addition, special insulating techniques for high voltages, like gas insulation, may have to be used to reduce sizes. Other than transformers and circuit breakers, such substations may also include reactors and capacitors that are used to control the voltage levels.

2.2.2 Protection and Control

Protecting all the equipment—generators, transformers, transmission lines, and distribution feeders—against short circuits is essential. The general principle is to detect the fault (the short circuit) and isolate the equipment. In its simplest form, a fuse detects the fault by burning out and thus isolating the line. In its most sophisticated form, microprocessor-based relays can detect the fault and analyze which circuit breakers need to be opened to isolate the equipment. Protection system details are covered in Chapter 9, Power System Protection.

Many other types of control are also used for the normal and emergency operations of the power system. For example, remote operation of circuit breakers can be manually initiated by operators through the supervisory control and data acquisition (SCADA) system at the control center. Voltage control is done automatically by generators, transformers, reactors, and capacitors, but the operator can remotely set the target voltages. Control and operation are covered in Chapter 8, Power System Operation and Control.

Hence, all of these subjects can be explored in more detail in the upcoming chapters in this section.

3

Power Transformers

Bob C. Degeneff
Department of Computer, Electrical, and Systems Engineering, Rensselaer Polytechnic Institute, Troy, New York, USA

3.1 Introduction

This chapter presents a very brief overview of the characteristics of a transformer. The basic theory and principles of application are introduced. A simple lumped-parameter equivalent circuit is presented. Magnetizing current and leakage reactance are introduced, and cooling methods are presented and compared. In addition, transformer applications are presented and discussed. The basic core and winding arrangements are also presented. Finally, transformer sound, overcurrent, and losses/efficiency are presented, and acceptance tests are outlined.

3.2 Transformers: Description and Use

A **transformer** is a static device used for transforming electric energy from one circuit to another magnetically (e.g., by induction rather than conduction). Normally, this transformation is accomplished between circuits of different voltages of the same frequency. A power transformer will have a magnetic core surrounded by two or more windings. These windings are insulated from each other and from the ground. The windings are connected together in a manner to achieve the desired voltage transformation ratio. The overall assembly of core and coils is generally insulated and cooled by immersion in mineral oil or other suitable liquid in an enclosing tank. Connection to the windings is usually by means of insulated bushings.

In a modern utility, electrical energy may undergo four or five voltage transformations between the generation site and the point of utilization. As such, a given system possesses approximately five times the kilovoltamperes [kVA] of transformers compared to that of generators.

3.3 Transformers: Theory and Principle

3.3.1 Equivalent Circuits

Figure 3.1 is a cross section of a two-winding transformer. Figure 3.1 illustrates how both windings are linked with the same magnetic circuit. A sinusoidal voltage is induced in the windings by a sinusoidal variation of flux $E = 4.44\ a_c BfN$, with a_c as the area of the core in square meters, B as the peak

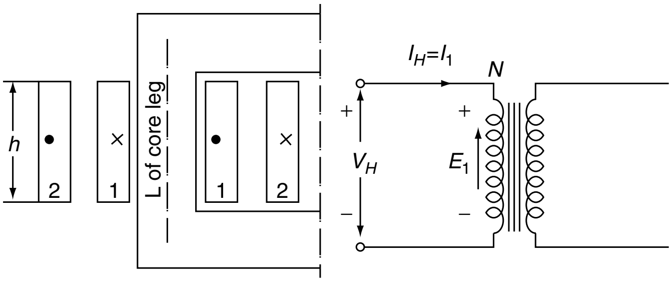

FIGURE 3.1 Cross Section of a Two-Winding Transformer

flux density in tesla, E as the rms-induced voltage, f as the frequency in hertz, and N as the numbers of turns in the winding. With no load on the secondary circuit, a small exciting current flows in the primary, which produces the alternating flux in the core. This flux links both windings and induces essentially the same volts per turn in each winding. To a close approximation:

$$\frac{E_1}{N_1} = \frac{E_2}{N_2},$$

where E_1 and E_2 are the primary and secondary voltages and where N_1 and N_2 are the primary and secondary turns. If a load is applied to the secondary of the transformer and the exciting current is small with respect to the load current, the currents in the primary and secondary are related by:

$$I_1N_1 = I_2N_2.$$

3.3.2 Magnetizing Current

Figure 3.2 is a lumped-parameter model of the transformer in Figure 3.1, with both the primary and secondary solidly grounded. If the secondary is open-circuited, the only current that flows is an exciting current in the primary winding. This exciting current contains only odd harmonics and is composed of a core loss component and a **magnetizing component**. The core loss component is in phase with the induced voltage, and the magnetizing component is lagging the induced voltage by 90° (i.e., in phase with the magnetizing flux). The core loss is represented in Figure 3.2 by b_m, and it is composed of both hysteresis and *eddy current* losses. *Hysteresis* losses are directly proportional to the frequency, and eddy current losses vary proportionally to the square of frequency.

3.3.3 Leakage Reactance

If the secondary of the transformer is shorted, the impedance of the transformer presented to the system is approximately $(R_1 + jX_{l1}) + (R_2 + jX_{l2})$. This is generally referred to as the **impedance of a transformer** or its leakage impedance. The R is the effective resistance of the primary and secondary winding and is composed of both dc and skin effect losses. Generally, R is much smaller than X and normally can be ignored in practical calculation.

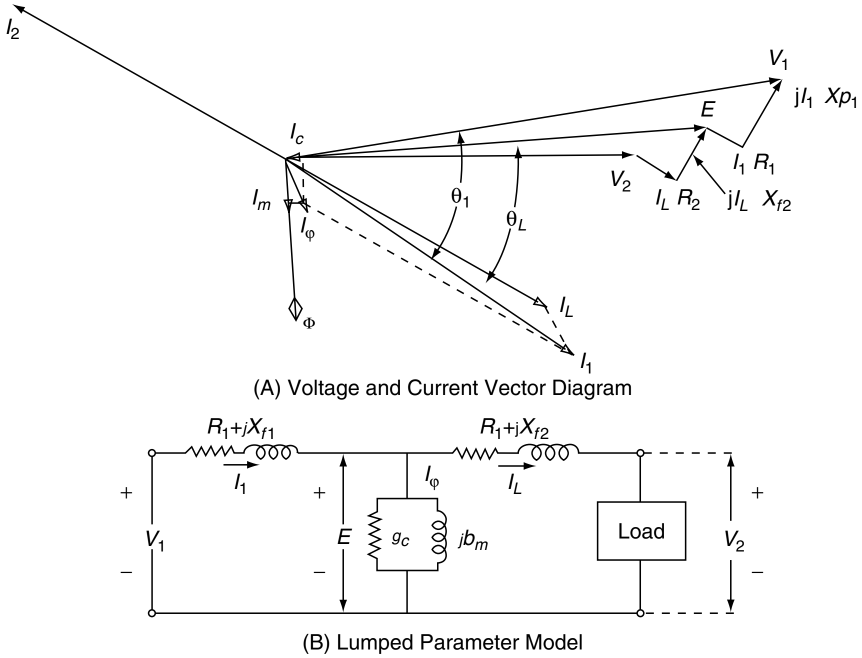

FIGURE 3.2 Lumped-Parameter Equivalent

3.3.4 Magnetizing Inrush

When a transformer is energized, the amount of current that flows will depend on the amount of residual flux that resides in the core. This residual is typically between 50 and 90% of the peak operating flux. In extreme cases, the peak flux in the core upon energization will be greater than twice the peak design limit, and, as such, the **inrush current** can be 3 to 40 times the load current (Grigsby, 2001). The actual inrush experienced depends on the point on the voltage wave during energization, the residual flux, air core inductance of the winding, and losses of the transformer and system.

3.4 Cooling Methods

3.4.1 Liquid-Filled Transformers

A **liquid-immersed transformer** consists of a magnetic core and coil assembly immersed in a fluid, normally mineral oil. The fluid must possess both good heat transfer characteristics and electrical insulating characteristics. An advantage of a liquid-immersed transformer is that it permits compact design. Generally, transformers above 10 MVA and/or 34.5 kV are liquid-filled. Since oils are flammable, liquid-immersed transformers must be applied with adequate precautions recognizing the flammability of oil. This has presented challenges for indoor applications.

Mineral oil used in transformer insulation systems degrades with prolonged exposure to oxygen. Moreover, mineral oil has a fairly large thermal expansion coefficient. In recognition of this disadvantage, several systems are used to minimize degradation. Liquid-filled transformers normally protect insulating oil with one of three types of preservation systems: **sealed tank system**, **nitrogen blanked**, or **conservator**.

3.4.2 Dry-Type Transformers

Dry-type transformers are generally more expensive per kVa than liquid-filled transformers but address the concern for indoor applications. Dry-type transformers use solid insulation systems or film coatings and/or paper tapes. A variation is the resin-encapsulated system (or cast coil). Dry-type transformers have less of an ability to withstand impulse voltages than corresponding liquid-filled designs. Dry-type transformers are offered in ventilated and nonventilated, totally enclosed systems for use in hostile industrial environments. Dry-type transformers are routinely offered up to 34.5 kV and 10 MVA.

3.5 Transformer Applications

The most common arrangement of a power transformer is two or more isolated windings wound around a common core. The advantage is complete electrical isolation between electrical circuits. These units can be of the **step-down** or **step-up** configuration. A step-down is designed to decrease the incoming voltage to a lower level more suitable for distribution. Power transformers of this type are frequently located in substations or at large industrial consumer locations. Transformers that perform this reduction in voltage from a primary feeder to the utilization level are referred to as **distribution transformers**. A step-up transformer takes the input voltage and raises it to a higher lever suitable for transmission. American National Standards Institute (ANSI) standards require the nameplate to indicate the transformer is suitable for this type of operation. A generator step-up transformer is an example of this type of power transformer. The majority of these type power transformers are three-phase units.

It is often more economical to transfer energy between two circuits of similar voltage using an autotransformer rather than a conventional two-winding transformer. Figure 3.3 provides an illustration of this arrangement. Most autotransformers are *Y*-connected with a delta tertiary (used to provide a path for third harmonic currents required for excitation). The autotransformer does not afford electrical separation between the two circuits but is a more economical transformer on a $/kVA basis. In addition, the autotransformer is not inherently self-protecting and typically will be subjected to higher short circuit currents and forces than a corresponding two-winding transformer. The autotransformer can also be used to increase or decrease voltage in a system. By using suitable on-load tap-changing equipment, it is possible to regulate the voltage of a system within desired limits. An autotransformer used in this manner is referred to as a voltage-regulating transformer. Typically, the range of the regulation is $\pm 10\%$ of the system voltage in 5/8% steps.

It may be desirable to create an electrical connection between systems that have different phase angles. These systems may also be at different voltages. The function of the phase–angle regulator is to provide this interconnection between systems possessing different phase angles and voltages. Figure 3.4 illustrates one method to accomplish this transformation.

In power system applications, there are two types of instrument transformers: **current transformers** and **voltage trans-**

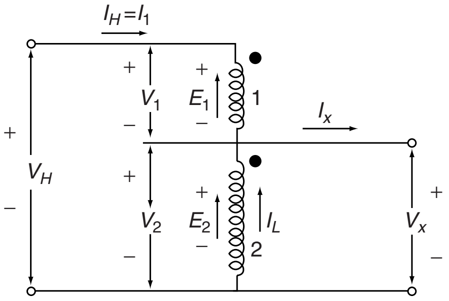

FIGURE 3.3 Autotransformer

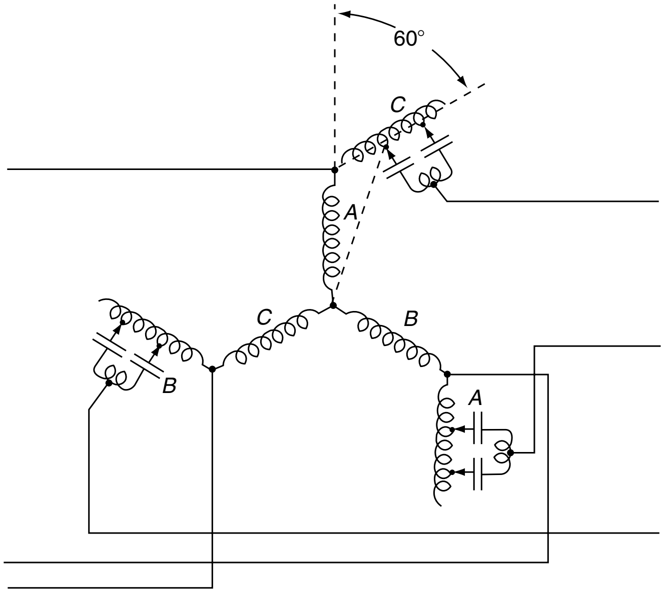

FIGURE 3.4 Phase-Angle Regulator

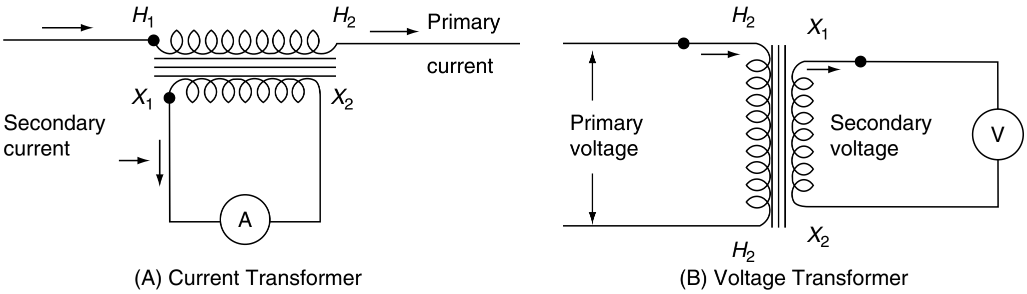
formers. Both are used to secure information about the condition and operation of the system. Typically, this information is used in relaying information and in operational control of the system. The current transformer is a series transformer. Its primary winding is connected in series with the circuit in which the current is to be measured, and the secondary winding supplies a current output that is proportional to the primary current (Figure 3.5). The voltage transformer primary winding is connected to the terminals of the circuit where the voltage is to be measured, and the secondary winding supplies a voltage proportional to the primary voltage.

3.6 Cores and Windings

The successful design of a commercial transformer requires the selection of a simple structure so that the core and coils are easy to manufacture. At the same time, the structure should be as compact as possible to reduce materials, shipping concerns, and footprints. The form should also allow convenient removal of heat, sufficient mechanical strength to withstand forces generated during system faults, acceptable noise characteristics, and an electrical insulation system that meets both the system steady-state and transient requirements. There are two common transformer structures in use today for power transformers. When the magnetic circuit is encircled by two or more windings, the transformer is referred to as a **core-type transformer**. When the primary and secondary windings are encircled by the magnetic material, the transformer is referred to as a **shell-type transformer**. Refer to Figure 3.6 for an illustration of each.

3.6.1 Core Form Transformer

Characteristics of the **core-form transformer** are a long magnetic path and a shorter mean length of turn. Commonly used core-form magnetic circuits are single-phase transformers with a two-legged magnetic path with turns wound around each leg, a three-legged magnetic path with the center leg wound with conductor, or a four-legged magnetic path with the two interior legs wound with conductors (Bean *et al.*, 1959; Massachusetts Institute of Technology, 1943). Three-phase core-form designs are generally three-legged magnetic cores with all three legs possessing windings or a five-legged core arrangement with the three center legs possessing windings. The simplest winding arrangement has the low-voltage winding nearest the core and the high-voltage winding on top of the low. Normally, in the core form construction, the winding system is constructed from helical, layer, or disk-type windings (Massachusetts Institute of Technology, 1943; Franklin, 1998). The disk-type winding itself can be constructed on several different winding configurations (i.e., continuous, interleaved, and internally shielded), all of which affect the transient voltage response and this insulation design. Often the design requirements, such as impedance or shipping size limitations, call for a core and winding arrangement that is a more complex arrangement (e.g., interleaving high- and low-voltage windings, interwound taps, and entry and exit points other than the top or bottom of the coil). All of these variations have an effect on the transformer's transient voltage



(A) Current Transformer

(B) Voltage Transformer

FIGURE 3.5 Instrument Transformers

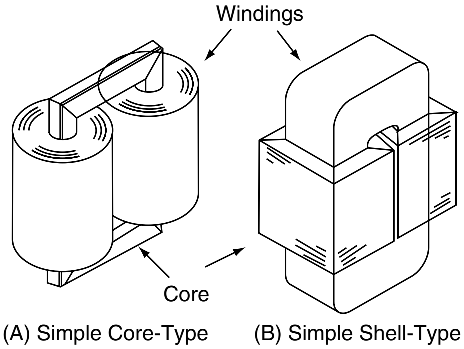


FIGURE 3.6 Core-Form and Shell-Form Transformers

response. To ensure an adequate insulation structure, each possible variation must be explored during the design stage to evaluate the variation's effect on the transient overvoltages.

3.6.2 Shell-Form Transformer

The **shell-form transformer** construction features a short magnetic path and a longer mean length of electrical turn. Bean *et al.* (1959) point out that this results in the shell-form transformer having a larger core area and a smaller number of winding turns than the core-form of the same output and performance. In addition, the shell-form will generally have a larger ratio of steel to copper than an equivalently rated core-form transformer. The most common winding structure for shell-form windings are the primary–secondary–primary (P–S–P), but it is common to encounter a shell form winding of P–S–P–S–P. The winding structure for both the primary and secondary windings are normally of the pancake-type winding structure (Bean *et al.*, 1959).

3.7 Transformer Performance

3.7.1 Losses and Efficiency

Total losses for transformer performance are made up of **no-load losses** and **load losses**. No-load losses are primarily hysteresis and eddy-current loss in the core. This loss is independent of load and exists whenever the transformer is connected to the system. The no-load loss is a function of the voltage of the system. The core's eddy-current loss is proportional to the square of the system frequency, and the hysteresis loss is proportional to the frequency. Load losses consist of I^2R loss in the windings, stray losses in the windings, and structural clamps and fittings. These losses are caused by the load current. On large well-designed transformers, the total rated losses are on the order of 0.3 to 0.5% of the rated kVA of the transformer. The cost per kilovoltampere is different for load and no-load losses and depends on a number of factors (Massachusetts Institute of Technology, 1943). Typically the no-load losses are 25 to 35% of the total losses and are 2.5 to 3.5 times the $/kVA of load losses.

3.7.2 Sound

Transformers are static devices; however, they vibrate due to a number of causes and because of the radiate sound. There are two distinct sources of sound: **auxiliary cooling equipment** and **magnetostriction**. The sound produced by the fans and pumps of a cooling system generally possesses a broadband frequency spectrum of approximately equal magnitude (white noise). The major source of a transformer's audible noise is caused by the dimensional change of the core laminations from the variation of flux density in each voltage cycle, referred to as **magnetostriction**. The core will radiate noise at the even harmonics of the voltage (e.g., for a 60-Hz system, the noise radiates at 120-, 240-, 360-, 480-Hz, and so on). The magnitude of this noise is measured by determining the sound-pressure level given in decibels:

$$P = 20 \log \frac{F}{0.0002},$$

with P the sound pressure in decibels and F the sound pressure in rms dynes. IEEE C57.12.90, Test Code for Liquid-Immersed Transformers, specifies the method for measuring the average sound level of a transformer. The goal is to avoid a transformer design and installation that produces noise at a level that is an annoyance. Sound reduction can be accomplished at the transformer design stage and/or by judicious application. During design, the most basic modification effecting noise production is to reduce the core's flux density. In addition, barriers or structural changes in the tank enclosure will reduce emitted noise. Upon installation, the erection of sound barriers is very effective in reducing noise levels. With proper design, reductions of 10 to 30 dB are possible; with the application of sound barriers at a site, an additional 10-dB reduction is achievable.

3.7.3 Overcurrent

A transformer may at some point be subjected to current in excess of its rated load current. Current up to approximately 2% of the rated load current can be anticipated from overload conditions on the system. These currents may last only a few minutes or several hours. Faults on the system will subject the transformer to peak overcurrents that may be up to 40 times the rated load current. These currents may produce either mechanical or thermal damage to the transformer. Mechanical forces are proportional to the square of the current and manifest themselves in a number of different failure mechanisms. These failure mechanisms include loosening of coils, conductor tipping, radial and axial conductor buckling, winding deformation, core deformation, and telescoping of windings.

3.8 Acceptance Tests

The desire of the purchaser is to obtain a transformer at a reasonable price that will achieve the required performance for an extended period of time. The desire of the manufacturer is to construct and sell a product, at a profit, that meets the customer's goals. The specification and purchase contract combines both the purchaser's requirements and manufacturer's commitment in a legal format. The specification will typically address the transformer's service condition, rating, general construction, control and protection, design and performance review, testing requirements, and transportation and handling. Since it is impossible to address all issues in a specification, the industry uses standards that are acceptable to purchaser and supplier. In the case of power transformers, the applicable standard would include IEEE C57, IEC 76, and NEMA TR-1.

ANSI/IEEE C57.12.00 defines routine and optional test and testing procedures for power transformers. The following are listed as routine tests for transformers larger than 501 kVA: winding resistance, winding turns ratio, phase–relationship tests, polarity, angular displacements, phase sequence, no-load loss and exciting current, load loss and impedance voltage, low-frequency dielectric tests (applied voltage and induced voltage), and leak test on a transformer tank.

The following are listed as type tests to be performed on only one of a number of similar design units for transformers 501 kVA and larger: temperature rise tests, lightning-impulse tests (full and chopped wave), audible sound tests, mechanical test from lifting and moving of transformer, and pressure tests on tank.

Other tests include short circuit forces and switching surge impulse tests.

The variety of transient voltages a transformer may experience in its normal useful lifetime are virtually unlimited. It is impractical to test each transformer for every conceivable combination of transient voltage. However, the electrical industry has found that it is possible, in most instances, to assess the integrity of the transformer's insulation systems to withstand transient voltages with the application of a few specific aperiodic voltage waveforms (Massachusetts Institute of Technology, 1943), illustrating the full, chopped, and switching surge waveforms. Each of these tests is designed to test the insulation structure for a different transient condition. The purpose of applying this variety of tests is to substantiate adequate performance of the total insulation system for all the various transient voltages a transformer may see in service.

Introduction to Electric Machines

Sheppard Joel Salon
Department of Electrical Power Engineering, Renssalaer Polytechnic Institute, Troy, New York, USA

4.1 Introduction

Essentially all electric energy is generated in a rotating machine, the **synchronous generator**, and most of it is consumed by electric motors. In many ways, the world's entire technology is based on these devices. The study of the behavior of electric machines is based on three fundamental principles: Ampère's law, Faraday's law and Newton's Law. Various configurations result and are classified generally by the type of electrical system to which the machine is connected: **direct current** (dc) machines or **alternating current** (ac) machines. Machines with a dc supply are further divided into permanent magnet and wound field types, as shown in Figure 4.1. The wound motors are further classified according to the connections used. The field and armature may have separate sources (separately excited), they may be connected in parallel (shunt connected), or they may be series (series connected).

Machines that have ac are usually single-phase or three-phase machines and may be synchronous or asynchronous. Several variations are shown in Figure 4.2.

The following sections state very briefly the basic principles on which all standard electric machines operate and then, for the most common devices, explain the principles of operation and the parameters for predicting and understanding their behavior.

4.1.1 Basic Electromagnetic Laws: Ampère's Law and Faraday's Law

The two principles that describe the electromagnetic behavior of electric machines are **Ampère's law** and **Faraday's law**. These are two of Maxwell's equations. Most electric machines operate by attraction or repulsion of electromagnets and/or permanent magnets. Ampère's law describes the magnetic field that can be produced by currents or magnets. In an electric machine, there will always be at least one set of coils with currents. A motor cannot be produced with permanent magnets alone.

Ampère's law states that the line integral of the component of the magnetic field along the path of integration is equal to the current enclosed by the path. This is exactly true for static fields and is a very good approximation for the low-frequency fields dealt with in electric machines:

$$\oint \vec{H} \cdot d\vec{\ell} = I_{\text{enclosed}}. \tag{4.1}$$

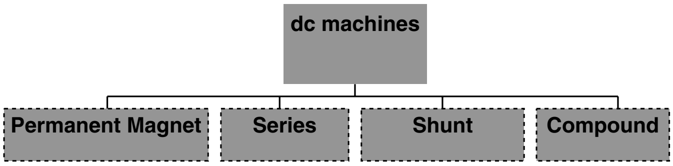

FIGURE 4.1 Direct Current Machine Classifications

The right-hand side of equation 4.1 represents the current enclosed by the integration path and is called the **magnetomotive force** (MMF). In electric machines, currents are frequently placed in slots surrounded by ferromagnetic teeth. An example illustrating the determination of the MMF is shown in Figure 4.3, where different integration paths are shown by dotted lines. The MMF corresponding to each path is the total current enclosed by the path. If the slots contain currents that are approximately sinusoidally distributed in space, then the MMF will be cosinusoidally distributed. In this way, the magnetic field or flux density in the air gaps of the machine will often have a sinusoidal or cosinusoidal distribution.

Faraday's law relates the induced voltage or electromotive force (EMF) to the time rate of change of the magnetic flux linkage:

$$\oint \vec{E} \cdot d\vec{\ell} = -\frac{d}{dt}\oint \vec{B} \cdot d\vec{S}, \qquad (4.2)$$

where $\vec{E}$ is the electric field and $\vec{B}$ is the magnetic flux density. This law states that the voltage induced in a loop is equal to the time rate of change of the flux linking the loop. The negative sign indicates that the voltage is induced such that the current would oppose the change in flux linkage. The change in flux linkage can be caused by a change in flux density and/or a change in geometry.

4.1.2 MMF and Traveling Waves

Presented now is the important concept of rotating MMF and fields in machines. Consider the following equation:

$$\mathfrak{F} = F_1 \sin(\omega t)\cos(P\theta). \qquad (4.3)$$

Equation 4.3 represents a standing wave. The sine term describes the time variation, while the cosine term describes the space variation. P is the number of pole pairs around the machine. At a fixed point on the wave θ is constant, and the amplitude is sinusoidally time varying. The peak of the wave and the nodes or zero crossings, however, are always located at the same position. This equation is contrasted with an expression of the form:

$$\mathfrak{F} = F_1 \sin(\omega t - P\theta). \qquad (4.4)$$

This equation represents a traveling wave. If the behavior of a fixed point in space is considered, as before, the amplitude varies sinusoidally in time. However, it is no longer true that the peak or any point on the wave remains in the same position. To see this, consider the argument of the sine function. The peak will be located at $\omega t - P\theta = \frac{\pi}{2}$. To remain at the peak of the wave as time moves forward, movement must be made in the positive θ direction. The expression therefore represents a wave traveling in the positive θ direction. If the minus sign in the argument is replaced by a plus sign, the wave travels backward or in the negative θ direction. The speed of the traveling wave can be determined by considering the argument of the sine function. In one cycle, the ωt term increases by 2π. To remain at the same point on the wave, the space term must also advance by 2π. This means that θ must increase by $\frac{2\pi}{P}$. Thus, the wave progresses one wavelength or two poles in one cycle.

A standing wave can be decomposed into two traveling waves, one going forward and one backward, each of half the amplitude of the standing wave. See Figure 4.4. This is seen by using a trigonometric identity:

$$\sin\omega t \cos P\theta = \frac{1}{2}(\sin\omega t + P\theta) + \sin(\omega t - P\theta)). \qquad (4.5)$$

The first term on the right-hand side of equation 4.5 represents a backward traveling wave, and the second term represents a forward traveling wave.

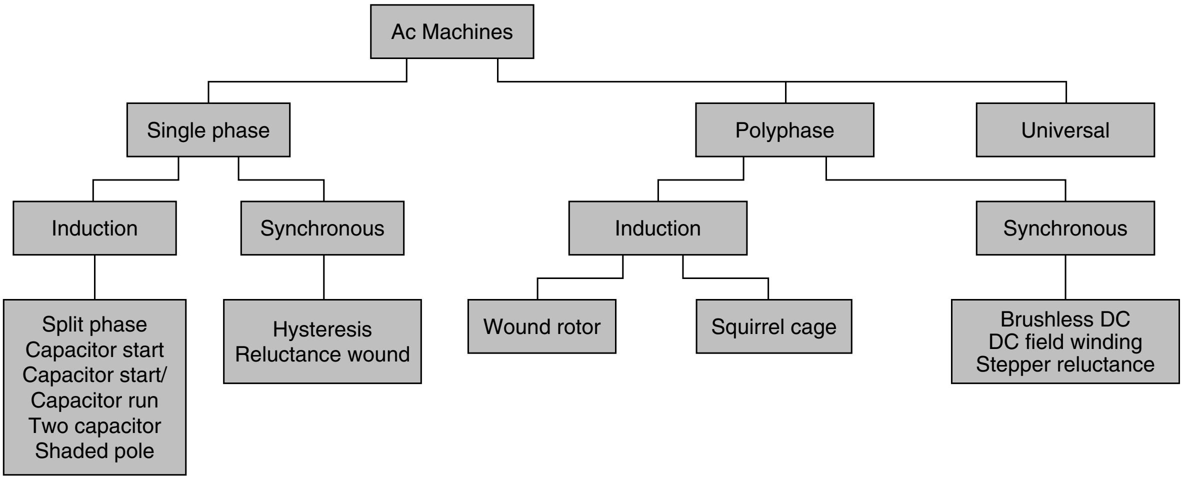

FIGURE 4.2 Alternating Current Machine Classifications

Let us consider the case of a three-phase winding in which each of the phases are displaced by 120° in space and the winding currents are displaced by 120° in time. For the first phase, phase *a*, the fundamental space component of the MMF has the form:

$$\mathcal{F}_a = K\sin(\omega t)\cos(P\theta) = \frac{K}{2}(\sin(\omega t - P\theta) + \sin(\omega t + P\theta)), \tag{4.6}$$

where *K* is a constant containing information on the winding geometry. Similarly, for phases *b* and *c*:

$$\begin{aligned}\mathcal{F}_b &= K\sin\left(\omega t - \frac{2\pi}{3}\right)\cos\left(P\theta - \frac{2\pi}{3}\right)\\ &= \frac{K}{2}\left(\sin(\omega t - P\theta) + \sin\left(\omega t + P\theta - \frac{4\pi}{3}\right)\right).\end{aligned} \tag{4.7}$$

$$\begin{aligned}\mathcal{F}_c &= K\sin\left(\omega t - \frac{4\pi}{3}\right)\cos\left(P\theta - \frac{4\pi}{3}\right)\\ &= \frac{K}{2}\left(\sin(\omega t - P\theta) + \sin\left(\omega t + P\theta - \frac{2\pi}{3}\right)\right).\end{aligned} \tag{4.8}$$

The forward waves of all three phases are the same, while the backward waves are 120° out of phase. By adding the MMFs of the three phases, a resultant wave is obtained in which the fundamental space component travels in the forward direction and has a magnitude 3/2 times the peak MMF of one phase alone. The backward waves cancel. This is the most common method of producing traveling magnetic fields in motors. Figure 4.5 shows a simplified 18-slot machine with three-phase sinusoidal currents. Each phase is placed into three consecutive slots with the return nine slots away. The MMF at different instants of time is plotted, and the wave moves to the right at a rate of one wavelength (two poles) per cycle. The wave is distorted due to the space harmonics included. These have little influence on the energy conversion process and are not dealt with here.

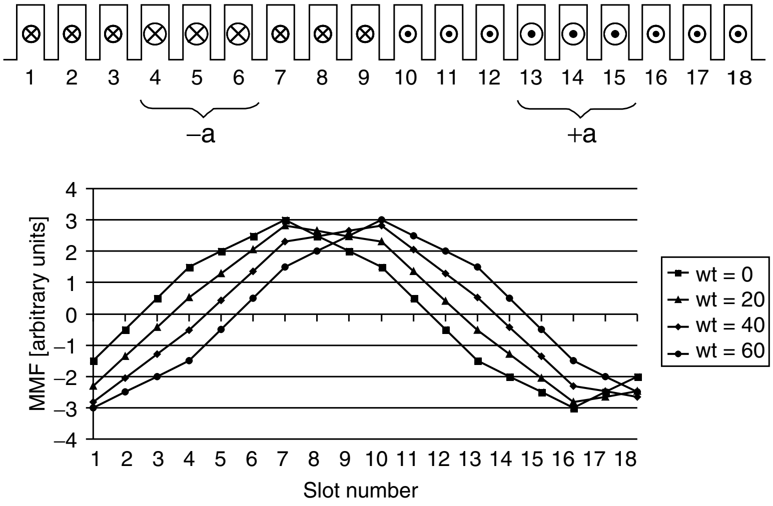

FIGURE 4.5 An 18-Slot Machine with MMF at 4 Times: The Movement of the Wave

4.1.3 Mechanical Description of a Drive System

An electrical machine will operate at a speed determined by the electric torque or force produced and the mechanical load (Figure 4.6). If these are equal and opposite, the machine will operate at a constant speed; if not, the machine will accelerate or decelerate at a rate proportional to the net accelerating force or torque. Newton's law describes this process. Writing this for a rotational system:

$$T_{em} - T_{\text{load}} = J\frac{d\omega_m}{dt}, \tag{4.9}$$

where T_{em} is the electromagnetic torque delivered to the load, T_{load} is the load torque, J is the moment of inertial of load and motor, and ω_m is the mechanical angular frequency [radians per second]. Figure 4.7 illustrates a typical motor and load torque characteristic. At point a, the motor torque is greater than the load torque and the system accelerates. At point b, the load torque is greater than the motor torque and the system decelerates. Point c is a stable equilibrium point, and the system will operate at this speed.

The electric machine may operate as a motor or as a generator. Only the direction of energy transfer is affected. In a motor, the electrical energy is transformed into mechanical energy, and in a generator, the mechanical energy is transformed into electrical energy. In either case, the machine may run forward or backward. These combinations are illustrated in Figure 4.8, where a four-quadrant operation is shown. Depending on the type of drive, an electromechanical system may have the ability to operate in any one or perhaps all four quadrants.

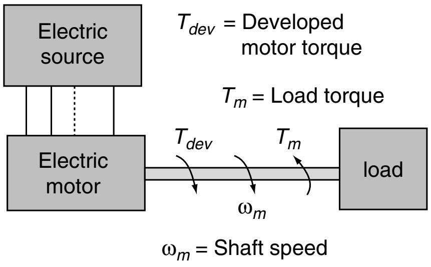

FIGURE 4.6 Drive System

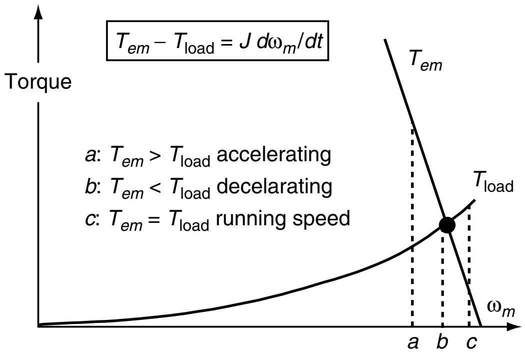

FIGURE 4.7 Motor and Load Torque

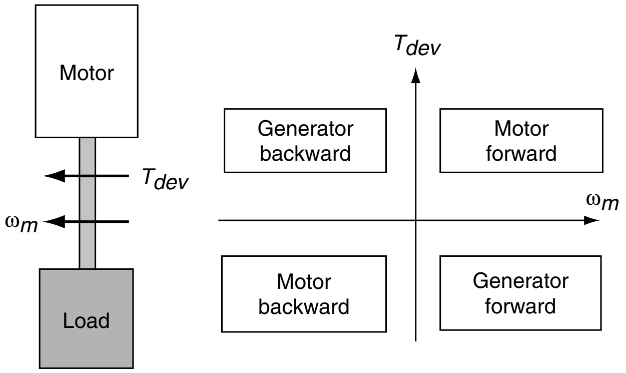

FIGURE 4.8 Four-Quadrant Operation

4.1.4 Energy Conversion

All of the devices considered here are **magnetic** (i.e., they use the energy in a magnetic field to produce force or torque). It is possible to construct electrostatic motors and actuators, but in standard sizes, the energy density is too low to make them competitive. Consider a simple linear system consisting of a resistance and a position-dependent inductance connected to an electrical supply. The circuit equation is as follows:

$$v = iR + \frac{d\psi}{dt} = iR + \frac{d}{dt}(L(x)i), \tag{4.10}$$

Where $\psi = Li$ is the flux linkage. Performing the differentiation yields:

$$v = Ri + L(x)\frac{di}{dt} + i\frac{\partial L(x)}{\partial x}\frac{dx}{dt}. \tag{4.11}$$

Note how the velocity dx/dt appears due to the position dependence of the inductance. The energy input from the source in time dt is as written here:

$$vi\ dt = i^2 R dt + iL(x)di + i^2\frac{\partial L(x)}{\partial x}dx. \tag{4.12}$$

The first term on the right-hand side of equation 4.12 is the joule heating. To understand the physical significance of the second and third terms, consider the change in stored magnetic energy. The energy stored in an inductor is as follows:

$$W_m = \frac{1}{2}L(x)i^2. \tag{4.13}$$

If both i and $L(x)$ change, the change in stored energy becomes:

$$dW_m = \frac{\partial W_m}{\partial i} di + \frac{\partial W_m}{\partial x} dx = iL(x)di + \frac{1}{2} i^2 \frac{\partial L(x)}{\partial x} dx. \quad (4.14)$$

The energy input from the circuit cannot completely be explained by losses and a change in stored energy. There is a missing $\frac{1}{2} i^2 (\partial L(x)/\partial x)dx$. This is the energy turned into mechanical work. This term is the one associated with motion. As a general rule, a situation must occur in which there is a change of inductance (self and/or mutual) with position.

Now consider the case of two coupled circuits. The losses can be treated as above. The total energy stored in the magnetic field is as written here:

$$W_m = \frac{1}{2} L_{11} i_1^2 + \frac{1}{2} L_{22} i_2^2 + L_{12} i_1 i_2. \quad (4.15)$$

Using the virtual work principle, the mechanical force in any direction is the partial derivative of the magnetic energy with respect to an incremental motion in that direction with the current held constant. To find torque, differentiate with respect to the rotational angle. Now look at the expression for torque in this two circuit system:

$$T = \frac{1}{2} i_1^2 \frac{\partial L_{11}}{\partial \theta} + \frac{1}{2} i_2^2 \frac{\partial L_{22}}{\partial \theta} + i_1 i_2 \frac{\partial L_{12}}{\partial \theta}. \quad (4.16)$$

There are three possible sources of torque: the change in the self-inductance of winding 1 with position, the change of the self-inductance of winding 2 with position, and the change of the mutual inductance with position. In an electric machine, one, two, or all three of these effects may be involved. Figure 4.9(A) shows a double salient structure in which all three effects are in operation. With winding 1 excited alone, there is a torque due to the position dependence of the winding 1 self-inductance. The torque will be in a direction to maximize L_{11} and thus make the air gap smaller. Similarly, if winding 2 is excited alone, a torque is obtained due to the variation of L_{22}. If both windings are excited together, there is also a torque due to the variation of the mutual inductance L_{12}. Figures 4.9(B) and 4.9(C) show the case of a single salient structure (one self and one mutual term) and a nonsalient structure (only the mutual term).

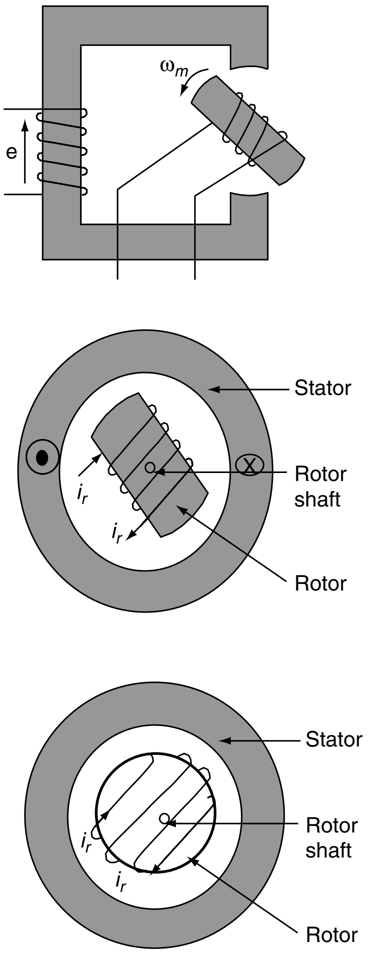

FIGURE 4.9 Double Salient Structure (Top), Single Salient Structure (Middle), and Nonsalient Structure (Bottom)

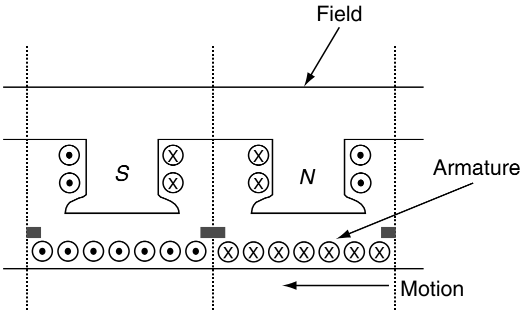

FIGURE 4.10 Typical Direct Current Motor

4.2 Direct Current Machines

The dc machine usually has a dc winding or a set of permanent magnets on the stator (the field) and a winding connected to brushes on the rotor (the armature). This configuration is shown in Figure 4.10. The armature currents produce a flux density that peaks approximately 90° from the peak of the flux density produced by the field. As the rotor turns, the currents in the armature conductors are switched by a commutator so that the field pattern remains the same. The dc machine is inherently a variable speed machine. The speed and torque can be controlled by the field current and by the armature voltage. Machines that are ac run at constant speed or near-constant speed, the speed being determined by the supply frequency.

4.2.1 Induced EMF in a Full-Pitched Winding

The expression for the induced voltage or back EMF in a full-pitched armature conductor is now formed (see Figure 4.11). **Full-pitched** means that the coil spans one pole. Assume that the flux density in the air gap has a periodic spatial relationship, and it may be expressed as:

$$B(\alpha) = B_1 \sin(\alpha) + B_3 \sin(3\alpha) + B_5 \sin(5\alpha) + \ldots. \quad (4.17)$$

Integrating to find the flux linkage yields:

$$\psi = N \cdot D \cdot L\left(B_1 \cos(\theta) + \frac{1}{3}B_3 \cos(3\theta) + \frac{1}{5}B_5 \cos(5\theta) + \ldots\right), \quad (4.18)$$

where N is the number of turns in a coil, D is the diameter, L is the length, and $\theta = \omega t$.

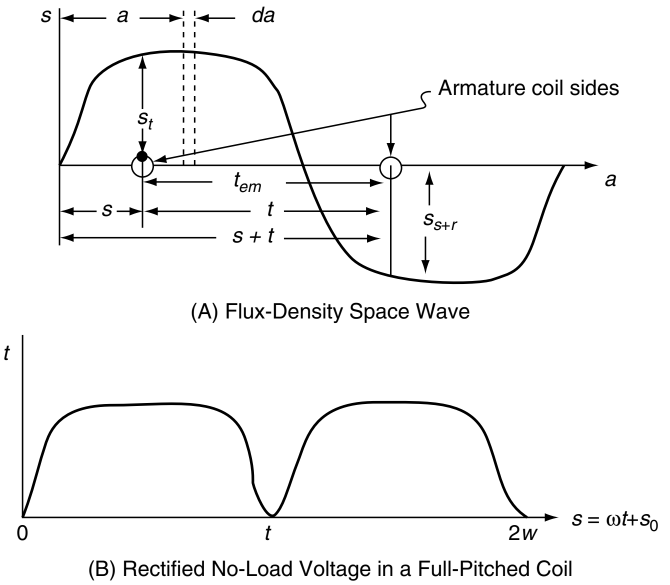
From Faraday's law:

$$e_a = \frac{d\psi}{dt} = \frac{d\psi}{d\theta} \cdot \frac{d\theta}{dt}. \quad (4.19)$$

So, for each armature coil:

$$e_a = \omega N \cdot D \cdot L(B_1 \sin(\theta) + B_3 \sin(3\theta) + B_5 \sin(5\theta) + \ldots). \quad (4.20)$$

Note that the induced voltage waveform has the same harmonic content as the flux density waveform.



(A) Flux-Density Space Wave

(B) Rectified No-Load Voltage in a Full-Pitched Coil

FIGURE 4.11 Direct Current Motor Field Distribution

The average value of the EMF is the following:

$$E_a = \frac{2}{T}\int_0^{T/2} e_a \, dt = \frac{1}{\pi}\int_0^{\pi} e_a \, d\theta, \quad (4.21)$$

where T is the period. Using symmetry to integrate over one pole pitch:

$$E_a = \frac{\omega}{\pi} N \int_0^{\pi} B(\theta) DL \, d\theta. \quad (4.22)$$

Note here that $D \cdot L \cdot d\theta = 2dA$, where dA is the incremental area shown in Figure 4.11. Now, the flux per pole is written as:

$$\Phi = \int_0^{\pi} B(\theta) \, dA. \quad (4.23)$$

Hence, the following is true:

$$E_a = \frac{2\omega_m}{\pi} N\Phi. \quad (4.24)$$

This is the average EMF per pole, per coil. To generalize, there may be P poles. Then:

$$E_a = \frac{P}{2} \cdot \frac{2}{\pi} \cdot N\Phi\omega_m. \quad (4.25)$$

If there are a parallel paths in the armature, and N_a is the total number of turns in the armature, then:[1]

$$E_a = \frac{P}{a\pi} N_a \Phi \omega_m. \quad (4.26)$$

In terms of the total number of active conductors in the armature, $Z = 2N_a$:

$$E_a = \frac{PZ}{2a\pi} \Phi\omega_m = K_i \Phi \omega_m, \quad (4.27)$$

where:

$$K_t = \frac{PZ}{2\pi a} = \frac{PN_a}{\pi a}. \quad (4.28)$$

4.2.2 Speed–Torque Relationships

Consider the circuit of Figure 4.12, where R_a is the armature resistance and V_a is the applied voltage. E_a represents the back EMF. Assume that there is no change in the energy stored in

[1] Direct current (dc) machines use two types of windings. In a lap winding, the number of parallels is equal to the number of poles. In a wave winding, there are two parallels.

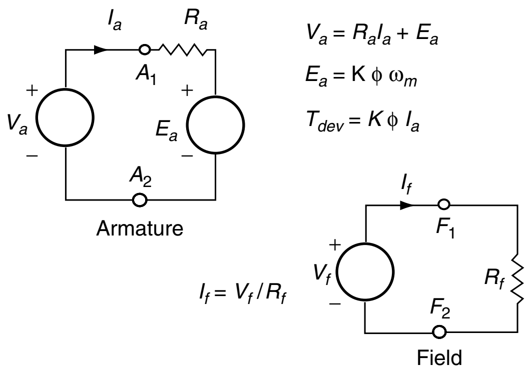


FIGURE 4.12 Direct Current Machine Diagram

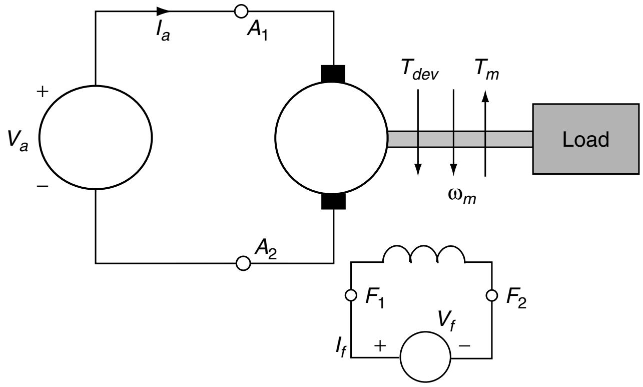

FIGURE 4.13 Separately Excited Direct Current Motor

the field. Then, the input power P_{in} must go into joule heating, P_L, and mechanical power, P_m:

$$P_{\text{in}} = P_L + P_m. \tag{4.29}$$

Therefore:

$$P_m = V_aI_a - R_aI_a^2 = I_a(V_a - R_aI_a) = E_aI_a. \tag{4.30}$$

So the mechanical power is the product of the armature current and the back EMF. The mechanical power is related to the torque by:

$$P_m = E_aI_a = \omega T_m. \tag{4.31}$$

Solving for the torque:

$$T_m = \frac{E_aI_a}{\omega} = I_a\frac{K_t\Phi\omega}{\omega} = K_t\Phi I_a. \tag{4.32}$$

The voltage equation is as written here:

$$V_a = E_a + R_aI_a = K_t\Phi\omega + R_aI_a, \tag{4.33}$$

which gives this equation:

$$\omega = \frac{V_a - R_aI_a}{K_t\Phi}. \tag{4.34}$$

Equation 4.34 gives a relationship between the motor speed and torque. Notice that the speed is inversely proportional to the field flux.

4.2.3 Direct Current Machine Connections

The dc machine can be connected in several ways to control the speed–torque characteristic, as explained in the following subsections.

Separately Excited Machine

When the field and the armature are excited by separate sources, as indicated in Figure 4.13, the machine is **separately excited**. The field flux is controlled by I_f, and the armature current depends on the applied voltage V_a and the back EMF.

The rotor speed is given by:

$$\omega_m = \frac{V_a - R_aI_a}{K_t\Phi}. \tag{4.35}$$

Equation 4.35 can be broken into two terms, one that depends on the applied armature voltage and one that depends on the armature current:

$$\omega_m = \omega_0 - \frac{R_aI_a}{K_t\Phi}, \tag{4.36}$$

where $\omega_0 = \frac{V}{K_t\Phi}$ is the no-load speed. There are two mechanisms for speed control. As the armature voltage increases while the field current holds constant, the velocity ω_0 increases. A number of parallel curves are obtained of ω_m versus I_a. If I_f is increased (and therefore Φ), both terms of ω_0 and $R_a/K_t\Phi$ decrease.

Shunt-Excited Machine

If both windings of a dc machine are connected in parallel, then the voltage to the armature and the field are the same. This is indicated in Figure 4.14 as a **shunt = excited machine**. Ignoring saturation, the result is the following:

$$K_t\Phi = K_1I_f = KV_a. \tag{4.37}$$

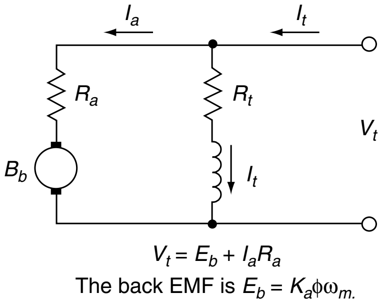

FIGURE 4.14 Shunt-Excited Direct Current Machine

So:

$$\omega_m = \frac{V_a - I_a R_a}{K_t \Phi} = \frac{V_a - I_a R_a}{K V_a} = \frac{1}{K} - \frac{R_a}{K V_a} I_a. \tag{4.38}$$

Therefore, at no load ($I_a = 0$):

$$\omega_m = \frac{1}{K}. \tag{4.39}$$

The no load speed is independent of the armature voltage. Speed control is achieved by controlling field current through a variable resistance connected to the field.

Series-Excited Machine

In the **series-excited machine**, the current through the field winding and armature winding are the same. Neglecting saturation yields:

$$K_t \Phi = K_2 I_f = K_2 I_a. \tag{4.40}$$

$$\omega_m = \frac{V - R_a I_a}{K_t \Phi} = \frac{V - R_a I_a}{K_2 I_a} = \frac{V}{K_2 I_a} - \frac{R_a}{K_2}. \tag{4.41}$$

If an external resistance is used for speed control, then:

$$\omega_m = \frac{V}{K_2 I_a} - \frac{R_a + R_{ext}}{K_2}. \tag{4.42}$$

For the torque, the result is as follows:

$$T = K_t \Phi I_a = K_2 I_a^2. \tag{4.43}$$

If the load torque increases, the current increases only as the square root of the torque, and the speed drops. This makes the series-excited dc machine a popular choice for traction applications.

4.3 Three-Phase Induction Motor

Induction motors are by far the most common type of motor used by industry. The most common **polyphase induction motor** has a laminated stator core and a three-phase winding contained in slots. The rotor has two standard configurations: **squirrel cage** and **wound rotor**. The squirrel cage is the most common and consists of solid rotor bars that are contained in slots. The bars are typically made of a good conductor, such as copper or aluminum. The rotor is usually laminated. The bars are connected together at each end by a short-circuiting ring. The squirrel cage has the advantage of being inexpensive and very rugged, having no insulation. In the wound rotor induction machine, the rotor winding is an insulated three-phase winding. The terminals are brought out through slip rings. The advantage of the wound rotor is that the resistance of the rotor can be controlled by inserting or removing stationary resistance through the slip rings. A squirrel cage induction motor cross section is shown in Figure 4.15 along with a plot of the flux lines for rated conditions.

At steady state, the three-phase stator winding produces a magnetic field rotating at synchronous speed. The rotor rotates at a speed slightly less than synchronous speed. The low-frequency currents induced on the rotor produce a field that also travels at synchronous speed. There is a fixed angle between these two fields. They react with each other to produce a constant torque. This is illustrated schematically in Figure 4.16.

4.3.1 Equivalent Circuit

A typical single-phase equivalent circuit for the induction machine is shown in Figure 4.17(A). This circuit is valid for steady-state sinusoidal conditions.

This circuit resembles a two winding transformer equivalent circuit, with the secondary (rotor) short-circuited. Here, V_1 is the phase voltage, r_1 the stator winding resistance per phase, X_1

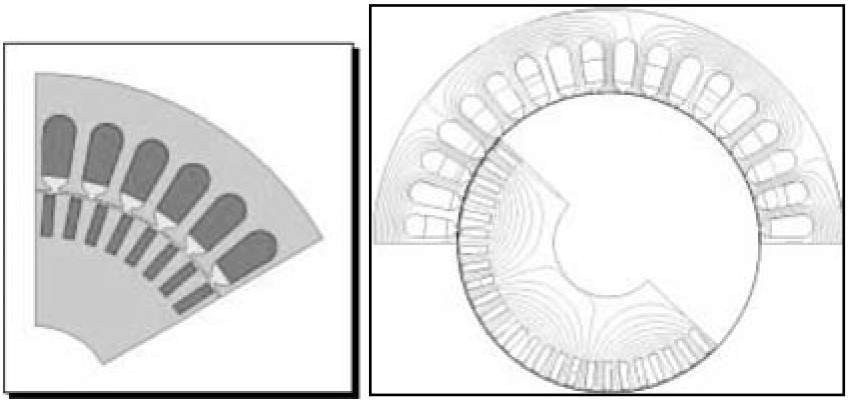

FIGURE 4.15 Squirrel Cage Induction Motor

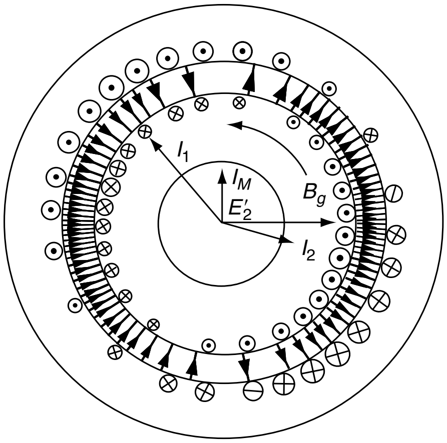

FIGURE 4.16 Induction Motor Rotor and Stator Currents and Fields

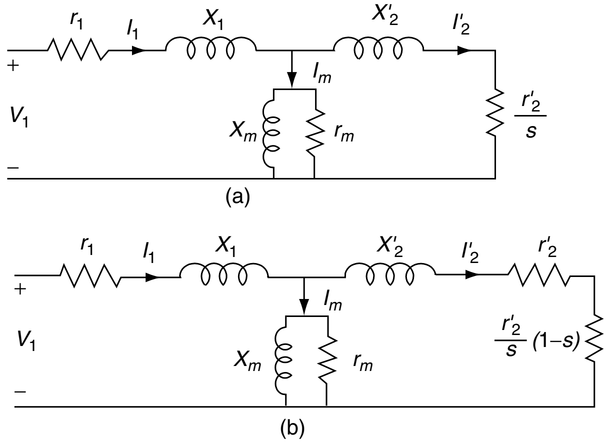

FIGURE 4.17 Phase-Equivalent Circuit of Polyphase Induction Motor

the stator winding leakage reactance per phase, X_m the magnetizing reactance, r_m the equivalent core resistance representing eddy and hysteresis losses, X'_2 the rotor reactance referred to the stator, and r'_2 the rotor resistance referred to the stator.

To understand the rotor circuit, consider the concept of slip. The application of a balanced three-phase supply to a three-phase winding produces a rotating flux distribution at synchronous frequency ω_s. The rotor of the induction machine will be rotating at frequency ω_m. The slip s can be defined as:

$$s = \frac{\omega_s - \omega_m}{\omega_s}. \tag{4.44}$$

Equation 4.44 shows that if the rotor is moving at synchronous speed, the slip is zero. If the rotor is stationary, the slip is one. Since the stator produces a rotating field at ω_s, an observer on the rotor sees a time-varying magnetic field at frequency $s\omega_s$. Applying Faraday's law to the rotor winding, the EMF is multiplied by the slip for a given mutual flux. The secondary parameters are then r_2 and sX_2. The rotor reactance per phase has been corrected by s due to the frequency change. Call the effective turns ratio between the rotor and the stator n. Using this value, first reflect the rotor quantities to the stator. Having done this, we connect the rotor and stator as is done in a normal transformer equivalent circuit if it were not for the frequency difference. The rotor current is then:

$$I_r = \frac{sE_2}{r'_2 + jsX'_2}. \tag{4.45}$$

To connect the two circuits together, divide the voltage sE_2 by the slip. To keep the current correct, also divide the denominator by s to give:

$$\frac{r'_2}{s} + jX'_2. \tag{4.46}$$

The reactance appears to be at stator frequency, while the resistance is divided by the slip. The two circuits may now be connected together. The rotor quantities have been reflected to the stator by both the turns ratio and the frequency. All current and voltage is at applied (stator) frequency. Now drop the primed notation and assume all quantities are referred to the stator. The significance of dividing the rotor resistance by the slip can be seen by considering an alternative form of the circuit shown in Figure 4.17(B). The real power crossing the air gap is:

$$P_g = I_2^2 \frac{r_2}{s}. \tag{4.47}$$

The heat dissipated in the rotor circuit is the following:

$$P_L = I_2^2 r_2, \tag{4.48}$$

where the power is in the first rotor resistance. The remaining power is as follows:

$$P_m = I_2^2 r_2 \frac{1-s}{s}, \tag{4.49}$$

which is the mechanical power delivered to the rotor. The output torque per phase is then:

$$T = \frac{P_m}{\omega_m}. \tag{4.50}$$

4.3.2 Torque–Speed Calculations

We obtain an expression for the output torque and power from the equivalent circuit by applying Thévenin's theorem.

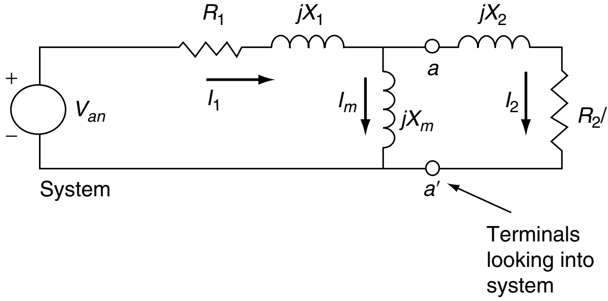

FIGURE 4.18 Induction Motor and System

Considering the circuit of Figure 4.18, we look back into the system from terminals $a - a'$ and find that the source voltage becomes the voltage at these terminals when the rotor is open circuited:

$$V_{th} = V_1 \frac{jX_m}{R_1 + j(X_1 + X_m)}. \tag{4.51}$$

The **Thévenin impedance** is the impedance seen from $a - a'$ with the voltage source shorted. This is the parallel combination of jX_m and $r_1 + jX_1$:

$$r_{th} + jx_{th} = \frac{(R_1 + jX_1)jX_m}{R_1 + j(X_1 + X_m)}. \tag{4.52}$$

Equation 4.52 gives a simple series circuit for the induction machine. The torque is now found as:

$$T = \frac{1}{\omega_s} \frac{3V_{th}^2(r_2/s)}{\left(r_{th} + \frac{r_2}{s}\right)^2 + (x_{th} + X_2)^2}. \tag{4.53}$$

For a constant voltage, the familiar torque versus slip characteristic is obtained and shown in Figure 4.19.

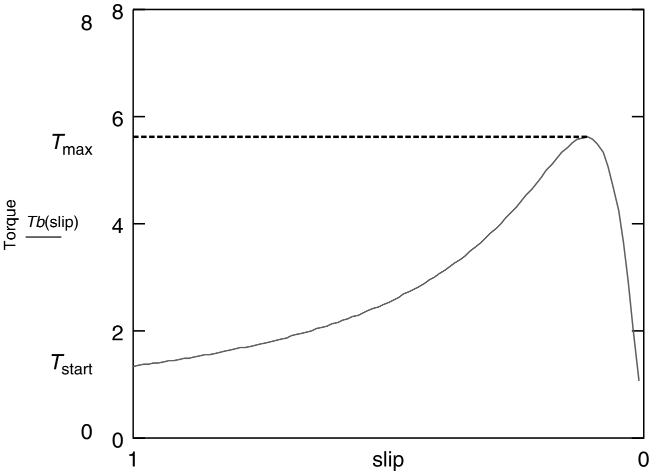

FIGURE 4.19 Torque Versus Slip

It is useful to have an expression for the maximum torque (pull-out torque) and the slip at which it occurs. This can be obtained from equation 4.53 by first differentiating with respect to the slip and setting the result to zero. This gives the slip at maximum torque as:

$$S_{\max} = \frac{r_2}{\sqrt{r_{th}^2 + (x_{th} + X_2)^2}}. \tag{4.54}$$

Substituting equation 4.54 into equation 4.53 yields:

$$T_m = \frac{1}{\omega_s} \frac{1.5V_{th}^2}{r_{th} + \sqrt{r_{th}^2 + (x_{th} + X_2)^2}}. \tag{4.55}$$

These expressions tell us that the slip at maximum torque is proportional to the rotor resistance but that the pull-out torque is independent of the rotor resistance. Figure 4.20 shows the torque slip curves for an induction motor with different values of rotor resistance. As the rotor resistance increases, the starting torque increases, but the running speed decreases and the losses increase. The increase of starting torque is obtained at the expense of lower running efficiency.

4.3.3 Performance Calculation Method

Given the equivalent circuit values, calculate the machine steady state performance at a fixed speed as follows:

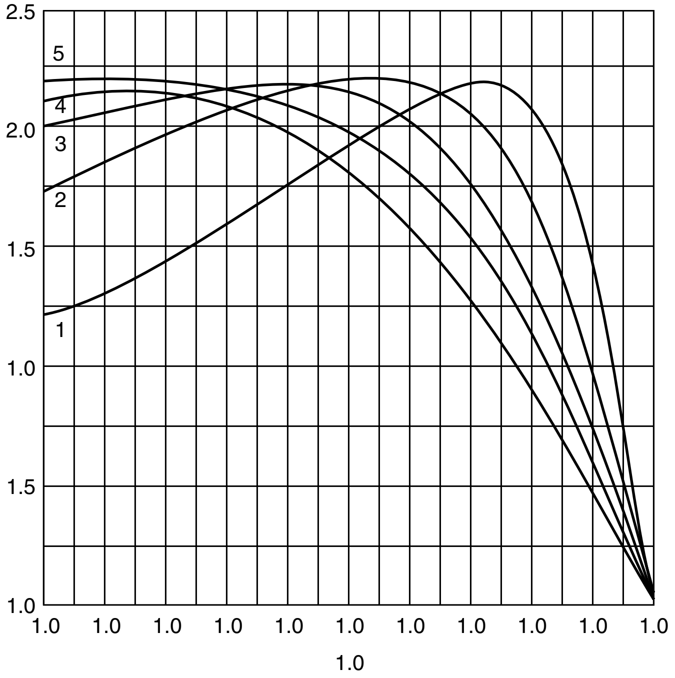

FIGURE 4.20 Torque–Slip Curves at Different r_2

1. Find synchronous speed as:

$$\omega_s = \frac{4\pi f_0}{P}. \tag{4.56}$$

2. Find the slip as:

$$s = \frac{\omega_s - \omega_m}{\omega_s}. \tag{4.57}$$

3. Find the rotor impedance as:

$$Z_2 = \frac{r_2}{s} + jX_2. \tag{4.58}$$

4. Find the equivalent secondary impedance as:

$$Z_{eq} = R_{eq} + jX_{eq} = jX_m \frac{r_2/s + jX_2}{r_2/s + j(X_2 + X_m)}. \tag{4.59}$$

5. Find the total impedance per phase as:

$$Z_{\text{in}} = r_1 + R_{eq} + j(X_1 + X_{eq}). \tag{4.60}$$

6. Find the phase current as:

$$I_1 = \frac{V_1}{Z_{\text{in}}}. \tag{4.61}$$

7. Find the power factor of the phase current as the cosine of the angle of the current.
8. Find the total input power as:

$$P_{\text{in}} = 3V_1 I_1 \cos\theta. \tag{4.62}$$

9. Find the stator copper loss as:

$$P_{scl} = 3I_1^2 r_1. \tag{4.63}$$

10. Find the air-gap power as:

$$P_g = 3I_1^2 R_{eq}. \tag{4.64}$$

11. Find the rotor copper loss as:

$$P_{rcl} = sP_g. \tag{4.65}$$

12. Find the developed mechanical power as:

$$P_{\text{mech dev}} = (1 - s)P_g. \tag{4.66}$$

13. Find the output torque as:

$$T = \frac{P_g}{\omega_s}. \tag{4.67}$$

14. Find the output power as:

$$P_{\text{out}} = P_{\text{mech dev}} - P_{\text{rot}}, \tag{4.68}$$

where P_{rot} are the rotational losses (windage and friction).

15. Find the output torque as:

$$T = \frac{P_{\text{out}}}{\omega}. \tag{4.69}$$

16. Find the efficiency as:

$$\eta = \frac{P_{\text{out}}}{P_{\text{in}}}. \tag{4.70}$$

4.3.4 NEMA Motor Types

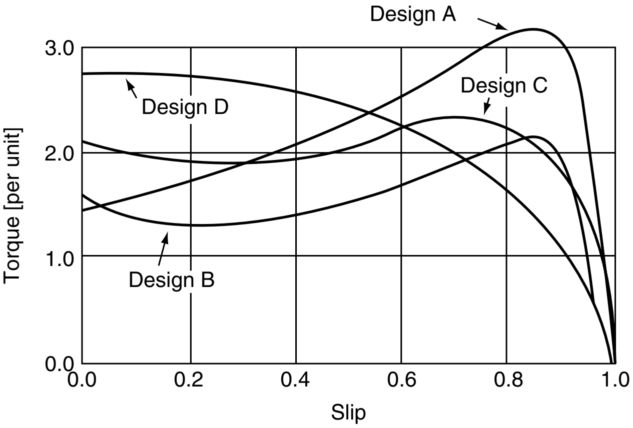

FIGURE 4.21 Typical Torque Speed Curves for NEMA Motors

NEMA, the National Electrical Manufacturers' Association, has developed standard design classifications for motors with particular speed–torque characteristics. Classes A through D are common squirrel cage designs. Typical torque–slip curves are shown in Figure 4.21. The motor designs differ mainly in the design of the rotor bars. As explained, by increasing the rotor resistance, the starting torque is increased and the slip at pull-out is reduced. By changing the rotor reactance, the starting current can be regulated. Class A machines have rotors with large bar cross sections, which give large starting currents, high efficiency, and relatively low starting torque. A class D motor, on the other hand, will have a smaller bar cross section and, therefore, has high starting torque, lower efficiency, and lower starting current.

4.3.5 Motor Tests

There are two basic tests used to obtain machine parameters. These are the **no-load test** and the **locked rotor test**. In the no-load test, the motor is run at rated voltage with no mechanical load attached. In this case, the slip is approximately zero, and very little current circulates on the rotor. There is a small amount of mechanical power required, enough to overcome friction and windage losses. Assuming that the rotor current is negligible, then, referring to the equivalent circuit, the stator current circulates in the mutual branch representing the excitation current. The stator resistance is measured independently with a bridge. The stator voltage, current, and power are measured. Since the stator resistance is known, the stator winding losses, $3I_1^2 r_s$, can be subtracted from the input power. The remaining losses are associated with the core loss and mechanical losses. The total reactance $X_{NL} = X_1 + X_m$ is now found as follows:

$$Z_{NL} = \frac{V_1}{I_1}. \tag{4.71}$$

$$R_{NL} = \frac{P_{NL}}{3I_{NL}}. \tag{4.72}$$

$$X_{NL} = \sqrt{Z_1^2 - R_{NL}^2}. \tag{4.73}$$

The second test is the locked (or blocked) rotor test. In this case, a balanced three-phase voltage is applied to the stator while the rotor is constrained so as not to turn. This test is done at low voltage to keep the torque low and reduce the losses. Because the voltage is low, the core flux density is reduced, and the core loss is also very low. At zero speed, the input voltage, current, and power are measured. The stator winding losses are subtracted as for the previous no-load test. There is no mechanical power and little core loss. The series reactances are much smaller than the magnetizing reactance, and it can be assumed the magnetizing current is negligible. Then, the impedance is found as $Z_{LR} = \frac{V_1}{I_1}$. After subtracting the stator losses from the measured power, the rotor resistance is found as:

$$r_2 = \frac{P_{LR} - P_{scl}}{3I_1^2}. \tag{4.74}$$

The series reactance is then found as:

$$X_{LR} = X_1 + X_2 = \sqrt{Z_{LR}^2 - (r_1 + r_2)^2}. \tag{4.75}$$

The total reactance is then divided into a stator and a rotor part by using the following empirical distributions. If the total reactance is X_{LR}, then for class A motors, $X_1 = X_2 = 0.5X_{LR}$. For class B motors, $X_1 = 0.4X_{LR}$ and $X_2 = 0.6X_{LR}$. For class C motors, $X_1 = 0.3X_{LR}$ and $X_2 = 0.7X_{LR}$. For class D motors, $X_1 = X_2 = 0.5X_{LR}$. For wound rotor machines, $X_1 = X_2 = 0.5X_{LR}$. Using these values of leakage reactance, the magnetizing reactance is found as:

$$X_m = X_{NL} - X_1. \tag{4.76}$$

4.4 Synchronous Machines

Essentially all of the world's electric power is generated by **synchronous machines**, the device in the power system where mechanical energy is converted into electrical energy. Further, much of the power system control is done via the synchronous machine. Synchronous motors have their applications as well, especially when constant speed operation is important. In terms of energy conversion, though, the synchronous machine is far more important as a generator, and this section describes the generating aspect of synchronous machines.

In its most common configuration, the synchronous machine stator has a three-phase winding in a laminated core. In this sense, the stator is the same as the stator in the three-phase induction motor. The rotor of the synchronous machine has a dc winding (the field) or permanent magnets. In steady-state, the rotor is moving at synchronous speed so an observer on the rotor will see a constant field. For this reason, the rotor may or may not be laminated. For high-speed machines, the rotor is often made of a solid steel forging in which slots are machined to hold the field winding. These are called round rotor machines. For lower speed machines, the rotors are usually built from laminations. A salient pole is constructed, and the field winding places around the pole.

4.4.1 Three-Phase Round Rotor Generator

A simplified analysis of a round rotor generator illustrates the important points of synchronous machine operation (see Figure 4.22). The machine consists of a balanced three-phase stator winding and a dc rotor winding. Assuming a steady-state balanced operation, it is not necessary to consider the effect of damper windings. The rotor to stator mutual inductances are a function of the rotor angle. With a round rotor machine, the stator to stator mutual inductances and the stator self-inductances are constant:

$$\begin{aligned} L_{af} &= L_{afm}\cos(\theta). \\ L_{bf} &= L_{afm}\cos\left(\theta - \frac{2\pi}{3}\right). \\ L_{cf} &= L_{afm}\cos\left(\theta - \frac{4\pi}{3}\right). \end{aligned} \tag{4.77}$$

The flux linkages of the windings are as follows:

$$\begin{aligned} \psi_a &= L_{aa}i_a - L_{ab}(i_b + i_c) + L_{af}i_f. \\ \psi_b &= L_{aa}i_b - L_{ab}(i_c + i_a) + L_{bf}i_f. \\ \psi_c &= L_{aa}i_c - L_{ab}(i_a + i_b) + L_{cf}i_f. \\ \psi_f &= L_{ff}i_f + L_{af}i_a + L_{bf}i_b + L_{cf}i_c. \end{aligned} \tag{4.78}$$

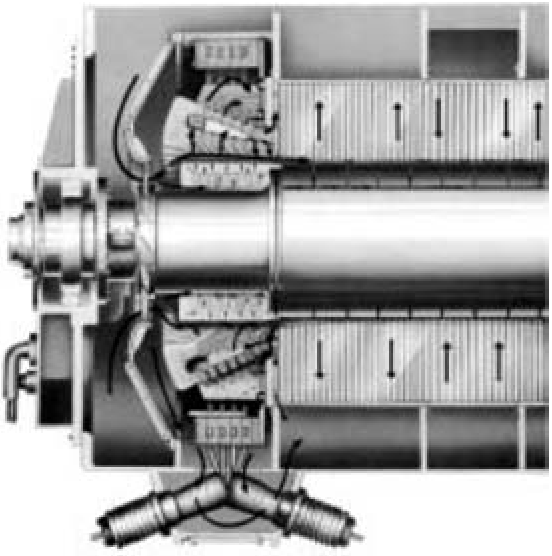

FIGURE 4.22 Round Rotor Synchronous Machine

Substituting the values of rotor to stator mutual inductances yields the following equations:

$$\psi_a = L_{aa}i_a - L_{ab}(i_b + i_c) + L_{afm}i_f \cos(\theta).$$
$$\psi_b = L_{aa}i_b - L_{ab}(i_c + i_a) + L_{afm}i_f \cos(\theta - \frac{2\pi}{3}).$$
$$\psi_c = L_{aa}i_c - L_{ab}(i_a + i_b) + L_{afm}i_f \cos(\theta - \frac{4\pi}{3}).$$
$$\psi_f = L_{ff}i_f + L_{afm}(i_a \cos(\theta) + i_b \cos(\theta - \frac{2\pi}{3}) + i_c \cos(\theta - \frac{4\pi}{3})). \tag{4.79}$$

The terminal voltages are written as:

$$\begin{aligned} e_{an} &= -R_a i_a - \frac{d\psi_a}{dt}. \\ e_{bn} &= -R_a i_b - \frac{d\psi_b}{dt}. \\ e_{cn} &= -R_a i_c - \frac{d\psi_c}{dt}. \\ e_f &= R_f i_f + \frac{d\psi_f}{dt}. \end{aligned} \tag{4.80}$$

For steady-state operation, the rotor velocity is constant as:

$$\theta = \omega t + \theta_0, \tag{4.81}$$

and the currents are balanced:

$$i_a + i_b + i_c = 0. \tag{4.82}$$

Using these, yields the following:

$$e_{an} = \sqrt{2}E_i \sin(\omega t + \theta_0) - R_a i_a - (L_{aa} + L_{ab})\frac{di_a}{dt}.$$
$$e_{bn} = \sqrt{2}E_i \sin(\omega t + \theta_0 - \frac{2\pi}{3}) - R_a i_b - (L_{aa} + L_{ab})\frac{di_b}{dt}.$$
$$e_{cn} = \sqrt{2}E_i \sin(\omega t + \theta_0 - \frac{4\pi}{3}) - R_a i_c - (L_{aa} + L_{ab})\frac{di_c}{dt}. \tag{4.83}$$

In these equations, E_i, the internal voltage, is the component of voltage induced by the field current.

The Phasor Diagram

In phasor form, the voltage equation can be written as:

$$E_{an} = E_i - (R_a + j\omega(L_{aa} + L_{ab}))I_a. \tag{4.84}$$

The synchronous reactance can be defined as:

$$X_s = \omega(L_{aa} + L_{ab}). \tag{4.85}$$

Hence, the result is as written here:

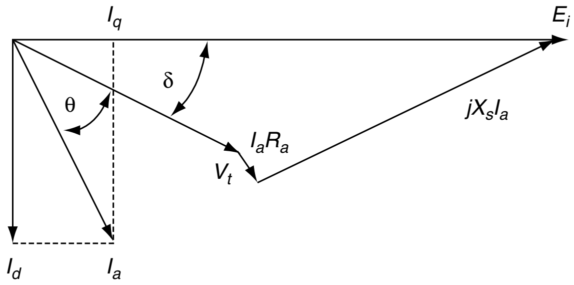

FIGURE 4.23 Phasor Diagram

$$E_{an} = E_i - (R_a + jX_s)I_a. \tag{4.86}$$

The phasor diagram is illustrated in Figure 4.23.

V Curve and Capability Curve

Two standard curves that describe the performance and operating limits of the synchronous machine are the ***V* curve** and the **reactive capability curve**. The *V* curve is a plot of the armature current versus the field current at constant real power. Considering the voltage to be fixed at rated conditions or 1.0 per unit, then the family of currents whose projection onto the voltage vector is the same all produce the same real power. The power factor is varying and the minimum current occurs at a unity power factor. In the phasor diagram in Figure 4.23, the field current is high in the overexcited (generator lagging power factor) condition and low in the underexcited (generator leading power factor) cases. Plotting the armature current versus the field current in a small range around unity power factor, which is the normal operating range of the machine, the curve is *V* shaped. A typical curve is shown in Figure 4.24 for different values of real power.

The reactive capability curve is used to indicate the safe thermal operating range of the synchronous machine. The machine is assumed to be operating at rated voltage. First consider stator heating, and operate at the maximum allowable stator current (1.0 per unit). The power generated is then:

$$VI^* = P + jQ. \tag{4.87}$$

Squaring both sides yields:

$$(VI)^2 = P^2 + Q^2. \tag{4.88}$$

Equation 4.88 represents a circle on the *P*, *Q* plane. If the voltage is constant, then the radius is proportional to the stator current. Power can be safely generated operating anywhere in the semicircle centered on the origin.

Supplying more reactive power to the system causes the rotor current to increase. Eventually, a heating limit of the rotor is reached. This condition can be analyzed by considering the locus of operating points having constant field current and

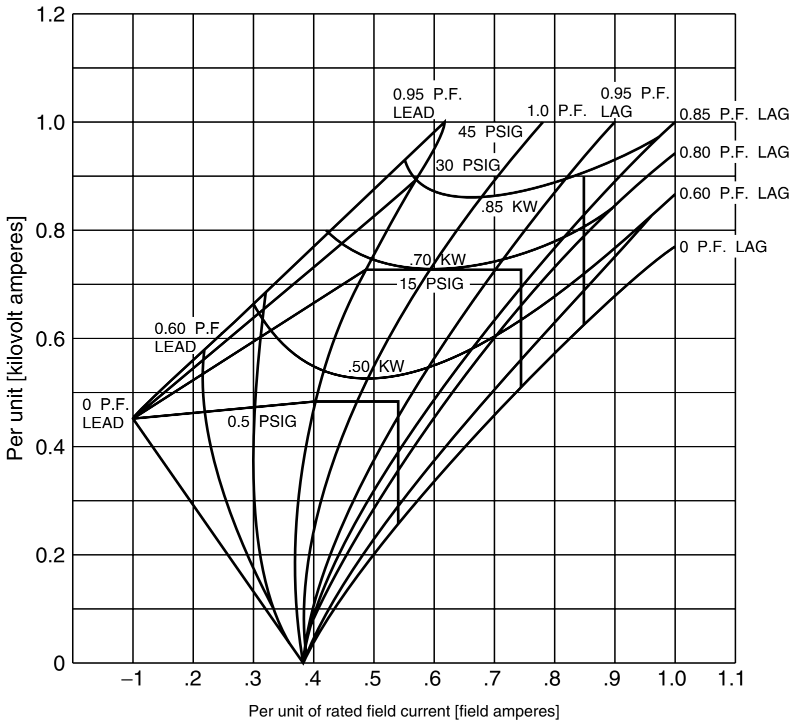

FIGURE 4.24 *V* Curve for a Turbine Generator

therefore constant internal voltage, E_i. The internal voltage transmits power to the terminals through an impedance X_s. The angle between these voltages is δ. Then:

$$P + jQ = VI^* = V\angle 0\left(\frac{E_i\angle\delta - V\angle 0}{jX_s}\right)^* \tag{4.89}$$

$$= V\angle 0\,\frac{(E_i\cos\delta - V\angle 0 + jE_i\sin\delta)^*}{jX_s}$$

$$= \frac{VE_i\sin\delta}{X_s} + j\frac{VE_i\cos\angle\delta - V^2}{X_s}. \tag{4.90}$$

Rearranging these equations results in:

$$P^2 + \left(Q + \frac{V^2}{X_S}\right)^2 = \left(\frac{VE_i}{X_s}\right)^2 = K. \tag{4.91}$$

The locus of constant field current is also a circle whose center is displaced on the negative Q axis by V^2/X_s and whose radius is VE_i/X_s. The region of safe operation of the rotor is inside this second circle. This rotor limit circle intersects the stator limit circle so that the operator must cut back power when moving to more lagging power factor to protect the rotor.

There is another limitation placed on operation. When moving to the leading power factor, the rotor and stator fields are reinforcing each other at the end of the core. Therefore the operation is limited in the leading power factor regime to keep the end of the stator core from overheating. The capability curve in this region does not represent a locus of maximum loss but is an approximation derived from temperature measurements on generators under test. The complete capability curve is shown in Figure 4.25.

4.4.2 Machine Tests

There are two standard tests that are performed on synchronous machines to determine their steady state parameters and verify the design. These are the **open circuit saturation test** and the **steady-state short circuit test** (also known as the synchronous impedance test). In the open circuit test, the machine is run at rated speed with the stator winding open circuited. The field current is varied, and the terminal voltage is plotted as a function of the field current. A typical test is shown in Figure 4.26.

As the field current rises the stator voltage increases proportionally. For most machines at about 80% of rated voltage, the curve becomes nonlinear, showing the effects of magnetic saturation. If the straight line characteristic is continued, the so-called **air-gap line** results, which is shown dotted in the figure.

In the short circuit test, the rotor is turned at rated speed with a three-phase short circuit on the stator. As before, increasing the field current allows the plotting of the stator current versus the field current. A typical short circuit characteristic is also shown in Figure 4.26. The short circuit characteristic is linear. The flux density in the machine is

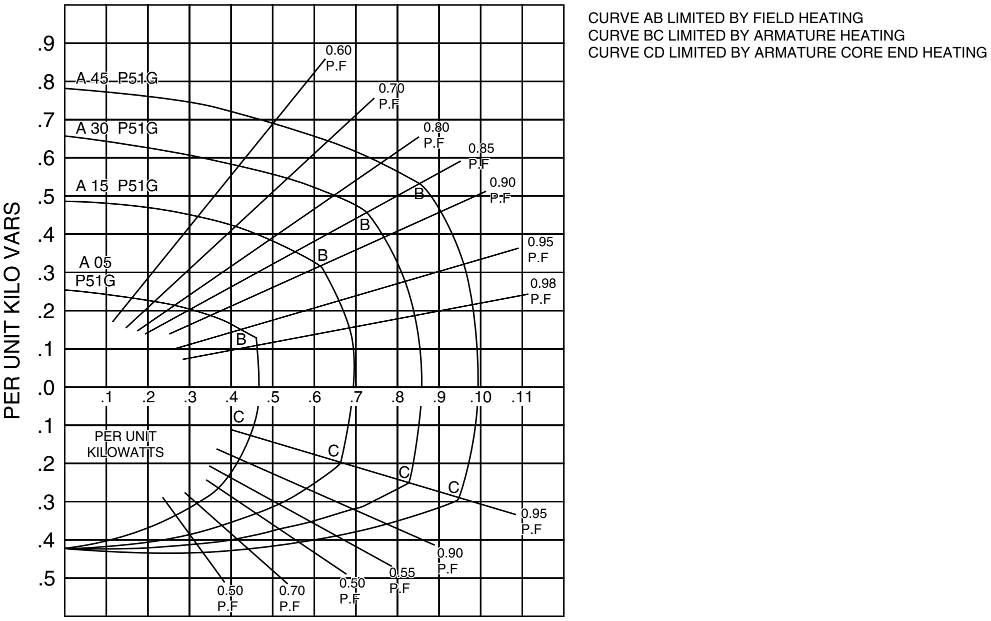

FIGURE 4.25 Reactive Capability Curve

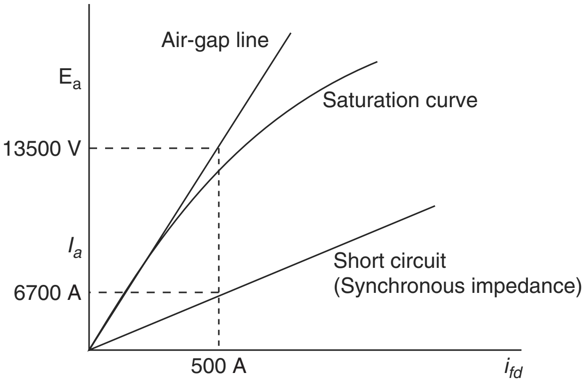

FIGURE 4.26 Open Circuit Test

very low since the terminal voltage is zero. The air-gap flux is sufficient to produce a voltage to overcome the leakage reactance drop.

From these two curves, the synchronous reactance can be found. For the open circuit condition, the terminal voltage is equal to the internal voltage E_i.

For the same field current, take the stator current from the short circuit test and find X_s as $X_s = E_i/I_a$. Referring to the figure, the synchronous reactance is $X_s = 13{,}500/6{,}700 = 2.01\ \Omega$.

4.5 Single-Phase Induction Machines

The electrical supply to most residences and many businesses is single phase, and, therefore, most appliances use **single-phase motors**. A single-phase winding produces a standing wave, which may be resolved into a forward and a backward rotating wave. These waves each produce a torque versus slip curve as shown in Figure 4.27. The net torque is the sum of the forward and backward components. As indicated by the figure, there is no starting torque. If we can manage, however, to start the motor (in either direction), it will continue to accelerate in that direction. In single-phase induction motors, a starting torque can be produced by using two stator windings situated 90° electrical distance apart. The power factor of these windings is different, producing a phase shift between the two currents and therefore a traveling wave. Once the motor begins to turn, one of the windings may be disconnected.

4.5.1 Split-Phase Motors

The **split-phase motor** has a main winding and an auxiliary winding that are situated 90° apart. The auxiliary winding has smaller wire and fewer turns than the main winding. When

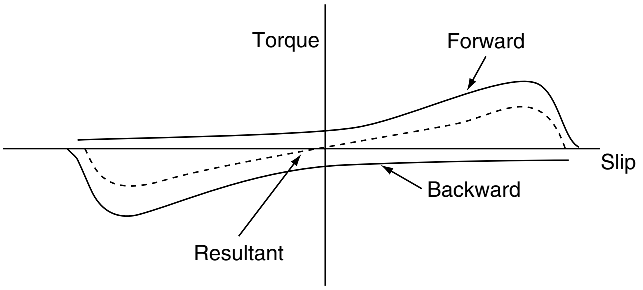

FIGURE 4.27 Single-Phase Induction Motor Torque Characteristic

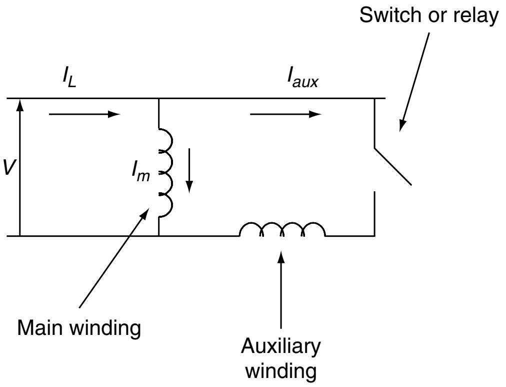

FIGURE 4.28 Split-Phase Motor

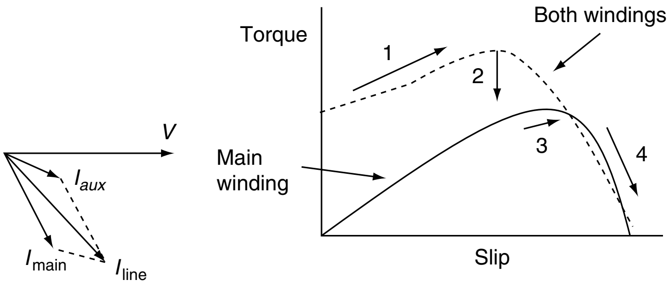

FIGURE 4.29 Split-Phase Motor Performance

connected in parallel, the current in the auxiliary winding leads the current in the main winding and produces a traveling wave. Once the motor comes up to speed, the auxiliary winding is switched out (Figure 4.28). Figure 4.29 shows the phasor diagram and torque speed curve. With both windings connected, the torque–slip characteristic follows path 1. When the auxiliary winding is disconnected, the characteristic moves via path 2 to the main winding curve and then along paths 3 and 4.

4.5.2 Capacitor Start Motor

In the capacitor start motor, a capacitor is used in the auxiliary winding to change the power factor to leading so that the auxiliary current can lead the main winding current by approximately 90°. The starting torque is higher and the starting current is lower than in the case of the split-phase motor.

4.5.3 Two-Value Capacitor and Permanent Capacitor Motors

The **two-value capacitor motor** is similar to the capacitor start motor, but the auxiliary winding is designed for continuous operation. The impedance of the auxiliary winding depends on the slip, so a smaller capacitor is needed for optimal running performance. Suitable values for starting and running are achieved by using a short-time rated capacitor in parallel with the running capacitor. The short-time rated capacitor is removed when the motor comes up to speed. The configuration of the two-value capacitor motor is illustrated in Figure 4.30. Because of the running capacitor, this motor basically has a two-phase supply and, therefore, runs more efficiently and quietly.

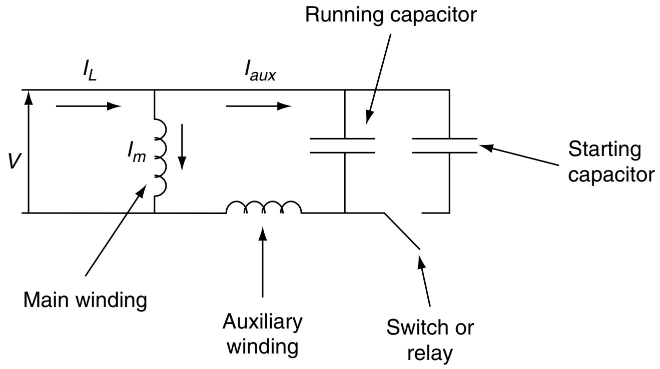

FIGURE 4.30 Two-Value Capacitor Motor

To avoid the extra expense of two capacitors and a switch, another type of motor, the **permanent capacitor motor**, uses a single capacitor in series with the auxiliary winding. This permanent split capacitor motor does not give optimum starting or running performance.

4.5.4 Shaded-Pole Motor

The shaded-pole induction motor does not use an auxiliary winding. Rather, there is a shorted turn or turns on part of the stator pole. The portion of the flux crossing the air gap through this turn produces an eddy current reaction, which effectively delays the flux. This produces a traveling wave that enables the motor to start. The starting torque is not as great as in the capacitor motors, but these motors are very reliable and inexpensive. They are often used in appliances where efficiency and torque requirements are not great.

4.5.5 Universal Motors

The **universal motor** is configured like a series dc motor. In fact, the universal motor can be run from a dc or ac supply. If the motor is connected to an ac supply, the armature current and the field flux change direction at the same time, and the torque is always in the same direction. The universal motor typically has a laminated rotor and stator core due to the ac operation. These motors are useful for high-speed, low-torque operations.

High-Voltage Transmission

Ravi S. Gorur
Department of Electrical Engineering,
Arizona State University,
Tempe, Arizona, USA

5.1 Introduction

Reliable and economical transport of power from generating stations to the load centers is accomplished by overhead lines operating at a high voltage. Transmission by underground cables is limited to special cases and for short spans as in water crossings and in metropolitan areas. Currently in the United States, there exists more than 200,000 miles of overhead transmission lines and about 3500 miles of underground transmission cables. Voltage in excess of 69 kV is considered **transmission**, and voltage below 69 kV is considered **distribution**.

The conductor current for a given Kilovoltampere [kVA] rating is inversely proportional to the voltage used; hence the higher the voltage, lower is the current and even lower is the power losses (I^2R) occurring during the transmission process. In the United States, the highest transmission voltage used is 765 kV; in Canada, it is 735 kV; in Western Europe, it is 400 kV; and in Japan, a 1000-kV line has been recently built. In most countries, the transmission voltage varies between 220 and 500 kV.

It is interesting to note that even though extensive research on higher voltages such as 1500 kV was performed in the 1970s in the United States, Canada, and Russia, there are no commercial lines operating at such voltages simply because of the exorbitant cost of equipment required. The electric stress occurring on the insulation varies nonlinearly with the voltage; hence, design requirements at such high voltages are not a simple extrapolation of the values used at lower voltages.

The demand for energy use is largely driven by increased urbanization. It is estimated that for a 2-fold increase in the energy use (usually expressed in terms of GWH or TWH), the transmission line capacity will increased by about 50%. This manifests either as an upgrade in the voltage or as new line construction.

The use of energy has increased slightly for industrialized countries but significantly for developing countries in the last 10 to 15 years. This is shown in Table 5.1. It can therefore be expected that the bulk of new activity, with respect to new transmission line construction, will be in the developing countries.

TABLE 5.1 Expected Increase in Energy for Various Regions of the World

Geographic region	Expected increase in energy use by 2010	Comments
North America	7.5%	Lower in Canada and Mexico, compared to USA
Western Europe	13%	
Industrialized Pacific	8%	Japan, Australia, New Zealand
Eastern Europe and former Soviet Union	10%	Difficult to get reliable information
China	40%	
India	25%	
Other parts of developing Asia	21.5%	S. Korea, Thailand, Taiwan, Phillipines, Indonesia, Malaysia
Africa	20%	
Middle East	10%	
Central and South America	15.5%	Largest growth to come in Brazil and Argentina

TABLE 5.2 Major Transmission Projects (by 2010)

Country or region	Voltage and length	Comments
Vietnam	500 kV, 500 km	500 kV line of 2400 km by 2010, 1.5 billion/year USD investment needed
India	400 kV, 436 km 220 kV, 600 km	
Brazil	500 kV, 2800 km	A 25 billion (USD) total investment anticipated
Southern Africa	400 kV, 400 km	Operated by ESKOM
Northern Africa	400 kV, Few thousand km (not clear)	Mediterranean Power Grid to be completed by 2015
China	220 kV, 6600 km (and above)	Some dc lines also created
Nigeria	330 kV, 144 km	Estimated as a $40 million USD project
Philippines	Build 24 new lines, rebuild 13 existing lines 110–230 kV (length not known but probably a few thousand kilometers)	Estimated as a $165 million USD project
North America	About 230 kV, 1000 km and 500 kV, 1000 km	A 500-kV line linking several states (in the planning stages)

From Table 5.1, it should be obvious that majority of transmission line construction should occur in China, India, and Brazil, followed by Africa and the rest of South America.

A listing of new major construction projects planned in the next 5 years in several of these regions is shown in Table 5.2. Based on Table 5.2, a cumulative length of about 15,000 km of transmission lines is to be built by 2010.

5.2 Design Considerations for Overhead Lines

The most popular conductor type used for transmission lines is the aluminum conductor steel reinforced (ACSR). Other conductor types such as all aluminum conductor (AAC), and all aluminum alloy conductor (AAAC) are also used and offer advantages such as higher operating temperature and low weight.

It is desirable to increase current carrying capacity of a conductor without increasing its weight (and hence sag). This has been possible by the substitution of the steel core of the conductor with composite materials, such as carbon fibers and fiberglass. There are claims that this permits a 2- to 3-fold increase in the electrical power transmitted. This increase is even more impressive when considering that it can be achieved without changing the towers. But it remains to be seen at what cost. Obviously, the new composite conductors are more expensive than the conventional conductors.

The conductor size is determined by the current. The electric field on the conductor's surface and at any other point in space is determined by the voltage. For overhead lines, clearances to ground are determined both by the voltage and current. Heating produced by resistive heating of the conductor causes it to sag between the support structures. The electric field on the surface of the conductor is inversely proportional to the conductor diameter.

For transmission lines below 230 kV, conductor size is determined by thermal heat dissipation of the conductor, whereas for lines operating at voltages greater than 230 kV, the conductor size is determined primarily by electric field considerations. Higher conductor diameters are required to keep the electric field on the surface of the conductor below the inception values that trigger corona. This is most effectively achieved by the use of bundled conductors. It is desirable to keep the maximum surface electric stress below 15 kV/cm under dry conditions.

A **corona** is the phenomenon of air breakdown when the electric stress at the surface of a conductor exceeds a certain value. At higher values, the stress results in luminous discharge. Corona produces undesirable effects like radio and television interference, ozone, audible noise, and power loss. The use of grading rings on dead-end towers is a common practice to reduce corona. When nonceramic insulators are used, the use of corona rings at the terminals of the insulators is a common practice for voltages above 230 kV. These along with ceramic or glass insulators are normally not used.

If the conductor diameter is inadequate to prevent corona, the remedial measures to fix the situation, although available, are very expensive. These include increasing the number of conductors per phase, applying special surface treatment of conductors, and isolating line sections with filters. Therefore, it is important to ensure that the conductor details are chosen after a careful review.

The clearance to ground is determined by the induced electric field with a magnitude that reduces with distance from the conductor. The clearances of the line from the tower are dependent on overvoltage produced by lightning surges and switching events. Transmission lines at 230 kV and below are governed by lightning overvoltages, whereas for lines at 345 kV and above, overvoltage produced by switching surges is the determining factor.

The magnitude of lightning produced overvoltage is mainly dependent on the lightning stroke current and impedence of the object struck. For a stroke to a tower, the lightning strike creates a traveling wave that travels down the tower and is reflected at the footing and is reflected back. The sign of the reflected wave depends on the relative tower footing resistance. If the footing resistance is high, a voltage wave will be reflected, which will be about double. This could raise the tower voltage to a level that a flashover could occur across the insulator. This is referred to as **back flashover**.

It is important to keep the tower footing resistance as small as possible as the reflected wave then will have the opposite sign and will reduce the tower voltage. Tower footing resistance can be reduced by using driven rods and counterpoises.

The magnitude of switching overvoltage can be reduced by the use of circuit breakers with preinsertion resistors and surge arresters. It has been realized that the preinsertion resistors are maintenance intensive and actually can be dispensed when using metal–oxide surge arresters.

The appropriate clearances of the conductor to the tower and ground are achieved by proper selection of insulators. More details about the different insulator types and important aspects of insulators are provided below.

5.2.1 Types of Outdoor Insulators

An insulator is actually a system of components consisting of the dielectric, terminal electrodes or end-fittings, and internal parts that help attach the dielectric to the electrodes. There are many details involved in these components and constructional methods. However, insulators are recognized largely by the classification of the dielectric employed. There are three main classes of dielectrics that have been used for outdoor HV insulator construction: **porcelain, glass**, and **polymer**. Hence, the nomenclature of porcelain, glass and polymeric insulators is well-known. Polymeric insulators are also commonly known by other names, such as composite (in Europe) and nonceramic (in North America).

Porcelain and glass insulators have been used for more than 100 years. The widespread use of composite insulators began in North America during the 1970s. Figure 5.2 shows a schematic of these insulators for use on outdoor lines (Gorur *et al.*, 1999).

The most widely used type of porcelain and glass insulator, worldwide, is the **cap and pin insulator** where each unit or bell is connected to each other by metal hardware. The number of bells is dependent on the voltage class. In Europe, the use of porcelain long-rod insulators, where intermediate metal electrodes are significantly reduced or eliminated, is equally popular. In comparison, composite insulators have a single piece of dielectric, which is the fiberglass rod that is covered by a polymer housing and is attached to the metal terminals.

The following dimensional details are relevant to insulators for transmission. Figure 5.1 shows an illustration of the important dimensions.

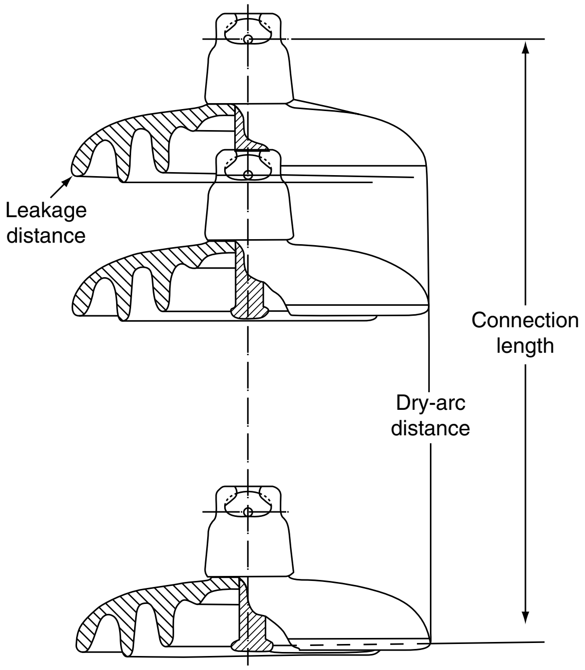

FIGURE 5.1 Illustration of Important Dimensions for Insulators

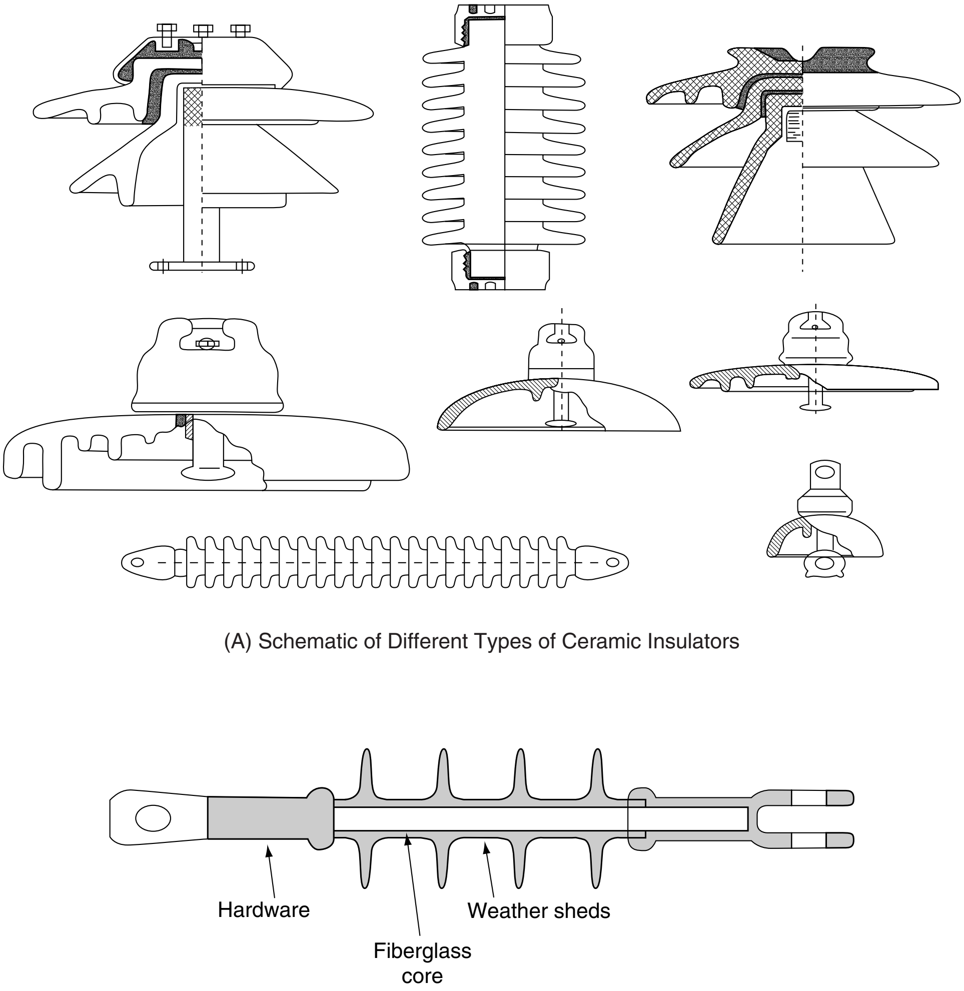
- **Dry-Arcing or strike distance**: The shortest distance through the surrounding medium between terminal electrodes, or the sum of the distances between intermediate electrodes, whichever is shorter
- **Connection length**: The shortest distance between the conductor and the support structure, including the strike distance plus the hardware dimensions
- **Leakage or creepage distance**: The sum of the shortest distances measured along the insulating surfaces between the conductive parts
- **Protected leakage or creepage distance:** Parts of the insulator surface that are not directly exposed to natural elements like sun and rain. (In porcelain and glass insulators, the ribs on the underside of the insulator contribute to the protected leakage distance.)

5.3 Stresses Encountered in Service

Outdoor insulators are subjected to a variety of stresses in service, such as mechanical, electrical, and environmental stresses. These stresses act in unison. The exact nature and magnitude of these stresses varies significantly and depends on the details of insulator design, application, and location. For example, suspension and dead-end insulators encounter a tensile load due to the weight and tension of the conductor. Wind and ice impose additional loading. Insulators used for a supporting station apparatus encounter a compressive mechanical load. Line-post insulators are subjected to a cantilever or bending load in supporting the conductor. These loads are to be expected under steady-state conditions. In additional, transient loading conditions can be generated. A torsional or a



(A) Schematic of Different Types of Ceramic Insulators

(B) Schematic of Nonceramic Insulator

FIGURE 5.2 Schematic Diagram of Insulators for Outdoor Lines

twisting type of load can be experienced by line insulators during line construction. Vibrational loads are imposed on insulators due to conductor vibration and movement. Shock (or impact) loading is also possible during natural events like earthquakes, ice-shedding, or man-made events, like vehicular impact on poles and vandalism (gun shots).

Electrical stresses include those imposed by power frequency nominal operating voltage, which is a steady-state stress. Voltage surges generated by lightning or switching operations impose a higher albeit momentary stress on the insulator. In the event of an insulator flashover, the insulator is subjected to a large fault current (several kiloamperes) at power frequency in the form of an arc, called **power arc**, until the protection isolates the fault.

Outdoor environmental conditions vary over a wide range. Temperature impacts the insulation properties of all materials as the conductivity increases with temperature. For polymers that are organic materials, ultraviolet (UV) radiation from sunlight can break certain chemical bonds and cause cross-linking on the surface, resulting in surface degradation. Moisture in any form (e.g., rain, dew, fog, melting ice and snow) lowers the surface insulation resistance significantly from the dry state. In the presence of contamination, the surface resistance is reduced even more drastically. Altitude or the elevation above sea level affects the insulation properties. Higher altitudes reduce the air density, hence, weakening the surface insulation strength.

All of these stresses could be acting on the insulators in various combinations. Hence, it is clear that the insulators have to perform under a wide range of service conditions. Needless to say, only insulators that are designed while suitably considering all these stresses will work satisfactorily in the field for many years.

5.4 Insulator Performance

5.4.1 Electrical Performance

Dielectric material is largely responsible for the electrical performance of an insulator. It is important to distinguish between bulk or volume properties and surface properties. The volume dielectric strength is determined by defects in the form of impurities and voids in the system. The presence of these defects serves to provide sites for electrical stress concentration, which could lead to the formation of a permanent failure path in the system. Failures along the bulk of the material, normally called **punctures**, are permanent in nature. The surface dielectric strength is determined largely by surface deposits and moisture. Resistivity values, which are indicative of the dielectric strength, are typically greater than $10^{10}\,\Omega$ per square for the bulk material (Looms, 1988). Under dry conditions, such high surface resistance is also obtained. In the presence of humidity, however, surface resistance values are lowered by several orders of magnitude and are even further lowered in the presence of ionic contaminants on the surface.

For dielectric materials that do not contain large voids or impurities, which is typical of a well-made insulator, the electric stress required for failure via the surrounding air medium is much lower than for bulk failure. Such failures are called **flashovers**. The arc produced by the flashover is usually away from the surface of the dielectric. Therefore, as far as flashovers are concerned, porcelain, glass, and composite insulators **are self-restoring types of insulation**.

Whether an insulator fails by surface flashover or a puncture depends on the magnitude and duration of the electric stress applied, insulator dimensions, and defects in the material. Breakdown requires the formation of an ionized channel, and this channel has to be established within the duration of the applied voltage. If the insulator is defective, (i.e., has large voids or impurities), puncture can be caused by extremely short duration and large magnitude pulses. Lightning surges, which have a rise time in the microsecond range, do not cause puncture if the insulator is sound. Similarly, switching surges normally do not cause puncture. Both lightning and switching surges can cause flashover if they have adequate magnitude, even under dry conditions. Longer duration stresses, such as those imposed by power frequency, do not result in a puncture. A flashover is, however, possible in a wet and contaminated environment at the nominal operating voltage, as illustrated in Figure 5.3.

5.4.2 Mechanical Performance

The mechanical performance of outdoor insulators is determined by all the main components of the insulator, namely, dielectric and end-fittings, as well as the details of internal attachment of the dielectric with the end-fittings. Failure of the insulator to perform mechanically results in dropping of the conductors. This type of insulator failure is not acceptable as it leads to a prolonged interruption of power, possible personnel injury and equipment damage.

5.4.3 Role of Insulators on Power System Reliability

Power system apparatuses are subjected to faults from both man-made and natural causes. In a system that uses many types of apparatus with costs that vary widely, it is important that expensive apparatuses are protected from faults, even if it is at the expense of a cheaper device. Outdoor insulators, especially the line insulators, are one of the least expensive devices in the power system. Therefore, it is understandable that to protect a more expensive apparatus, such as a transformer or circuit breaker in a station, a line insulator must fail first under *overvoltages*. When an insulator fails, it is required that the failure mode is a flashover rather than a puncture.

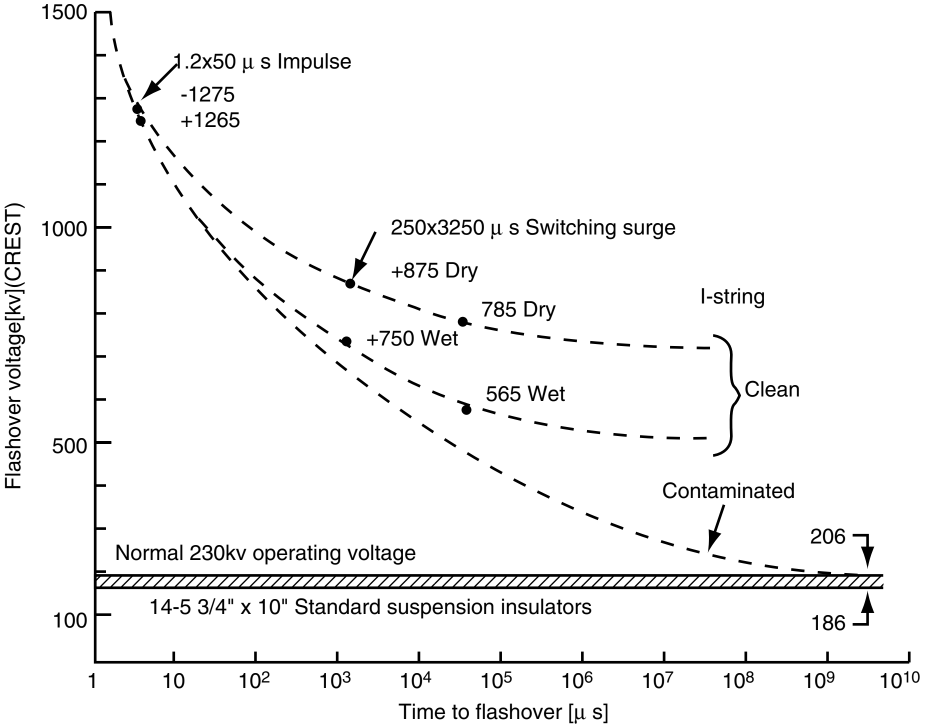


FIGURE 5.3 Illustration of Reduction in Flashover Voltage with Increasing Duration of Voltage Application. Note that the contaminated conditions represent the most onerous conditions for outdoor insulator operation.

Voltage surges produced by lightning and/or switching operations are a major factor to be considered in the electrical design of the insulator. Insulators should be designed so that they do not fail at surge voltage magnitudes that are lower than the value for which the power system apparatus has been designed. For higher magnitude surges, the insulator should be a flashover. The determining values of these surges are defined by the **basic lightning impulse insulation level** (BIL) and **basic switching impulse insulation level** (BSL).

Insulator design for voltage 230 kV and below is largely dependent on lightning-produced surges, whereas for 345 kV and above, the design is dependent on switching surges. However, regardless of the voltage class, in locations where contamination is a serious problem, insulator design is determined by the required contamination performance.

Flashovers usually cause momentary interruption of power flow in the circuit. Interruption may cause customer interruption depending on the system configuration. Such interruptions, although a nuisance, can be tolerated in rural locations. In urban areas with high-tech industries that use semiconductors and in pharmaceutical and automotive fields even temporary interruptions are not acceptable because they lead to huge financial losses from lost production, jammed machinery, and loss of process control.

Therefore, today's power system reliability is to a large measure linked with the avoidance of insulator failure.

Flashover due to surges is determined by the shortest spacing in air between the electrodes of an insulator, called the **dry-arcing distance**. Moisture has little effect on the flashover voltage due to lightning surges. The flashover voltage under surges is dependent on the dry-arcing distance. The flashover under contaminated conditions, however, is dependent on the **leakage** or **creepage distance**.

If the dielectric material is not altered during service, electrical characteristics like power frequency wet withstand or flashover, lightning and switching surges are defined by dry arcing distance. The shape or profile of the dielectric, which determines the leakage distance, is important for the contamination performance.

To increase the leakage distance and to help maintain certain parts of the insulator dry, it is common to see corrugations on the underside of porcelain and glass cap and pin insulators. The required dry-arcing and leakage distance is obtained by stacking several units, the number being dependent on the voltage level, contamination severity, and the profile of the insulator. Many shapes of porcelain and glass insulators have been developed, as shown in Figure 5.2.

For composite insulators, because there are no intermediate electrodes, the required leakage distance can be obtained with relatively simple shapes. The long-rod porcelain insulator, used commonly in Europe, also has a simple shape, with no corrugations or under-ribs.

5.4.4 Mechanical and Electrical Ratings of Insulators

Because insulators perform both mechanical and electrical functions, they are identified by a combined **mechanical and electrical** (M and E) **rating**. The M and E rating is defined as the mechanical load at which the insulator fails to perform its function either electrically or mechanically and when voltage and stress are applied simultaneously. It is normal to design the insulator such that the daily and the maximum loads experienced by the insulator are 20% and 50% of the M and E rating, respectively. International standards require that every suspension insulator unit is routinely test with a 50% (per ANSI) or 60% (per IEC) of the M- and E-rated load for 10 sec.

Composite insulators are rated by their **specified mechanical load**, which is defined as the tensile load specified by the manufacturer that has to be verified during a mechanical load test. International standards require that every suspension insulator unit is routinely tested with a 50% M- and E-rated load for 10 secs. The relationship between the M and E rating or SML rating of insulators, everyday load, maximum load, and routine test load that every insulator is subjected to is shown in Figure 5.4. It is clear that there is a comfortable safety factor in the mechanical rating of the insulator.

Comparison of Porcelain, Glass, and Composite Insulators

Porcelain and glass are inorganic materials, which historically are known to resist degradation from natural elements for many hundreds of years. They have melting points in excess of 1500°C. They are inert to most chemicals. Consequently, insulators made from porcelain and glass are known to possess extremely high resistance to heat from electrical discharge activity in the form of arcs or sparks, corona, and chemicals encountered during service. Their high stability is related to the strong electrostatic bonds between the various atoms in the material. This attribute also imparts a high value of **surface free energy**, a thermodynamic quantity that determines the strength of adhesion of the surface with water. In simple terms, porcelain and glass are easily rendered wettable by water. Hence, insulators made from these materials need to have sufficient leakage distance and complicated shapes to retain a sufficiently high surface resistance under wet and contaminated conditions.

FIGURE 5.4 Relationship of M and E/SML Ratings with Daily, Maximum, and Routine Test Loads

Porcelain and glass are also dense materials. Hence, insulators made from these materials are heavy. They possess a compressive strength that is at least an order of magnitude higher than the tensile strength. They are brittle materials, and such insulators need to be handled with great care to avoid breakages.

The housings or weathersheds of composite insulators are made by organic materials, mainly hydrocarbons. Organic materials, in comparison with inorganic porcelain and glass, have weaker electrostatic bonds that can be broken more easily. Therefore, composite insulators are more easily prone to deterioration by heat from electrical discharge activity, chemicals (including water), and natural elements like sunlight, humidity, and temperature. Hence, composite insulators can undergo a reduction in the electrical and mechanical properties with time, and these changes are irreversible.

Aging is the term used to describe irreversible permanent changes. All materials undergo aging at different rates. Because organic materials are more susceptible to changes from the environment and applied stress, it is more common to talk of aging with composite insulators than it is with porcelain and glass insulators. However, it should be mentioned that even porcelain and glass insulators are subjected to aging.

When chemical bonds in hydrocarbons are broken, free carbon is generated, which is conducted even in the dry state. This is obviously not desirable. The formation of a carbonaceous conducting path on the surface of composite materials is called **tracking.** Materials can be formulated such that the carbon is physically dislodged from the surface or removed in the form of gaseous products. Such modes of carbon removal will lead to a loss of material, which is termed **erosion**. Erosion is a much slower mode of degradation than tracking. Hence, the resistance to tracking and erosion of materials is an extremely important aspect of composite insulators.

Owing to the weak nature of the electrostatic bonds, organic materials have a much lower surface free energy; hence, they are not easily wetted by water. In fact, on new composite insulators, water usually forms small individual beads instead of a continuous film. This property of water repellency is called hydrophobicity. This resistance to water wetting is desirable because it increases the surface resistance of the insulator under wet and contaminated conditions.

Composite insulators are much lighter in weight than equivalent porcelain and glass insulators. Also, the materials are nonbrittle. Therefore, composite insulators are much easier to handle and install as well as more resistant to breakages from handling and acts of vandalism.

5.4.5 Methods to Improve Performance Under Contaminated Conditions

Making insulating systems work satisfactorily under contaminated or polluted conditions is critical for maintaining high reliability of power delivery. This has been accomplished by a combination of design and a variety of periodic maintenance procedures, retrofits, and product innovation. It is worthwhile to note that while many situations in service can and have been dealt with satisfactorily by relatively simple means, others need a more in-depth analysis and require research and development.

Even a momentary loss of power can cause huge losses to industrial productivity. Losses incurred depend on the type of customer affected and the socioeconomic conditions. For example, in the United States, a 0.25 sec interruption to a paper plant can result in a loss of revenue in excess of $100,000, and this figure does not include legal liabilities. Insulators used on overhead lines and in stations are responsible for a significant part of factors that cause power outages. Hence, such interruptions, especially if originating from man-made causes, should be eliminated.

Contamination-related failures of traditional porcelain and glass insulators usually manifest as flashovers, a self-restoring failure mode. This is true provided the quality of insulators is good, which means that there will be no internal failure. Flashovers mostly result in short-term interruptions in power delivery. For nonceramic/composite insulators, failure could be in the form of a flashover and/or degradation of the insulator, in which case the insulator has to be replaced, leading to a prolonged outage.

Contamination Flashover Process

The processes that lead to flashover under contaminated conditions have been extensively researched and documented. A simplified model, originally developed around 1930, is shown in Figure 5.5 and is adequate to explain the process. Leakage current that is promoted on a wet surface in the combined presence of moisture and contamination initiates surface discharges, often called **dry band arcing**. The existence of a highly nonlinear distribution of the applied voltage along the insulator and the insulator shape that has surface areas with widely differing diameters, contribute significantly to the initiation of surface discharges. Normally, these discharges are self-limiting and localized to the narrow parts of the insulator. But, under conditions usually associated with increased contamination (or a decreased resistance in series with the arc), the discharges elongate and can bridge the air gap between the electrodes causing a flashover.

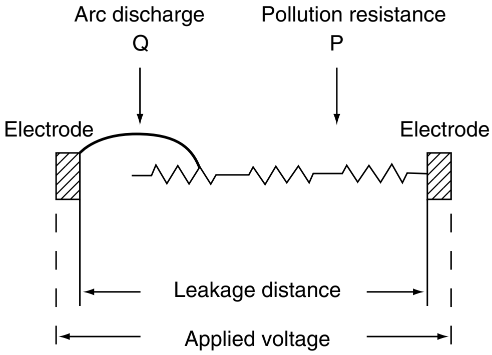

FIGURE 5.5 Simplified Schematic for Modeling Contaminated Insulators

TABLE 5.3 Principle of Improving Contamination Performance and Methods Used

Method	Principle
Additional insulators or longer leakage distance insulators	Increase leakage/creepage distance
Complicated shapes	Protect part of insulator from getting wet
Creepage extenders	Increase leakage distance
Cleaning	Reduce contamination buildup
Semiconducting or resistance glazed (RG) insulators	Improve voltage distribution and maintain dry surface due to heating produced by leakage current
High-voltage insulator coatings (HVIC), such as greases and RTV silicone rubbers	Maintain hydrophobic surface
Nonceramic insulators	Maintain hydrophobic surface and smaller diameter sheds

Making insulators work under contamination usually revolves around increasing the surface resistance in series with the arc (P in Figure 5.5). Linearizing the voltage distribution is also an effective method for improving the contamination performance. The different techniques and the underlying principle that helps achieve improvement in contamination performance are listed in Table 5.3.

5.5 Established Methods Employed for Installations In-Service

5.5.1 Insulator Cleaning

A frequent occurrence involves the contamination severity changing significantly in a region after the station or a section of the line has been built. Construction of new roads or industrial sites cannot always be predicted at the design stage. Under such situations, insulator cleaning is a method commonly used by utilities. Insulator cleaning is covered by the IEEE Standard 957. **High-pressure water washing** is routinely employed and is effective for most types of contamination. However, there are certain types of contaminants (e.g., cement, greasy deposits, certain fertilizers) that adhere intimately with the insulator surface and cannot be easily removed easily by high-pressure water. In such cases, cleaning is performed by using dry-type abrasive agents, such as crushed corncob mixed with limestone. Water washing can be done online (without de-energizing the circuit) or off-line (after de-energization).

The major limitation with this method is that it is labor intensive and expensive (more so when using dry-type cleaning agents). In addition, there is no reliable method other than past service experience to determine when, and if, insulator cleaning is necessary. Caution should be exercised in cleaning nonceramic insulators because not all designs and materials can be washed at high-pressure with water.

Grease Coatings

Another technique employed by utilities for servicing existing porcelain insulators is the application of **high-voltage insulator coatings**. Grease coatings have been used for many years. Greases used fall into two main categories: **hydrocarbon greases** (or petroleum jellies) and **silicone greases**. Petroleum jellies are cheaper than silicone greases, which explain their popularity. But they are not as stable as silicone greases at both extremes of operating temperature. In addition, silicone greases offer superior resistance to tracking than petroleum jellies. IEEE Standard 957 also addresses grease coatings for insulators. This practice is used mainly for station insulation. Most greasing applications are done off-line, although online application is possible.

The big disadvantage of grease coatings is the short time interval (typically less than 1 to 2 years) between subsequent applications to prevent any contamination-related outages. During this time, the grease becomes saturated with dirt and loses its water repellency. Removal of spent grease is labor intensive, involving the use of dry cleaning agents and followed by water washing. Failure to remove the spent grease can lead to heavy surface arcing that can cause the porcelain insulator to crack. In addition, in some countries like the United States, disposal of spent grease is becoming increasingly difficult due to environmental issues

5.6 Newer Developments to Improve Performance of Installations In-Service

5.6.1 Silicone Rubber Coatings

Room temperature vulcanized (RTV) **coatings** were developed with the intention of making a high-voltage insulator coating that would be effective for a much longer time than grease coatings. These coatings consist of a polydimethylsiloxane (PDMS) polymer, an alumina trihydrate (ATH) or alternate filler for increased tracking and erosion resistance, a catalyst, and a cross-linking agent. Coating formulations may also contain a condensation catalyst, adhesion promoter, reinforcing filler, and pigments (for color). The coating systems are dispersed in an organic solvent. Naphtha and 1-1-1 trichloroethane are the solvents commonly used. The solvent merely acts as a carrier medium to transfer the RTV coating to the ceramic insulator surface and serves the same purpose as a thinner for paints. As the solvent evaporates from the surface, moisture from the air triggers vulcanization, forming a solid rubber coating. The speed at which this takes place depends on the type of solvent, cure system chemistry, and relative humidity. Recommended coating thickness is about 0.5 mm (20 ml).

RTV coatings can be applied online (energized application) or off-line (after de-energizing the circuit). Coatings that use a combustible solvent like naphtha, however, are not suitable for energized applications.

RTV coatings offer superior contamination performance by virtue of their inherent hydrophobicity. The hydrophobic surface breaks up the water into discrete droplets, resulting in suppression of leakage current even in the presence of contamination. This is illustrated in Figure 5.6.

Under conditions of long-term corona or dry-band discharge activity promoted by wetting and contamination deposition, the RTV-coated insulator surface can lose its hydrophobicity in those areas subjected to the discharges. The hydrophobic loss is usually temporary, and the surface will recover its hydrophobicity if the surface is dry for a few hours. This is due to the dynamic nature of the silicone polymer that allows polymer chains to migrate and reorient

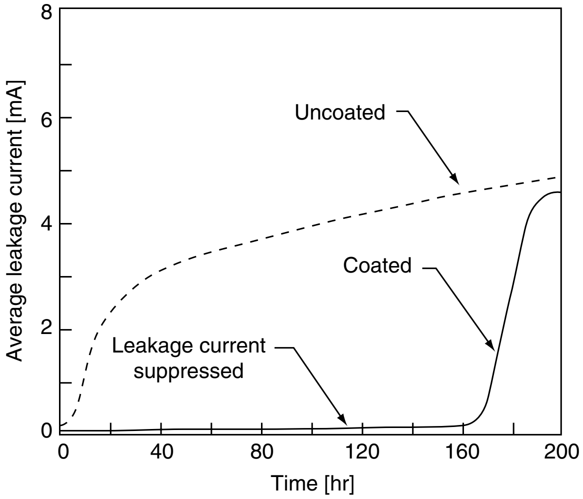

FIGURE 5.6 Leakage Current Suppression Capability of Uncoated and RTV-Coated Porcelain Insulator. The results were obtained in the laboratory using a salt-fog test.

themselves to the surface in the least surface energy configuration (Gorur *et al.*, 1999).

Details of application of coatings to ceramic insulators are partially covered in the IEEE Standard 957. Important aspects are insulator cleaning, coating preparation, and details of equipment to be used for application of the coating. The interested reader is referred to the documents listed in the reference section. Proper adhesion of the coating to the ceramic surface is critical for successful operation of the coated insulators.

5.6.2 Creepage Extenders

Retrofitting existing insulators with attachments called **creepage extenders** has been adopted successfully. Figure 5.7 shows a photograph of a field installation in a transmission line.

Presently, creepage attachments are made from an ethylene vinyl acetate (EVA) polymer compound and are formulated for properties desirable for outdoor insulation. These devices increase the leakage distance, prevent cascading of rain, and can also maintain a certain part of the insulator surface dry by the umbrella effect. They could also be effective in reducing bird excrement-related flashover problems. Reports from field experience suggest that they provide long-term improvement in contamination performance. Adhesion of the creepage extender to the porcelain surface is critical for satisfactory performance. Some creepage extenders require the use of a heat source (flame torch) to ensure good bonding with the ceramic insulator surface. Obviously, such systems should be installed off-line.

5.7 Methods for Improving Contamination Performance of New Installations

5.7.1 Additional Units and Longer Leakage Units

If the line or station is in the design stage, increasing **leakage distance** by adding additional bells or using longer leakage distance bells (such as the fog-type insulator) in a string is a practice followed routinely by users for both line and station insulation and is quite successful. It is common to see insulators normally rated for the next higher voltage to be used for lower voltage-rated systems in areas with contamination problems. This practice works well for most cases, except in those with severe contamination. In such regions, this method has only reduced the frequency of outages but not eliminated it, thus calling for additional measures such as water washing to prevent contamination-related power interruptions.

5.7.2 Resistive (or Semiconducting) Glazed Porcelain Insulators

The use of **resistive** or **semiconducting glazed** porcelain insulators, in place of normal porcelain insulators for contaminated locations (RG) is a well-known practice that was first tried more than 50 years ago. The semiconducting glaze offers a lower resistance than the normal insulating glaze and promotes a steady current (less than 1 mA) at the nominal operating voltage. This current ensures a more linear voltage distribution, and the resulting I^2R heating keeps the surface warm, ensuring that large areas of the insulator are dry. This combination of factors significantly reduces dry-band discharges and improves the contamination performance. The ability to curtail discharges in the presence of wet contamination is shown schematically in Figure 5.8.

RG insulators have demonstrated their success for station- and line-post applications. However, for cap and pin suspension insulators, judging from previous service experience, their record has not been as good. One problem for line insulators is the corrosion of the glaze near the pin where the current density is the highest, which ultimately causes a discontinuity or "opening" of the glaze in that region. Once the glaze has been opened, the effectiveness of the glaze is lost as surface discharges can develop in areas similar to those for a regular glazed porcelain insulator. Another problem experienced with RG cap and pin suspension insulators is related to the expan-

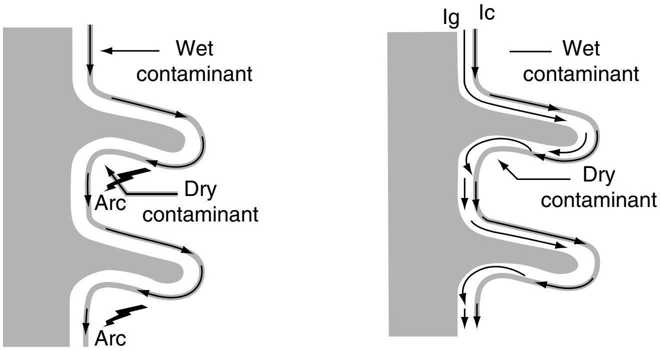

FIGURE 5.8 Schematic of Discharge Formation on Conventional Glazed Porcelain and Suppression with the Use of RG Porcelain

sion of the cement in the pin area that ultimately shatters the porcelain dielectric in the event of a flashover. These problems, however, are not insurmountable, and RG cap and pin insulators are available presently. New products have hopefully addressed the issues experienced by earlier products.

5.7.3 Nonceramic and Composite Insulators

The use of **nonceramic and composite insulators** in place of traditional porcelain and glass insulators for line insulation has become widespread in the last 20 years. Such insulators have several advantages over porcelain and glass insulators, such as lighter weight, easier handling, better resistance to damage from vandals, lower cost (in some countries), and superior contamination performance. Different material families have been used for the exposed part of the insulator (hereafter called the housing). High temperature vulcanized (HTV) silicone rubber, ethylene propylene rubber (EPR), cycloaliphatic epoxy, and EVA are among the materials proven suitable for outdoor use, with the first two varieties dominating for transmission voltages.

A nonceramic and composite insulator's performance under polluted conditions merits careful consideration. For porcelain or glass insulators, flashover resulting in a temporary outage is the end result of a contamination event. This does not usually cause any major permanent damage to the insulator string although burning of the glaze and/or fragmentation of the bells in contact with the power-follow fault current can occur. There is little risk of the insulator failing mechanically. It is also unlikely that the inorganic dielectric is degraded due to surface discharge activity, which could be long-lasting.

For nonceramic insulators, there is actually less risk than with the porcelain or glass insulators from the flashover event itself due to the elastic nature of the material. But it is from the surface discharge activity that the exposed insulation can be subjected to degradation, and this can be a major concern. In addition, the organic nature of the insulating materials can make them vulnerable to degradation from natural elements, such as heat, UV from sunlight, moisture, and chemicals. A permanent reduction of their desirable properties under service conditions can occur with time, referred to as aging. It is also important to note that some degradation modes may actually occur even in clean conditions, such as from exposure to corona activity. In fact, mechanical failure of nonceramic insulators from a mode of failure called **brittle fracture** has been experienced in relatively benign outdoor conditions. Users should be aware of all these possibilities.

Despite these concerns, it should be said that judicious selection and application of nonceramic insulators has resulted in improved reliability and lower installation costs for both transmission and distribution lines. Progress at all fronts, namely research, development, testing, manufacturing, and usage, has made this possible.

Just from geometrical considerations alone, nonceramic insulators should offer superior performance under contaminated conditions when compared to their porcelain and glass counterparts due to their smaller diameter. Additional improvement in contamination performance can be obtained by using materials that are hydrophobic, hence suppressing leakage current and discharge activity; they can remain in this state for a long time in service. Silicone rubber is one type of material that fits into this category. Within a particular material family, the leakage current suppression capability is dependent on the formulation, but in general, silicone polymers have better leakage current suppression capability than other outdoor insulating materials.

The typical practice is to use a leakage distance similar to porcelain for silicone rubber insulators; and for nonceramic insulators employing materials other than silicone rubber, the leakage distance is about 20 to 30% higher than the distance for porcelain insulators.

5.8 Underground Transmission Cables

Power cable technology can be traced back to 1880, just shortly after the introduction of incandescent lighting. Prior to World War I, oil-impregnated paper cables were extensively used. These had a three-conductor belted core made of copper and were used up to 25 kV. Due to the nonuniform electric field distribution inside the cable, this method of cable construction was extremely prone to partial discharges. This problem was solved by shielding the individual conductors with thin copper tapes, and it was possible to raise the voltage to as high as 69 kV.

At higher voltages, partial discharges were found to occur in voids in the insulation. This problem was solved by the use of a low-viscosity oil-impregnated paper insulation system. Voltages as high as 132 kV could be reached. Present day self-contained oil-filled cables have not changed much from this design that was first introduced in 1917. Self-contained oil-filled cables are in operation in Canada and the United States at 230 kV, 315 kV, and 500 kV.

In North America, starting around 1932, the first installation of oil-filled pipe-type cables occurred. The pipe-type cables proved to be more economical, and by 1954, the total circuit mileage of installed pipe-type cable surpassed that of the self-contained oil-filled cable in the United States. The first 230-kV pipe-type cables were installed in 1956. With increasing loads, neither increasing cooling nor operating voltage can cope up with the increased dielectric losses in the oil-impregnated paper dielectric. Thus, for higher operating voltage, synthetic dielectrics, such as cross-linked polyethylene (XLPE) and paper-polypropylene laminates (PPL), were introduced and have inherently lower dielectric losses.

PPL has lower dielectric losses and significantly higher dielectric strength. However, the widely used material is cross-linked polyethylene (XLPE) due to a combination of cost and performance considerations.

Transmission cables use a hermetic seal over the core to protect it from water exposure. Extruded lead, extruded- or seam-welded aluminum, or seam-welded copper sheath provides both the hermetic barrier and path for short circuit currents. Due to the presence of a good seal, problems such as **water treeing** widely experienced with distribution XLPE cables has not been an issue with transmission cables. Presently, extruded XLPE cables are being designed for operation at 500 kV. The use of thermoplastic-type low-density polyethylene (LDPE) is widespread in France on 225 kV cables. These cables have been in service since 1969. In 1985, the voltage of the LDPE cables was extended to 400 kV and subsequently to 500 kV in 1995.

The operating temperature allowable for LDPE cables has increased to 200° C. Much of the work on power transmission cables has been done in Norway, Japan, Sweden, and the United States. Work done in the United States has resulted in improved cleanliness of the insulation and semiconducting shield interfaces, a more uniform distribution of the cross-linking agent, and reduced void formation by increasing the extrusion pressure and replacing the wet curing process by a dry curing process. In Japan, the present practice is to use XLPE cables that are being used at 275 kV and 500 kV.

Power Distribution

Turan Gönen
College of Engineering and Computer Science, California State University, Sacramento, Sacramento, California, USA

6.1 Distribution System

In a broad definition, the **distribution system** is the part of the electric utility system between the bulk power source and the consumers' service switches. It includes a subtransmission system; distribution substations; primary distribution feeders; distribution transformers; secondary circuits, including the services to the consumer (called **service drops**); and appropriate protective and control equipment. Some distribution engineers, however, define the distribution system as that part of the power system between the distribution substations and the consumers' service entrance. Figure 6.1 shows a one-line diagram of a typical distribution system.

6.1.1 Subtransmission

The **subtransmission system** is the part of the power system that delivers power from bulk-power sources, such as large transmission substations. The subtransmission may be composed of overhead open-wire construction on wood poles or underground cables. Although the voltages of these circuits can occasionally range from 12.47 to 345 kV, the majority are at 69-, 115-, and 138-kV voltage levels. There is a trend toward the use of the higher voltages as a result of increasing use of the higher transmission voltages. The subtransmission-system designs vary from simple radial-type and/or loop-type systems to a grid- or network-type subtransmission. In the radial system, the circuits radiate from the bulk-power stations to the distribution substations. The radial system is simple and has a low cost but it also has a low service continuity. In general, due to higher service reliability, the transmission system is designed as loop circuits or multiple circuits forming a subtransmission grid or network. In the loop-type subtransmission system, a single circuit originating from a bulk-power bus runs through a number of substations and returns to the same bus. The major considerations affecting the design are cost and reliability.

6.1.2 Substation

The distribution **substation** is an assemblage of equipment for the purpose of switching, regulating, and changing the level of supply voltage from subtransmission level to primary distribution level. A typical substation may have:

- Power transformers
- Circuit breakers
- Disconnecting switches
- Station busses and insulators
- Current-limiting reactors
- Shunt reactors
- Current transformers
- Potential transformers
- Capacitor voltage transformers

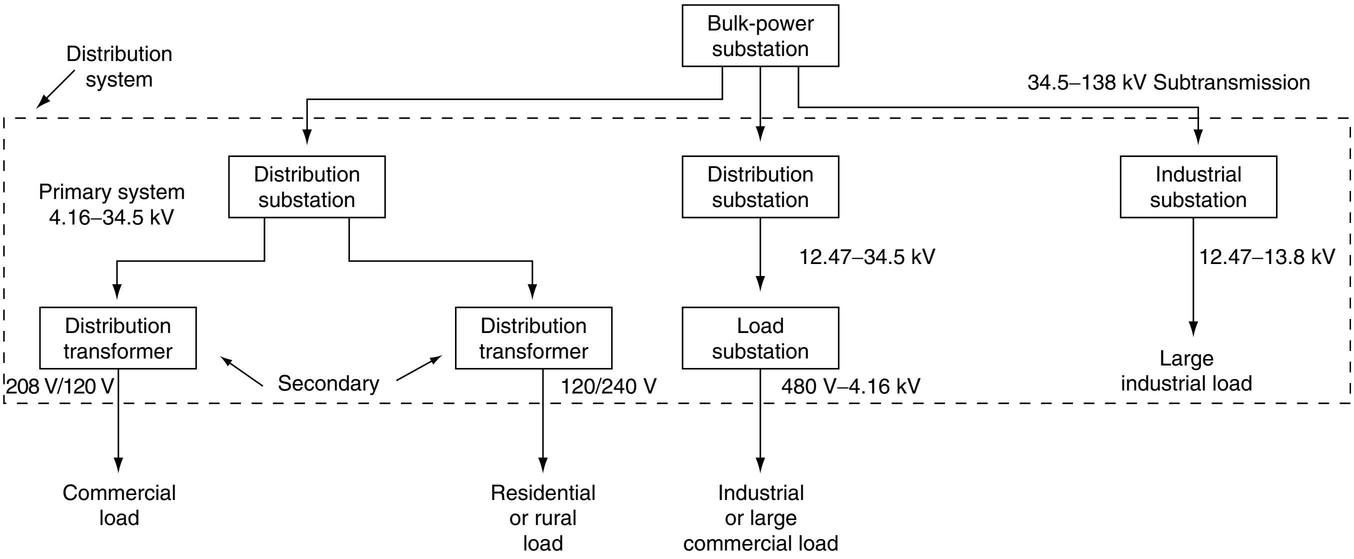

FIGURE 6.1 Overview of the Power Distribution System

- Coupling capacitors
- Series capacitors
- Shunt capacitors
- Grounding systems
- Lightning arresters and/or gaps
- Line traps
- Protective relays
- Station batteries
- Other equipment

More important substations are designed so that the failure of a piece of equipment in the substation or one of the subtransmission lines to the substation will not cause an interruption of power to the consumer. The location of a substation is dictated by the voltage levels, voltage regulation considerations, subtransmission costs, substation costs, and the primary feeders, mains, and distribution transformers. Location is also restricted by esthetic considerations.

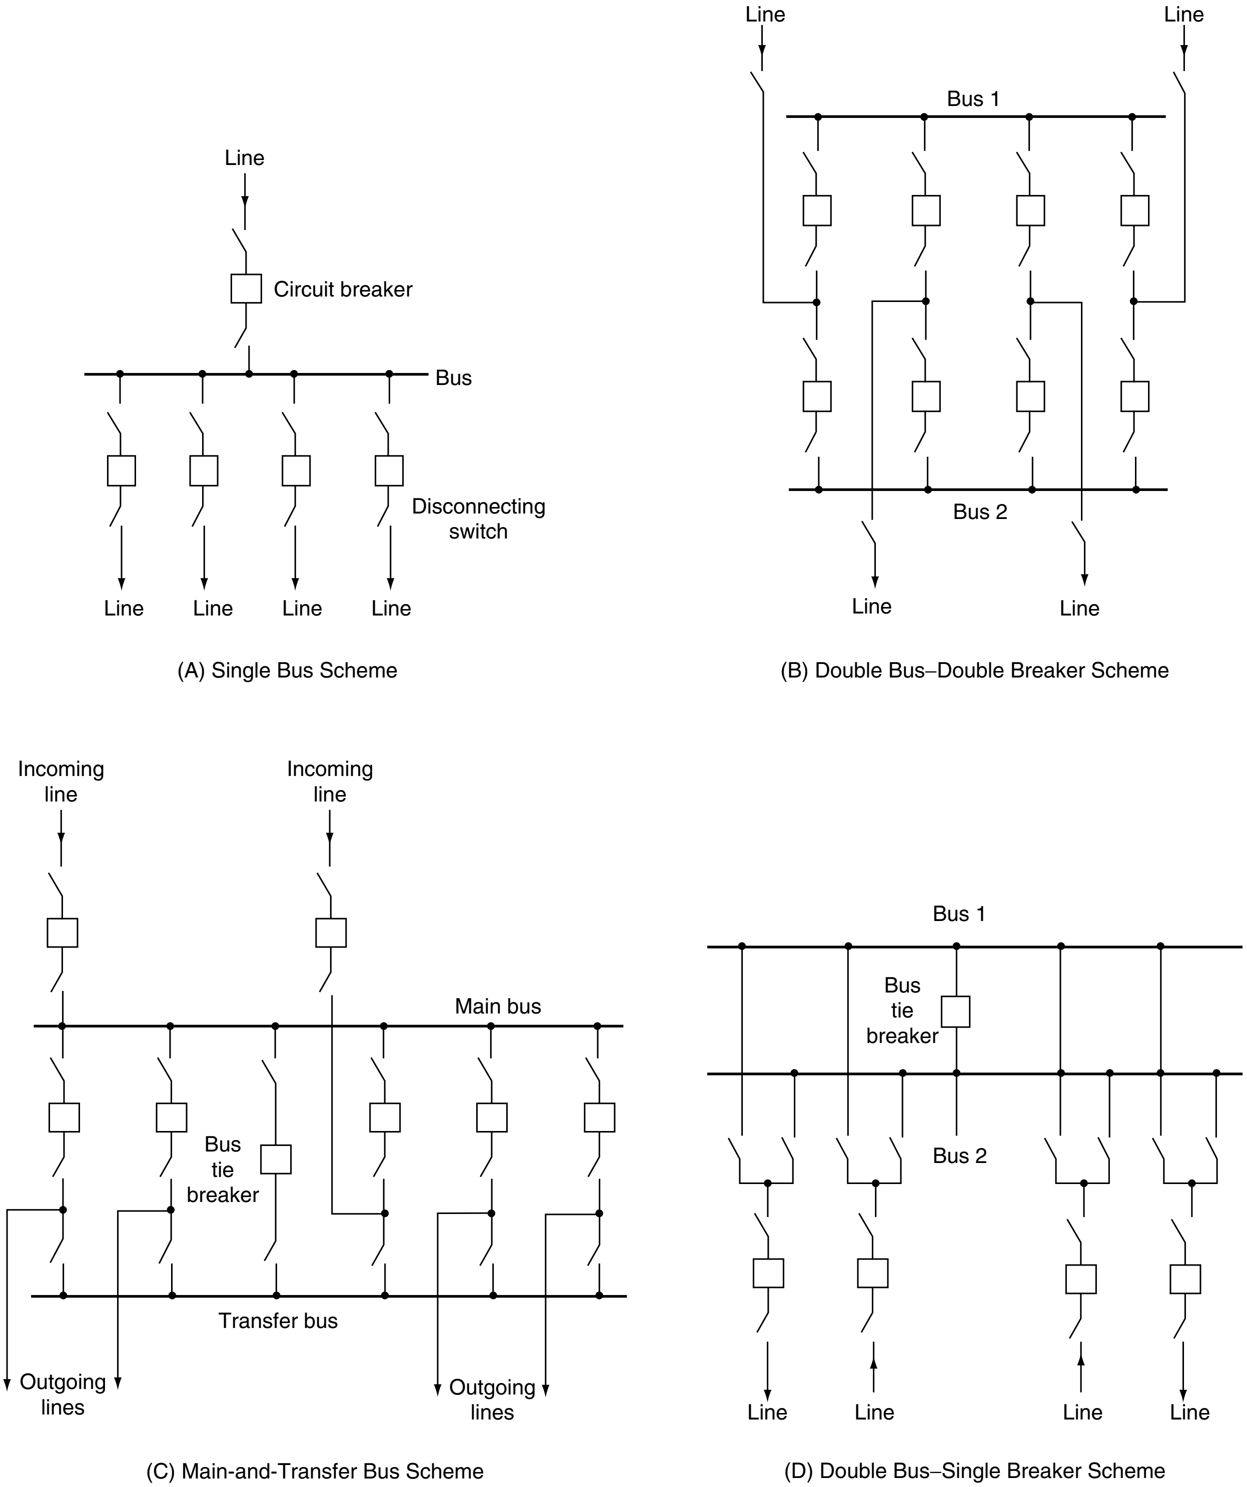
The electrical and physical arrangements of the switching and bussing at the subtransmission voltage level are determined by the selected substation scheme (or diagram). On the other hand, the selection of a particular substation scheme is based on safety, reliability, economy, simplicity, and other considerations. The most commonly used substation bus schemes include (1) single bus scheme, (2) double bus–double breaker (or double main) scheme, (3) main-and-transfer bus scheme, (4) double bus–single breaker scheme, (5) ring bus scheme, and (6) breaker-and-a-half scheme. Figure 6.2 shows various bus schemes.

Each scheme has some advantages and disadvantages depending on economical justification of a specific degree of reliability. For example, the advantage of the **single bus scheme** is its lowest cost; its disadvantages include (a) the shutdown of the entire substation because of the failure of bus or any circuit breaker, (b) the difficulty in performing any maintenance work, (c) its limited use where loads can be interrupted or have other supply arrangements, and (d) the inability to be extended without completely de-energizing the substation.

The advantages of the **double bus–double breaker scheme** include (a) two dedicated breakers in each circuit, (b) breakers that can be taken out of service for maintenance, (c) high reliability, and (d) flexibility in allowing feeder circuits to be connected to either bus. Its disadvantages include high cost and the loss of half the circuits for breaker failure if circuits are not connected to both busses.

The advantages of the **main-and-transfer scheme** include (a) its low initial and ultimate cost, (b) breakers that can be taken out of service for maintenance, and (c) potential devices that may be used on the main bus for relaying. Disadvantages include (a) its requirement of one extra breaker for the tie bus, (b) switching that is somewhat complicated when maintaining a breaker and (c) the failure of bus or any circuit breaker resulting in the shutdown of the entire substation.

The advantages of the **double bus–single breaker scheme** include (a) some flexibility with two operating busses, (b) the ability of either main bus to be isolated for maintenance and (c) transferring the circuit readily from one bus to the other by using bus-tie breaker and bus selector disconnect switches. Disadvantages include (a) one extra breaker required for the bus tie, (b) four switches required per circuit, (c) a bus protection scheme that may cause loss of substation when it operates if all circuits are connected to that bus, (d) high exposure to bus faults, (e) line breaker failure taking all circuits connected to that bus out of service, and (f) bus-tie breaker failure taking the entire substation out of service.



(A) Single Bus Scheme

(B) Double Bus–Double Breaker Scheme

(C) Main-and-Transfer Bus Scheme

(D) Double Bus–Single Breaker Scheme

FIGURE 6.2 Typical Substation Bus Schemes

The advantages of the **ring bus scheme** include (a) low initial and ultimate cost, (b) flexible operation for breaker maintenance, (c) the ability of any breaker to be removed for maintenance without interrupting the load, (d) the requirement of only one breaker per circuit, (e) its ability to run without using the main bus, (f) all circuits that are fed by two breakers, and (g) all switching that is performed with breakers. Disadvantages include (a) the ability of the ring to

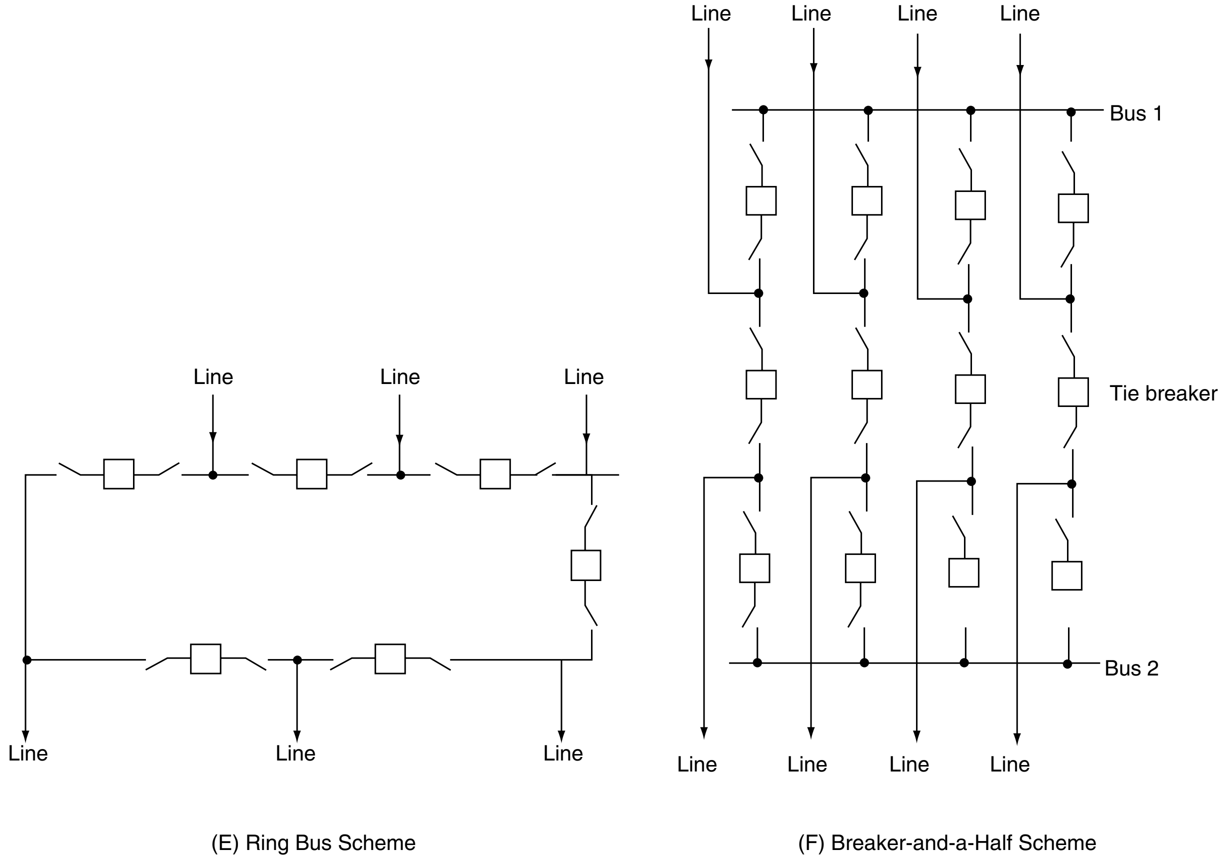


FIGURE 6.2 Typical Substation Bus Schemes (*continued*)

be separated into two sections if a fault occurs during a breaker maintenance period, (b) complex automatic reclosing and protective relaying circuitry, (c) taking the circuit out of service to maintain the relays (common on all schemes if a single set of relays is used), (d) the requirement of potential devices on all circuits since there is no definite potential reference point (these devices may be required in all cases for synchronizing, live-line, or voltage indication), and (e) the breaker failure during a fault on one of the circuits that causes loss of one additional circuit (owing to operation of breaker-failure relaying).

The advantages of the **breaker-and-a-half scheme** include (a) most flexible operation, (b) high reliability, (c) breaker failure of bus side breakers removing only one circuit from service, (d) all switching being performed with breakers, (e) simple operation without disconnect switching for normal operation, (f) the ability of either main bus to be taken out of service at any time for maintenance, and (g) no removal of any feeder circuits, from service during bus failure. Disadvantages include 1.5 breakers per circuit and relaying and automatic reclosing that are somewhat involved because the middle breaker must be responsive to either of its associated circuits.

6.1.3 Primary System

The **primary system** is made up of circuits known as primary feeders or distribution feeders. A feeder includes the main or main feeder (which usually is a three-phase four-wire circuit) and branches or laterals (which usually are single-phase or three-phase circuits) tapped off the main, as shown in Figure 6.3. A feeder is usually sectioned by means of reclosing devices at various locations to remove as little as possible of a faulted circuit and hinder service to as few consumers as possible. This is accomplished through the coordination of all the fuses and reclosers.

The factors that affect the design of the primary system include the cost, importance of the load it serves, and the required level of service continuity and reliability. The simplest and least expensive and, therefore, the most common design is **radial design**. The low reliability of this design is improved by a modification called the **loop-type primary design**, in which the feeder loops through the feeder load area and returns to the substation bus. The most expensive and reliable design is the **primary-network type**, in which a system of interconnected feeders is supplied by a number of substations. Such a system supplies a load from several directions and consequently provides the maximum reliability and quality of service.

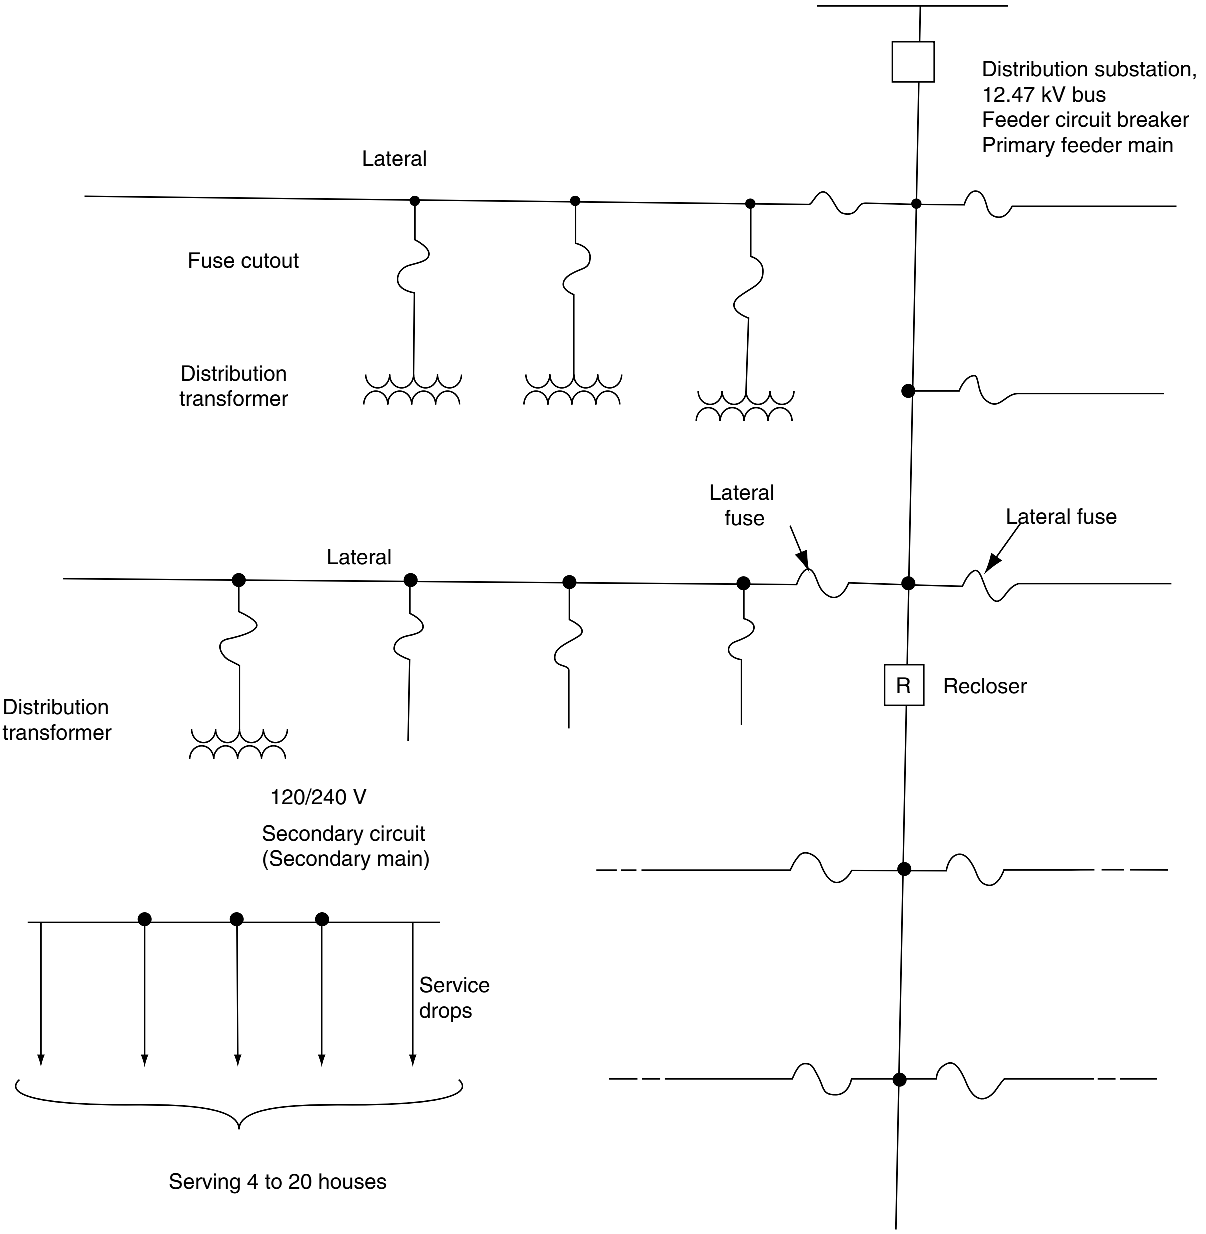

FIGURE 6.3 Typical Power Distribution Feeder

The primary system leaving the substation is most often in the 11,000 to 15,000-V range. A specific voltage used is 12,470-V line-to-line and 7,200-V line-to-neutral (conventionally written 12,470Y/7,200 V). Some utilities still use a lower voltage, such as 4,160Y/2,400 V. In recent years, however, the use of primary distribution circuits in the 25- and 35-kV classes is increasing; all of these circuits are four-wire systems. Single-phase loads are connected line-to-neutral on the four-wire systems. Congested and heavy-load locations in metropolitan areas as well as new residential areas are customarily served by underground primary feeders made up of radial three-conductor cables.

6.1.4 Secondary System

The **secondary system** is the part of the electric power system between the primary system and the consumer's property. The secondary distribution system includes distribution transformers, secondary circuits (secondary mains), consumer services (or service drops), and meters to measure consumer energy consumption. Usually, the secondary systems are designed in single phase for areas of residential consumers and in three phase for areas of industrial or commercial consumers with high load densities. Secondary voltages are provided by distribution transformers that are connected to the primary system, which are usually associated with utilization voltages. Residential and most rural consumers are supplied by 120Y/240-V single-phase, three-wire systems. Commercial and small industrial consumers are supplied by 208Y/120-V or 480Y/277-V three-phase, four-wire systems. The secondary voltage also supplies multiple street lights.

6.1.5 Spot Networks

Spot networks are used in downtown areas for high-rise buildings with extremely high load densities and sometimes also for areas of industrial or commercial consumers. Often, large shopping centers are supplied by spot networks. In such a network, all transformers and protecting equipment are placed at the same location.

6.1.6 Good Voltage and Continuity

Basically, **good voltage** means that the average voltage level is correct, that variations are within acceptable voltage limits, and that sudden and momentary changes in voltage level do not cause objectionable light flicker. Naturally, the utilization voltage of the consumer varies with changing load on the system as well as the location of the consumer on the system. Voltage variation, however, is usually less then 5% at the consumer's meter.

Service continuity is the provision of uninterrupted electric power to the consumer. **Good continuity** means that such service is almost always provided.

6.1.7 Backup Systems and Overhead Construction

To increase the service reliability for critical loads, such as hospitals, computer centers, and crucial industrial loads, **backup systems**, such as emergency generators or batteries, with automatic switching devices are provided. Computer installations are backed up by uninterruptible power supplies (UPS).

Most existing distribution systems in residential, industrial, and rural areas are of **overhead construction**. The distribution transformers are mounted near the tops of poles, and bare primary and secondary conductors are strung from pole to pole.

6.1.8 Underground Construction

Almost all residential developments now being built are served by **underground residential distribution** (URD) **systems** using underground cables for esthetic and safety reasons. In general, underground distribution systems cost more than comparable overhead systems. An URD system is free from service outages and accompanying repair expenses caused by lightning, rain, ice, sleet, snow, and wind storms as well as by any man-made hazards. Some other costs, such as the cost of tree trimming, is totally eliminated by using the URD systems. The URD systems used in residential areas do not require all the refinements and operating advantages found in conventional downtown commercial underground systems. Extensive duct banks, transformer vaults, manholes, and submersible apparatuses are not required in residential systems.

In the past, the favored underground cable was stranded copper with an oil-impregnated paper insulation wrapped in a lead sheath. It was expensive to buy, install, and splice, but it had a long service once in service. For example, it is common to see a 50-year-old paper-insulated cable still in service in duct vaults. Today, URD cables are made up of a relatively inexpensive plastic insulation, typically cross-linked polyethylene (XLPE), and practical elbow connectors. They are buried directly into ground or placed in narrow and shallow trenches, which naturally reduces installation and maintenance costs. In general, the heavy three-phase feeders are overhead along the periphery of a residential development, and the laterals to the pad-mount transformers are buried about 40 in deep. The lateral cable conductors come up from underground into the high voltage compartment of the transformer. The secondary service lines then run to the individual houses at a depth of about 24 in and come up into a meter through a conduit. The service conductors are run along easement and do not cross adjacent property lines.

The frequency of faults is lower on underground systems than on overhead systems. Faults, however, are much more difficult and time-consuming to find, isolate, and repair on underground systems. Service-restoration requirements dictate that primary-system designs should operate as a normally open loop. In the event of a cable fault, such design facilitates location and isolation of the failure and faster service restoration to all consumers on the unfaulted segment of the primary loop. A well-designed URD system should permit ease of sectionalizing to isolate a faulted portion; it should be flexible to accept load growth with a minimum number of changes. The looped primary and single-phase banked secondary system provide these requirements at about the lowest cost. The banked secondary system takes better advantage of diversity among loads and permits a smaller installed kilovoltampere of transformer capacity and possibly fewer transformers. Compared to the simple radial system, the secondary system also provides better voltage conditions at the loads and less voltage dip due to motor starting for a given transformer rating, conductor size, and spacing among transformers.

Transformers used for the URD system are hermetically sealed against moisture, including their bushings and terminals. The terminals may have one or more insulated disconnecting elbows, enabling the disconnection of the transformer and the sectioning of the primary circuits. The transformer may be completely buried or installed on ground-level pads or semiburied pads. **Pad-mounted transformers** are the predominant type of transformer being used for URD. They are usually installed on concrete slabs or pads. Pad-mounted transformers may use **dead-front** configuration with separable insulated connectors or elbows. There are many other combinations of pad-mount construction and accessory equipment available including **live-front** primary connections with stress cones for the cables, internal or external primary fuses and switches, and secondary breakers. **Residential subsurface transformers** (RSTs) are used much less frequently. RSTs are installed in relatively tight-fitting vaults with the cover grating of the vault at ground level. Cooling is usually accomplished by natural convection of air. RSTs are submersible and, therefore, have dead-front primary cable terminations. Switches, fuses, and circuit breakers are located on the cover of the transformer so that they can be operated by a lineman standing on the surface of the ground. The last type of URD transformer is a **direct-buried transformer**. This type of transformer is not popular because of the problem of accessory equipment and its poor operation under adverse weather conditions, such as with snow and ice. There also are concerns about galvanic corrosion under certain conditions.

6.2 Quality of Service and Voltage Standards

In general, performance of distribution systems and quality of the service provided are measured in terms of freedom from interruptions and maintenance of satisfactory voltage levels at the consumer's premises that are within limits appropriate for this type of service. Due to economic considerations, an electric utility company cannot provide each consumer with a constant voltage matching exactly the nameplate voltage on the consumer's utilization equipment. Thus, a common practice among the utilities is to stay with preferred voltage levels and ranges of variation for satisfactory operation of equipments set forth by the ANSI standard.

The nominal voltage standards for a majority of the electric utilities in the United States to serve residential and commercial consumers are as follows:

1. 120/240-V three-wire, single-phase
2. 240/120-V four-wire, three-phase delta
3. 208Y/120-V four-wire, three-phase wye
4. 480Y/277-V four-wire, three-phase wye

The voltage on a distribution circuit varies from a maximum value at the consumer nearest to the source (first consumer) to a minimum value at the end of the circuit (last consumer). For any given voltage level, the actual operating values can vary over a large range. This range has been segmented into three zones: (1) the **favorable zone** or preferred zone, (2) the **tolerable zone**, and (3) the **extreme zone**. The favorable zone includes the majority of the existing operating voltages that produce satisfactory operation of the customer's equipment. The tolerable zone contains a band of operating voltages slightly above and below the favorable zone. The operating voltages in the tolerable zone are usually acceptable for most purposes. The extreme or emergency zone includes voltages on the fringes of the tolerable zone, usually within 2 or 3% above or below the tolerable zone. Usually, the maximum voltage drop in the customer's wiring between the point of delivery and the point of utilization is accepted as 4 V based on 120 V.

6.2.1 Voltage Control

To keep distribution–circuit voltages within permissible limits, means must be provided to control the voltage. There are numerous ways to improve the overall voltage regulation of a distribution system. The complete list includes the following:

1. Use of generator voltage regulators
2. Application of voltage-regulating equipment in the distribution substations
3. Application of capacitors in the distribution substation
4. Balancing of the loads on the primary feeders
5. Increasing of conductor size
6. Changing of feeder sections from single-phase to multiphase
7. Transferring of loads to new feeders
8. Installing of new substations and primary feeders
9. Increasing of primary voltage level
10. Application of voltage regulators out on the primary feeders
11. Application of shunt capacitors on the primary feeders
12. Application of series capacitors on the primary feeders

The selection of a technique or techniques depends on the particular system requirement. However, automatic voltage regulation is always provided by (1) bus regulation at the substation, (2) individual feeder regulation in the substation, and (3) supplementary regulation along the main by regulators mounted on poles. Distribution substations are equipped with **load-tap-changing** (LTC) transformers that operate automatically under load or with separate voltage regulators that provide bus regulation.

Voltage-regulating equipment is designed to maintain a predetermined level of voltage automatically that would otherwise vary with the load. As the load increases, the regulating equipment boosts the voltage at the substation to compensate for the increased voltage drop in the distribution feeder. In cases where consumers are located at long distances from the substation or where voltage along the primary circuit is excessive, additional regulators or capacitors located at selected points on the feeder provide supplementary regulation. Many utilities have experienced that the most economical way of regulating the voltage within the required limits is to apply both step voltage regulators and shunt capacitors. Capacitors are installed out on the feeders and on the substation bus in adequate quantities to accomplish the economic power factor. Many of these installations have sophisticated controls designed to perform automatic switching. Of course, a fixed capacitor is not a voltage regulator and cannot be directly compared to regulators, but, in some cases, automatically switched capacitors can replace conventional step-type voltage regulators for voltage control on distribution feeders.

6.2.2 Feeder Voltage Regulators

Feeder voltage regulators are used extensively to regulate the voltage of each feeder separately to maintain a reasonable constant voltage at the point of utilization. They are either the induction-type or the step-type regulators. However, today's modern step-type voltage regulators have practically replaced induction-type regulators.

Step-type voltage regulators can be either (1) **station-type**, which can be single- or three-phase regulators and can be used in substations for bus voltage regulation or individual feeder voltage regulation or (2) **distribution type**, which can be only single-phase regulators and are used pole-mounted out on overhead primary feeders. Single-phase step-type voltage regulators are available in sizes from 25 to 833 kVA, whereas three-phase step-type voltage regulators are available in sizes from 500 to 2,000 kVA. For some units, the standard capacity ratings can be increased by 25 to 33% by forced-air cooling. Standard voltage ratings are available from 2,400 to 19,920 V, allowing regulators to be used on distribution circuits from 2,400 to 34,500 V grounded wye/19,920 V multigrounded wye. Station-type voltage regulators for bus voltage can be up to 69 kV.

A step-type voltage regulator is basically an autotransformer with a common winding and a tapped (stepped) series winding. A reversing switch enables the series winding to be connected for either raising or lowering of the line voltage. The number of steps depends on the percentage of increments in voltage regulation desired per step. Typically, step voltage regulators have 16 steps of 5/8% per step, for a total regulation range of ±10%.

6.2.3 Line-Drop Compensation

Voltage regulators located in the substation or on a feeder are used to keep the voltage constant at a fictitious regulation or regulating point without regard to the magnitude or power factor of the load. The regulating point is usually selected to be somewhere between the regulator and the end of the feeder. The automatic voltage maintenance is achieved by dial settings of the adjustable resistance and reactance elements of a unit called the **line-drop compensator** (LDC) located on the control panel of the voltage regulator. Determination of the appropriate dial settings depends on whether any load is tapped off the feeder between the regulator and the regulating point.

In the event that no load is tapped off the feeder between the regulator and the regulating point, the R dial setting of the line-drop compensator can be determined from:

$$R_{set} = \frac{CT_P}{VT_N} \times R_{eff}, \tag{6.1}$$

where CT_P is the rating of the current transformer's primary; VT_N is the voltage transformer's turns ratio, which is V_{pri}/V_{sec}; and R_{eff} is the effective resistance of a feeder conductor from regulator station to regulating point. The *Reff* can be determined from:

$$R_{eff} = r_a \times \frac{l - s_1}{2}. \tag{6.2}$$

In equation 6.2, the r_a is the resistance of a feeder conductor from regulator station to regulation point, Ω/mi per conductor; s_1 is the length of three-phase feeder between regulator station and substation, mi (multiply length by 2 if feeder is in single-phase); and l is the primary feeder length, mi.

In addition, the X dial setting of the line-drop compensator can be determined from:

$$X_{est} = \frac{CT_P}{VT_N} \times X_{eff}, \tag{6.3}$$

where X_{eff} is the effective reactance of a feeder conductor from regulator to regulation point:

$$X_{eff} = x_L \times \frac{l - s_1}{2}, \tag{6.4}$$

and

$$x_L = x_a + x_d. \tag{6.5}$$

In equation 6.5, the x_a is the inductive reactance of an individual phase conductor of feeder at 12-in spacing, Ω/mi; x_d is the inductive-reactance spacing factor, Ω/mi; and x_L is the inductive reactance of feeder conductor, Ω/mi.

Note that since the R and X settings are determined for the total connected load, rather than for a small group of customers, the resistance and reactance values of the transformers are not included in the effective resistance and reactance calculations.

On the other hand, in the event that load is tapped off between the regulator station and the regulating point, the R setting of the line-drop compensator can still be determined from equation 6.2, but the determination of the R_{eff} is somewhat more involved. In this case, the effective resistance is calculated from:

$$R_{eff} = \frac{\sum_{i=1}^{n} |VD_R|_i}{|I_L|}, \tag{6.6}$$

and

$$\sum_{i=1}^{n} |VD_R|_i = |I_{L,1}| \times r_{a,1} \times I_1 + |I_{L,2}| \times r_{a,2} \times I_2 + \ldots + |I_{L,n}| \times r_{a,n} \times I_n. \tag{6.7}$$

In equation 6.7, $|VD_R|_i$ is the voltage drop due to line resistance of the *i*th section of feeder between regulator station and regulating point, *V*/section; $\left|\sum_{i=1}^{n} VD_R\right|_i$ is the total voltage drop due to line resistance of feeder between regulating station and regulation point; $|I_L|$ is the magnitude of load current at regulator location; $|I_{L,i}|$ is the magnitude of load current in the *i*th feeder section; $r_{a,i}$ is the resistance of a feeder conductor in the *i*th section of feeder, Ω/mi; and l_i = length of *i*th feeder section, mi.

Also, the *X* dial setting of the line-drop compensation can be found from equation 6.4, but the determination of the X_{eff} is again somewhat more involved. The following equations need to be used:

$$X_{eff} = \frac{\sum_{i=1}^{n} |VD_x|_i}{|I_L|}, \tag{6.8}$$

and

$$\sum_{i=1}^{n} |VD_X|_i = |I_{L,1}| \times X_{L,1} \times I_1 + |I_{L,2}| \times X_{L,2} \times I_2 + \ldots + |I_{L,n}| \times X_{L,n} \times I_n. \tag{6.9}$$

In this equation, $|VD_X|_i$ is the voltage drop due to line reactance of the *i*th section of a feeder between the regulator station and regulating point, V/section; $\left|\sum_{i=1}^{n} VD_X\right|_i$ is the total voltage drop due to line reactance of a feeder between the regulating station and regulation point; and $X_{L,1}$ is the inductive reactance as defined in equation 6.6, of *i*th section of feeder, Ω/mi.

Since the methods just described to find the effective *R* and *X* are rather involved, an alternative and practical method can be used to measure the current (I_L) and voltage at the regulator location and the voltage at the regulating point. The difference between the two voltage values is the total voltage drop between the regulator and the regulation point, which can be found as:

$$VD = |I_L| \times R_{eff} \times \cos\theta + |I_L| \times X_{eff} \times \sin\theta, \tag{6.10}$$

from which the R_{eff} and X_{eff} values can be found easily if the load power factor of the feeder and average *r*/*x* ratio of the feeder conductors between the regulator and the regulating point are known.

6.2.4 Voltage Regulation

Customer taps along the feeder draw current through the line, causing the voltage to drop as one gets further from the substation. If the voltage at the substation is set at the nominal voltage, the consumers at the end of the feeder have too low a voltage under peak load. If the voltage is set so that consumers at the end of the feeder receive the nominal voltage under heavy load, the consumers near the substation have too high a voltage, and the voltage is too high for all of the consumers at light load. Therefore, a compromise voltage setting must be chosen so that the voltage is at an acceptable level for all consumers regardless of the load, and the line drop must be acceptably low under all load conditions. However, a favorable compromise of voltage drop and voltage settings is not always possible for all load conditions, so other means of voltage regulation have been devised for such conditions.

In voltage regulation studies, it is customary to express the primary feeder voltage values in a 120-V base. The voltage-regulating relay (VRR) of a voltage regulator is adjustable within the approximate range from 110 to 125 V. The VRR measures the voltage at the regulating point by means of LDC. The LDC has *R* and *X* settings that are both adjustable within the approximate range from 0 to 24 Ω (often called volts because the current transformers used with regulators have 1-A secondaries). The bandwidth (BW) of the VRR is adjustable within the approximate range from ±0.75 to ±1.5 V based on 120 V. The time delay is adjustable between about 10 and 120 sec. The location of the regulating point is controlled by the *R* and *X* settings of the LDC. If the *R* and *X* settings are set at zero, the regulator adjusts the voltage at its local terminal to the setting of the VRR ± BW. Good advantage sometimes can be taken of this designed "overload" type of limited-range operation. If load growth occurs, however, both a larger range of regulation and larger regulator size may be required.

The peak-load voltage profile is not in linear but in parabolic shape. The voltage-drop value for any given point *s* between the substation and the regulator station can be found from:

$$VD_x = K\left(S_{3\phi} - \frac{S_{3\phi} \times s}{l}\right)s + K\left(\frac{S_{3\phi} \times s}{l}\right)\frac{s}{2} \quad [\text{pu}], \tag{6.11}$$

where *K* is the percentage of voltage drop per kilovoltampere–mile [kVA] characteristic of feeder; $S_{3\phi}$ is the uniformly distributed three-phase annual peak load, kVA; *l* is the primary feeder length, mi; and *s* is the distance from substation, mi.

Alternatively, the voltage-drop value for any given point *s* between the substation and the regulator station can be found from:

$$VD_s = I(r \times \cos\theta + x \times \sin\theta)s\left(1 - \frac{s}{2l}\right), \tag{6.12}$$

where:

- I_L = load current in feeder at substation end

$$= \left(\frac{S_{3\phi}}{\sqrt{3} \times V_{L-L}}\right) \tag{6.13}$$

- r = resistance of feeder main, Ω/mi per phase
- x = reactance of feeder main, Ω/mi per phase

Thus, the voltage drop in per unit can be found as:

$$VD_s = \frac{VD_s}{V_{L-N}}. \tag{6.14}$$

The voltage-drop value for any given point s between the end of the feeder and the regulator station can be found from:

$$VD_s = K\left(S_{3\phi} - \left(\frac{S_{3\phi} \times s}{1-s}\right)\right)s + K\left(\frac{S_{3\phi} \times s}{1-s}\right)\frac{s}{2}, \tag{6.15}$$

where:

- $S_{3\phi}$ = uniformly distributed three-phase annual peak load at distance s_1, kVA

$$= S_{3\phi}\left(1 - \frac{s_1}{l}\right) \tag{6.16}$$

- s_1 = distance of feeder regulator station from substation, mi

The voltage profiles for annual peak load can be found by plotting the primary voltage values, $V_{P,pu}$, against the s distance on the feeder. Because there is no voltage drop at zero load, the primary voltage values, $V_{P,pu}$, remain constant. Thus, the voltage profile for the zero load is a horizontal line.

6.2.5 Use of Capacitors for Voltage Regulation

Because most loads lag and the line reactance is much greater than the line resistance, switching shunt capacitors across a line will increase the voltage by reducing the inductive vars drawn. If so much capacitance is switched across the line that the current becomes leading, the method is not cost-effective because the vars begin to rise again. Shunt capacitors are only useful with lagging load power factors.

In general, capacitor banks are installed near load points. If only fixed-type capacitors are installed, the utility will experience an excessive leading power factor and voltage rise at that feeder. Therefore, some of the capacitors are installed as switched-capacitor banks so they can be switched off during light-load conditions. Because of this, the fixed capacitors are sized for light load and connected permanently. The switched capacitors can be switched as a block or in several consecutive steps as the reactive load becomes greater from light-load level to peak load and sized accordingly.

A system survey is required in choosing the type of capacitor installation. As a result of power flow program runs or manual load studies on feeders or distribution substations, the system's lagging reactive loads (i.e., power demands) can be determined and the results can be plotted on a curve. This curve is called the **reactive load duration curve** and is the cumulative sum of the consumer's reactive loads and the system's reactive power requirements. Once the daily reactive load curve is obtained, then, by visual inspection of the curve, the size of the fixed capacitors can be found to meet the minimum reactive load. All capacitor banks require protection. The entire bank will be protected with a fuse or circuit breaker, and each capacitor will be fused. The capacitors can be connected via either delta or wye. The ungrounded wye is a preferred configuration because if a capacitor should short out in one leg of the wye, the other two legs will limit the fault current.

6.2.6 Voltage Regulation by Use of Tap Changers

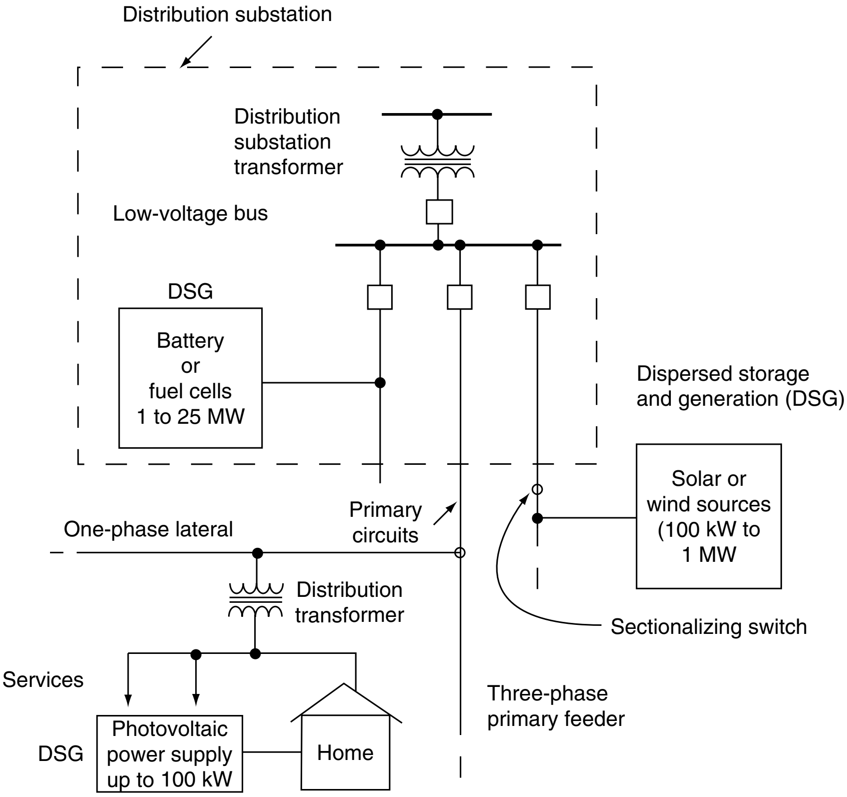
Another method of line voltage regulation is **tap changing**. Taps are connections on a transformer winding that change the turns ratio slightly. The ratio change is normally ±10% (0.625% per step). The taps are usually located on the primary because less current has to be switched by the tap changing connections than would be necessary on the secondary. Tap changers can be manual or automatic. Some distribution transformers and distribution substation transformers have manual tap changers so that added load can be compensated for. Motor-driven automatic tap changers are necessary for voltage regulation with widely fluctuating loads. This is called **tap changing under load** (TCUL) or **load tap changing** (LTC). LTC is used in distribution and subtransmission substations to keep the secondary line voltage at the proper level in response to load and primary voltage changes.

6.2.7 Voltage Regulation by Use of Voltage Regulating Transformers

Regulating transformers are designed to provide a boost in voltage magnitude along a line or a change in phase. They are used basically to control the flow of power between two systems with different sources, or they are used along a tie feeder between two load centers that are fed by the same bulk power substation. Phase-regulating transformers are employed to control the power flow around loops with two or more sources. They are almost always motor driven and have extensive control and protection systems.

6.2.8 Dispersed Storage and Generation

Electric distribution systems are undergoing major changes to accommodate the development of alternative sources for generating electric energy and provide enhanced opportunities for small power producers and cogenerators. In general, these generators are small (typically ranging from 10 kW to 10 MW and connectable to either side of the meter) and can be



Distribution substation
Distribution substation transformer
Low-voltage bus
DSG
Battery or fuel cells 1 to 25 MW
Dispersed storage and generation (DSG)
Solar or wind sources (100 kW to 1 MW
One-phase lateral
Primary circuits
Distribution transformer
Sectionalizing switch
Services
Three-phase primary feeder
DSG
Photovoltaic power supply up to 100 kW
Home

FIGURE 6.4 Small Dispersed Storage and Generation Units. These example units are attached to a distribution system

economically connected only to the distribution system, as shown in Figure 6.4.

If properly planned and operated, **dispersed storage and generation** may provide benefits to distribution systems by reducing capacity requirements, improving reliability, and reducing losses. Dispersed-storage-and-generation technologies include hydroelectric systems, diesel generators, wind-electric systems, solar-electric systems, batteries, storage space and water heaters, storage air conditioners, hydroelectric pumped storage, photovoltaics, and fuel cells.

Power System Analysis

Mani Venkatasubramanian
and Kevin Tomsovic
*School of Electrical Engineering
and Computer Science,
Washington State University,
Pullman, Washington, USA*

7.1 Introduction

The **interconnected power system** is often referred to as the largest and most complex machine ever built by humankind. This may be hyperbole, but it does emphasize an inherent truth: there is a complex interdependency between different parts of the system. That is, events in geographically distant parts of the system may interact strongly and in unexpected ways. **Power system analysis** is concerned with understanding the operation of the system as a whole. Generally, the system is analyzed either under steady-state operating conditions or under dynamic conditions during disturbances.

Electric power is primarily transmitted as a three-phase signal. Three ac current currents are sent that are out of phase by 120° but of equal magnitude. Such balanced currents sum to zero and, thus, obviate the need for a return line. If the voltages are balanced as well, then the total power transmitted will be constant in time, which is a more efficient use of equipment capacity. For large scale systems analysis, the assumption is usually made that the system is balanced. Each phase can be then analyzed independently, greatly simplifying computations. In the following paragraphs, the implicit assumption is that three-phase systems are being used.

7.2 Steady-State Analysis

In **steady-state analysis**, any transients from disturbances are assumed to have settled down, and the system state is assumed as unchanging. Specifically, system loads including transmission system losses, are precisely matched with power generation so that the system frequency is constant (e.g., 60 Hz in North America). Perhaps the foremost concern during steady-state analysis is economic operation of the system; reliability is also important as the system must be operated to avoid outages should disturbances occur. The primary analysis tool for steady-state operation is the so-called **power flow analysis**, where the voltages and power flow through the system are determined. This analysis is used for both operation and planning studies and throughout the system at both the high and low transmission voltages.

The power system can be roughly separated into three subcomponents: **generation**, **transmission and distribution**, and **load**. The transmission and distribution network consists of power transformers, transmission lines, capacitors, reactors, and protection devices. The vast majority of generation is produced by synchronous generators. Loads consist of a large number and a diverse assortment of devices, from home appliances and lighting to heavy industrial equipment and sophisticated electronics. As such, modeling the aggregate effect is a challenging problem in power system analysis. In the following sections, the appropriate models for these components in the steady-state are introduced.

7.2.1 Modeling

Transformers

A transformer is a device used to convert voltage levels in an alternating current (ac) circuit. The device has numerous uses in power systems. To begin, it is more efficient to transmit power at high voltages and low current than low voltages and high current. Conversely, lower voltages are safer and more economic for end use. Thus, transformers are used to step-up voltages from generators and then used to stepdown the voltage for end use. Another wide use of transformers is instrumentation: sensitive equipment can be isolated from the high voltages and currents of the transmission system. Transformers may also be used as means of controlling real power flow by phase shifting.

Transformers function by the linkage of magnetic flux through a core of ferromagnetic material. Figure 7.1(A) illustrates a magnetic core with a single winding. When a current I is supplied to the first set of windings, called the **primary windings**, a magnetic field, H, will develop, and magnetic flux, ϕ, will flow in the core. Ampère's law relates the enclosed current to the magnetic field encountered on a closed path. If H is constant throughout the path, then:

$$Hl = NI, \tag{7.1}$$

where l is the path length through the core; N is the number of turns of the winding on the core so that NI is the enclosed current by the path referred to as the **magnetomotive force** (mmf).

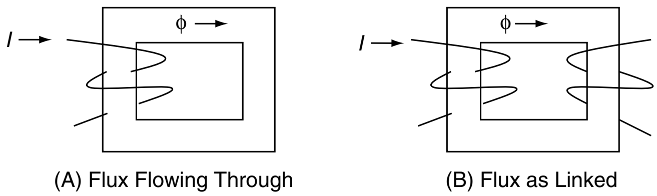
The **magnetic field** is related to the **magnetic flux** by the properties of the material, specifically the permeability. If a linear relationship is assumed (i.e., neglecting hysteresis and saturation effects), then the flux density, B, or the flux, ϕ, is as follows:

$$B = \mu H = \mu \frac{NI}{l} \text{ or } \phi = \mu A \frac{NI}{l}, \tag{7.2}$$

where A is the cross-sectional area of the core. This relationship between the flux flow in the core and the mmf is called the **reluctance**, R, of the core so that:

$$R\phi = NI. \tag{7.3}$$

Now, if a second set of windings, the secondary windings, is wrapped around the core as shown in Figure 7.1(B), the two currents will be linked by magnetic induction. Assuming that no flux flows outside the core, then the two windings will see the exact same flux, ϕ. Because the two windings also see the same core reluctance, the two mmfs are identical:



(A) Flux Flowing Through (B) Flux as Linked

FIGURE 7.1 (A) The Flux Flows Through Core from First Winding; (B) The Flux is Linked to a Second Set of Windings.

$$N_1 I_1 = N_2 I_2. \tag{7.4}$$

If the flux ϕ or, equivalently, the current I are changing in time, then according to Faraday's law, a voltage will be induced. Assuming this ideal transformer has no losses, the power input will be the same as the power output, so:

$$V_1 I_1 = V_2 I_2, \tag{7.5}$$

where V_1 and V_2 are the primary and secondary voltages, respectively. Substituting (7.4) and rearranging shows:

$$\frac{V_2}{V_1} = \frac{N_2}{N_1}. \tag{7.6}$$

Thus, the voltage gain in an ideal transformer is simply the ratio of the primary and secondary windings' turns. A practical transformer experiences several non-ideal effects. Specifically, these include nonzero winding resistance, finite permeability of the core, eddy currents that flow in the core, hysteresis (the effect arising from the energy required to reorient the magnetic dipoles as the magnetic polarity changes), and magnetic saturation. For steady-state studies of the large system, linear circuit models are desired. These effects are typically modeled as a combination of series and parallel impedances in the following way:

- **Series impedances**: Because the transformer core has a finite permeability, some of the magnetic flux flows outside the core. This leakage flux will not link the primary and secondary windings. Thus, the voltage at the input sees not only the voltage that links the primary and secondary windings but also a voltage drop caused by this leakage inductance. Similarly, the finite winding resistance causes an additional voltage drop to be seen at the terminals.
- **Shunt impedances**: Finite permeability implies nonzero core reluctance and requires current to magnetize the core (i.e., a nonzero mmf). This difference between the primary and secondary mmfs can be modeled as a shunt inductance. Hysteresis and eddy currents lead to energy losses in the core that can be approximately modeled by a shunt resistor. Saturation is an important nonlinear effect that results in additional losses and the creation of odd order harmonics in the current and voltage signals. Because in steady-state system analysis only the 60-Hz component of the currents and voltages is considered, saturation effects are typically ignored.

An equivalent circuit for the transformer model just described is shown in Figure 7.2.

The main difficulty with the model in Figure 7.2 as it now stands concerns the ideal transformer component. Carrying this component around in the calculations creates unnecessary complexity. Further, from an engineering point of view, the

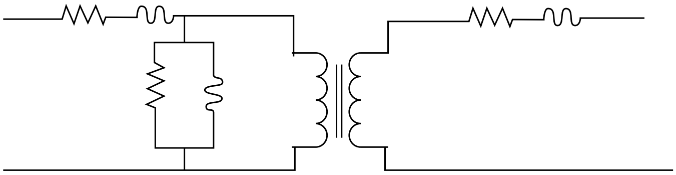


FIGURE 7.2 Transformer Circuit Model

voltages and currents in the system are most easily seen relative to their rated values. Thus, most system analysis is done on a normalization called the per unit system. In the per unit system, a system power base is established, and the rated voltages at each point in the network are determined. All system variables are then given relative to this value. These base quantities for the currents can be found as:

$$I_B = \frac{S_B}{V_B}, \tag{7.7}$$

and for impedances:

$$Z_B = \frac{V_B}{I_B} = \frac{V_B^2}{S_B}. \tag{7.8}$$

This normalization has the great added advantage of reducing the need to represent the ideal transformer in the circuit. One must simply keep track of the nominal base voltage in each part of the network. In this way, the equivalent transformer model is as given in Figure 7.3. Note that phase shifting and off-nominal transformer ratios result in asymmetric circuits and require some additional manipulation in the per unit framework. Those details are omitted here for brevity.

Transmission Line Parameters

As mentioned previously, electric power is transmitted in three phases. This accounts for the common site of three lines or for dual circuits of six lines seen strung between transmission towers. Typically, a high-voltage transmission line has several feet of spacing between the three conductors. The conductors are stranded wire for improved mechanical as well as electrical properties. If the currents are expected to be large, several conductors may be strung per phase. This improves cooling compared to using one large conductor. This geometry is important as it impacts the electrical properties of the line.

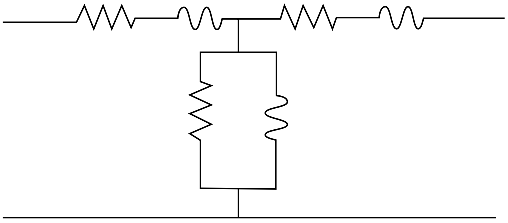

FIGURE 7.3 Simplified Transformer Circuit Model Under Per Unit System

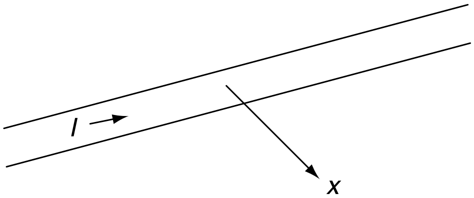

FIGURE 7.4 Infinite Transmission Line

As current flows in each conductor, a magnetic field develops. Adjacent lines then may induce voltages in nearby conductors through mutual induction (as seen for transformers, only now with coupling that is not as tight). This interaction largely determines the inductance seen by the respective phase currents. To understand this phenomenon, consider a single line of radius r and infinite length with some current flow, I, as sketched in Figure 7.4. Similar to what is done for the transformer development, apply Ampère's law to characterize the magnetic field. The magnetic field at some distance x from the line can be found by assuming that the field is constant at all points equal distance from the line. The closed path is then a circle with circumference $2\pi x$, which gives:

$$2\pi x H = I \text{ or } H = \frac{I}{2\pi x}. \tag{7.9}$$

If x is less than the line radius, the closed path will not link all of the current. Assuming an equal distribution of current throughout the wire:

$$2\pi x H = I\frac{x^2}{r^2} \text{ or } H = \frac{Ix}{2\pi r^2}. \tag{7.10}$$

Once again, the flux density is determined by the permeability of the material, which in this case is either the conductor itself if $x < r$ or that of free space for $x > r$. Then, the flux relationship is the following:

$$d\phi = \mu \frac{Ix}{2\pi r^2} dx. \tag{7.11}$$

For $x > r$, the flux linked up to some radial distance R per unit of length is simply:

$$\lambda_{\text{external}} = \int_r^R \mu_0 \frac{I}{2\pi x} dx = \frac{\mu_0 I}{2\pi} \ln \frac{R}{r}. \tag{7.12}$$

For $x < r$, only the enclosed current will be linked. Continuing with the even distribution of current assumption, the flux linked is as written here:

$$\lambda_{\text{internal}} = \int_0^r \mu_c \frac{Ix^3}{2\pi r^4} dx = \mu_c \frac{I}{8\pi}. \quad (7.13)$$

For simplicity, assume the permeability of the conductor is that of free space, and then the total flux linkage is as follows:

$$\lambda = \frac{\mu_0 I}{8\pi} + \frac{\mu_0 I}{2\pi} \ln \frac{R}{r} = \frac{\mu_0 I}{2\pi} \ln \frac{R}{re^{-1/4}}. \quad (7.14)$$

Typically, $re^{-1/4}$ is written as r'. Consider a three-phase transmission line of phase currents I_a, I_b, and I_c, with each line spaced equally by the distance D. Flux from each of the currents will link with each of the other conductors. The flux linkage for phase a out to some point R a far distance away from the conductors is approximately:

$$\lambda_a = \frac{\mu_0}{2\pi}\left(I_a \ln \frac{R}{r'} + I_b \ln \frac{R}{D} + I_c \ln \frac{R}{D}\right). \quad (7.15)$$

Assuming balanced currents (i.e., $I_a + I_b + I_c = 0$) and recalling that inductance is simply the ratio of flux linkage to current, the series inductance in phase a per unit length of line will be the following:

$$\tilde{L}_a = \frac{\mu_0}{2\pi} \ln \frac{D}{r'}. \quad (7.16)$$

In practice, the phase conductors may not be equally spaced as they are in Figure 7.5. This results in unbalanced conditions due to the imbalance in mutual inductance. High-voltage transmission lines with such a layout can be transposed so that, on average, the distance between phases is equal canceling out the imbalance. The equivalent distance of separation between phases can then be found as the geometric mean of this spacing. Similarly, if several conductors are used per phase, an equivalent conductor radius can be found as the geometric mean.

Transmission lines also exhibit capacitive effects. That is, whenever a voltage is applied to a pair of conductors separated by a nonconducting medium, charge accumulates, which leads to capacitance. Similar to the previous development for inductance, the capacitance can be determined based on Gauss's law. For a point P at a distance x from a conductor with charge q, the electric flux density D is:

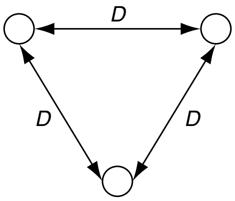

FIGURE 7.5 End View of Equally Spaced Phase Conductors

$$D = \frac{q}{2\pi x}. \quad (7.17)$$

Assuming a homogeneous medium, the electric field density E is related to D by the permitivity ε of the dielectric, which, in this case, will be assumed to be that of free space:

$$E = \frac{q}{2\pi\varepsilon_0 x}. \quad (7.18)$$

Integrating E over some path (a radial path is chosen for simplicity) yields the voltage difference between the two end points:

$$V_{12} = \int_{R_1}^{R_2} \frac{q}{2\pi\varepsilon_0 x} dx = \frac{q}{2\pi\varepsilon_0} \ln \frac{R_1}{R_2}. \quad (7.19)$$

Now consider a three-phase transmission line again with each line spaced equally by the distance D. Superposition holds so that the voltage arising from each of the charges can be added. To find the voltage from phase to ground arising from each of the conductors, assume a balanced system with $q_a + q_b + q_c = 0$ and a neutral system located at some far distance R from phase a:

$$V_{an} = \frac{1}{2\pi\varepsilon_0}\left(q_a \ln \frac{R}{r} + q_b \ln \frac{R}{D} + q_c \ln \frac{R}{D}\right) = \frac{1}{2\pi\varepsilon_0} q_a \ln \frac{D}{r}. \quad (7.20)$$

Now since the capacitance is the ratio of charge to voltage, the capacitance from phase a to ground per unit length of line will be:

$$\tilde{C}_{an} = \frac{q_a}{V_{an}} = \frac{2\pi\varepsilon_0}{\ln D/r}. \quad (7.21)$$

If the conductors are not evenly spaced, transposition results in an equivalent geometric mean distance, and using bundled conductors per phase can also be accommodated by using a geometric mean.

Finally, conductors have finite resistances that depend on the temperature, the frequency of the current, the conductor material, and other such factors. For most systems analysis problems, these can be based on values provided by manufacturers or from tables for commonly used conductors and typical ambient conditions.

Transmission Line Circuit Models

Transmission lines may be classified according to their total length. If the line is around 50 miles or less, a so-called **short line**, capacitance can be neglected, and the series inductance

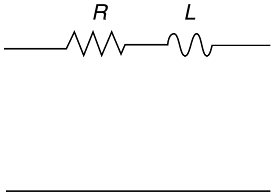

FIGURE 7.6 Short Line Model

and resistance can be modeled as lumped parameters. Figure 7.6 depicts the short line model per phase. The series resistance and inductance are simply found by calculating the per unit distance parameters times the line length; therefore, at 60 Hz for line length l, the line impedance is the following:

$$Z = \tilde{R}l + j120\pi\tilde{L}l = R + jX. \tag{7.22}$$

For lines longer than 50 miles, up to around 150 miles, capacitance can no longer be neglected. A reasonable circuit model is to simply split the total capacitance evenly with each half represented as a shunt capacitor at each end of the line. This is depicted as the π–circuit model in Figure 7.7. Again, the total capacitance is simply the per unit distance capacitance times the line length:

$$Y = j120\pi\tilde{C}_{an}l = jB. \tag{7.23}$$

For line lengths longer than 150 miles, the lumped parameter model may not provide sufficient accuracy. To see this, note that at 60 Hz for a low-loss line, the wavelength is around 3000 miles. Thus, a 150-mile line begins to cover a significant portion of the wave, and the well-known wave equations must be used. The relationship between voltage and current at a point x (i.e., distance along the line) to the receiving end voltage, V_r, and current, I_r, is seen through the following equations:

$$V(x) = V_r\cosh\,\gamma x + I_r Z_c\sinh\,\gamma x. \tag{7.24}$$

$$I(x) = I_r\cosh\,\gamma x + \frac{V_r}{Z_c}\sinh\,\gamma x. \tag{7.25}$$

The $Z_c = \sqrt{z/y}$ is the **characteristic impedance** of the line, and $\gamma = \sqrt{zy}$ is the **propagation constant**. It would be useful, and it turns out to be possible, to continue to use the π–model for the transmission line and simply modify the circuit parameters to represent the distributed parameter effects. The relationship between the sending end voltage, V_s, and current, I_s, to the receiving end voltage and current in a π–model can be found as:

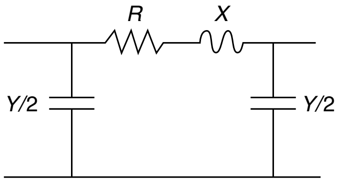

FIGURE 7.7 Medium Line Model

$$V_s = V_r\left(1 + \frac{YZ}{2}\right) + I_r Z. \tag{7.26}$$

$$I_s = V_r Y\left(1 + \frac{YZ}{4}\right) + I_r\left(1 + \frac{YZ}{2}\right). \tag{7.27}$$

Now equating 7.24 and 7.25 for a line of length l to equations 7.26 and 7.27 and solving shows the equivalent shunt admittance and series impedance for a long line as:

$$Z' = Z_c\sinh\,\gamma l = Z\frac{\sinh\,\gamma l}{\gamma l}. \tag{7.28}$$

$$\frac{Y'}{2} = \frac{1}{Z_c}\,\tanh\,\frac{\gamma l}{2} = \frac{Y}{2}\frac{\tanh\,\gamma\mathrm{l}/2}{\gamma l/2}. \tag{7.29}$$

In these equations, the prime indicates the modified circuit values arising from a long line.

Generators

Three-phase synchronous generators produce the overwhelming majority of electricity in modern power systems. Synchronous machines operate by applying a dc excitation to a rotor that, when mechanically rotated, induces a voltage in the armature windings due to changing flux linkage. The per phase flux for a balanced connection can be written as:

$$\lambda = K_f I_f \sin\theta_m, \tag{7.30}$$

where I_f is the field current, θ_m is the angle of the rotor relative to the armature, and K_f is a constant that depends on the number of windings and the physical properties of the machine. The machine may have several poles so that the armature will "see" multiple rotations for each turn of the rotor. So, for example, a four pole machine appears electrically to be rotating twice as fast as two pole machine. For a machine rotating at ω_m radions per second with p poles, the electric frequency is as follows:

$$\omega_s = \omega_m\frac{p}{2}, \tag{7.31}$$

with ω_s as the desired synchronous frequency. If the machine is rotated at a constant speed Faraday's law indicates that the induced voltage can be written as:

$$V = \frac{d\lambda}{dt} = K_f I_f \omega_s \sin(\omega_s t + \theta_0). \tag{7.32}$$

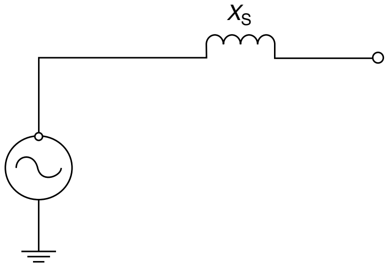

FIGURE 7.8 Simple Synchronous Generator Model

If a load is applied to the armature windings, then current will flow and the armature flux will link with the field. This effectively puts a mechanical load on the rotor, and power input must be matched to this load to maintain the desired constant frequency. Some of the armature flux "leaks" and does not link with the field. In addition, there are winding resistive losses, but those are commonly neglected. The circuit model shown in Figure 7.8 is a good representation for the synchronous generator in the steady-state. Note that most generators are operated at some fixed terminal voltage with a constant power output. Thus, for steady-state studies, the generator is often referred to as a *PV* bus since the terminal node has fixed power *P* and voltage *V*.

Loads

Modeling power system loads remains a difficult problem. The large number of different devices that could be connected to the network at any given time renders precise modeling intractable. Broadly speaking, loads may vary with voltage and frequency. In the steady-state, frequency is constant, so the only concern is voltage. For most steady-state analysis, a fixed (i.e., constant over an allowable voltage range) power consumption model can be used. Still, some analysis requires consideration of voltage effects to be useful, and then the traditional exponential model can be used to represent real power consumption *P* and reactive power consumption *Q* as:

$$P = P_0 V^a. \tag{7.33}$$

$$Q = Q_0 V^b. \tag{7.34}$$

In these equations, the voltage *V* is normalized to some rated voltage. The exponents *a* and *b* can be 0, 1, or 2 where they could represent constant power, current, or impedance loads, respectively. Alternatively, they can represent composite loads with *a* generally ranging between 0.5 and 1.8 and *b* ranging between 1.5 and 6.0.

7.2.2 Power Flow Analysis

Power flow equations represent the fundamental balancing of power as it flows from the generators to the loads through the transmission network. Both real and reactive power flows play equally important roles in determining the power flow properties of the system. Power flow studies are among the most significant computational studies carried out in power system planning and operations in the industry. Power flow equations allow the computation of the bus voltage magnitudes and their phase angles as well as the transmission line current magnitudes. In actual system operation, both the voltage and current magnitudes need to be maintained within strict tolerances for meeting consumer power quality requirements and for preventing overheating of the transmission lines, respectively. The difficulty in computing the power flow solutions arises from the fact that the equations are inherently nonlinear because of the balancing of power quantities. Moreover, the large size of the power network implies that power flow studies involve solving a very large number of simultaneous nonlinear equations. Fortunately, the sparse interconnected nature of the power network reflects itself in the computational process, facilitating the computational algorithms.

In this section, we first study a simple power flow problem to gain insight into the nonlinear nature of the power flow equations. We then formulate the power flow problem for the large power system. A classical power flow solution method based on the Gauss-Seidel algorithm is studied. The popular Newton-Raphson algorithm, which is the most commonly used power flow method in the industry today, is introduced. We then briefly consider the fast decoupled power flow algorithm, which is a heuristic method that has proved quite effective for quick power flow computations. Finally, we will discuss the dc power flow solution that is a highly simplified algorithm for computing approximate linear solutions of the power flow problem and is becoming widely used for electricity market calculations.

Simple Example of a Power Flow Problem

Let us consider a single generator delivering the load $P + jQ$ through the transmission line with the reactance *x*. The generator bus voltage is assumed to be at the rated voltage, and it is at 1 per unit (pu). The generator bus angle is defined as the phasor reference, and hence, the generator bus voltage phase angle is set to be zero. The load bus voltage has magnitude *V* and phase angle δ. Because the line has been assumed to be lossless, note that the generator real power output must be equal to the real

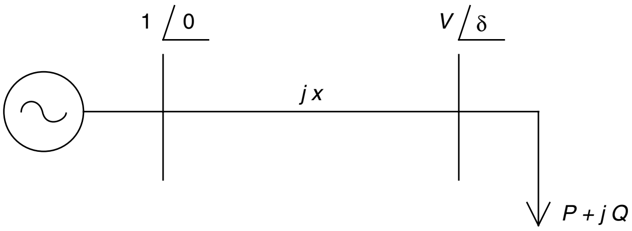

FIGURE 7.9 A Simple Power System

power load P. However, the reactive power output of the generator will be the sum of the reactive load Q and the reactive power "consumed" by the transmission line reactance x.

Let us write down the power flow equations for this problem. Given a loading condition $P + jQ$, we want to solve for the unknown variables, namely, the bus voltage magnitude V and the phase angle δ. For simplicity, we will assume that the load is at unity power factor of $Q = 0$. The line current phasor $\boldsymbol{I}$ from the generator bus to the load bus is easily calculated as:

$$\boldsymbol{I} = \frac{1\angle 0 - V\angle\delta}{jx}. \tag{7.35}$$

Next, the complex power $\boldsymbol{S}$ delivered to the load bus can be calculated as:

$$\boldsymbol{S} = \boldsymbol{V}\boldsymbol{I}^* = \frac{V\angle(\delta + \pi/2)}{x} - \frac{V^2\angle(\pi/2)}{x}. \tag{7.36}$$

Therefore, we get the real and reactive power balance equations:

$$P = \frac{-V\sin\delta}{x} \text{ and } Q = \frac{-V^2 + V\cos\delta}{x}. \tag{7.37}$$

After setting $Q = 0$ in equation 7.37, we can simplify equation 7.37 into a quadratic equation in V^2 as follows:

$$V^4 - V^2 + x^2P^2 = 0. \tag{7.38}$$

Therefore, given any real power load P, the corresponding power flow solution for the bus voltage V can be solved from equation 7.38. We note that for nominal load values, there are two solutions for the bus voltage V, and they are the positive roots of V^2 in the next equation:

$$V^2 = \frac{1 \pm \sqrt{1 - 4x^2P^2}}{2}. \tag{7.39}$$

Equation 7.39 implies that there exist two power flow solutions for load values $P < P_{\max}$ where $P_{\max} = 1/(2x)$, and there exist no power-flow solutions for $P > P_{\max}$. A qualitative plot of the power flow solutions for the bus voltage V in terms of different real power loads P is shown in Figure 7.10.

From the plot and from the analysis thus far, we can make the following observations:

1. The dependence of the bus voltage V on the load P is very much nonlinear. It has been possible for us to compute the power flow solutions analytically for this simple system. In the large power system with hundreds of generators delivering power to thousands of loads, we have to solve for thousands of bus voltages and their phase angles from large coupled sets of nonlinear power flow equations, and the computation is a nontrivial task.
2. Multiple power flow solutions can exist for a specified loading condition. In Figure 7.10, there exist two solutions for any load $P < P_{\max}$. Among the two solutions, the solution on the upper locus with voltage V near 1 pu is considered the nominal solution. For the solutions on the lower locus, the bus voltage V may be unacceptably low for normal operation. The lower voltage solution also requires higher line current to deliver the specified load P, and the line current values can become unacceptably high. In general, for any specified loading condition, we would like to locate the power flow solution that has the most acceptable values of voltages and currents among the multiple power flow solutions. In this example of a single generator delivering power to a single load, there exist two power flow solutions. In a large power system, there may exist a very large number of possible power flow solutions.
3. Once the bus voltage V has been computed from equation 7.39, the bus voltage phase angle δ can be computed from equation 7.37. Then, the line current phasor $\boldsymbol{I}$ can be solved from equation 7.35. Specifically, we would like to ensure that the magnitude of the line current I stays below the thermal limit of the transmission line for preventing potential damage to the expensive transmission line.
4. Power flow solutions may fail to exist at high loading conditions, such as when $P > P_{\max}$ in Figure 7.10. The loading value $P_{\max}$ beyond which power flow solutions do not exist is called the **static limit** in the power literature. Because power flow solutions denote the steady-state operating conditions in our formulation, lack of power flow solutions implies that it is not possible to transfer power from the generator to the load in a steady-state fashion, and the dynamic interactions of the generators and the loads become significant. Operating the power system at loading conditions

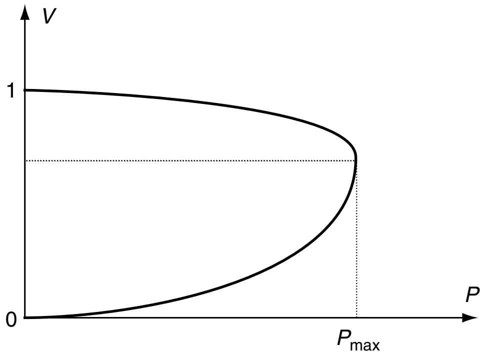

FIGURE 7.10 Qualitative Plot of the Power-Flow Solutions

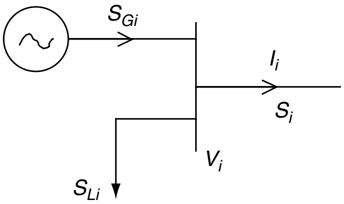

FIGURE 7.11 Complex Power Balance at Bus i

beyond the static limit may lead to catastrophic failure of the system.

Power flow Problem Formulation

In this subsection, we will construct the power flow equations in a structured manner using the admittance matrix $\boldsymbol{Y}_{\text{bus}}$ representation of the transmission network. The admittance matrix $\boldsymbol{Y}_{\text{bus}}$ is assumed to be known for the system under consideration. Let us first look at the complex power balance at any bus, say bus i, in the network.

The power balance equation is given by:

$$\boldsymbol{S}_i = \boldsymbol{V}_i \boldsymbol{I}_i^* = \boldsymbol{S}_{G_i} - \boldsymbol{S}_{L_i}. \tag{7.40}$$

Let us denote the vector of bus voltages as $\underline{\boldsymbol{V}}_{\text{bus}}$ and the vector of bus injection currents as $\underline{\boldsymbol{I}}_{\text{bus}}$. By definition, the admittance matrix $\underline{\boldsymbol{Y}}_{\text{bus}}$ provides the relationship $\underline{\boldsymbol{I}}_{\text{bus}} = \underline{\boldsymbol{Y}}_{\text{bus}}\underline{\boldsymbol{V}}_{\text{bus}}$. Suppose the ith or jth entry $\boldsymbol{Y}_{ij}$ of the $\underline{\boldsymbol{Y}}_{\text{bus}}$ matrix has the magnitude Y_{ij} and the phase γ_{ij}. Then, we can simplify the current injection $\boldsymbol{I}_i$ as:

$$\boldsymbol{I}_i = \sum_j \boldsymbol{Y}_{ij}\boldsymbol{V}_j = \sum_j Y_{ij} V_j \angle(\delta_j + \gamma_{ij}). \tag{7.41}$$

Then, combining equations 7.40 and 7.41, we get the complex power balance equations for the network as:

$$\boldsymbol{S}_i = \boldsymbol{S}_{G_i} - \boldsymbol{S}_{L_i} = \sum_j Y_{ij} V_i V_j \angle(\delta_i - \delta_j - \gamma_{ij}). \tag{7.42}$$

Taking the real and imaginary parts of the complex equation 7.42 gives us the real and reactive power flow equations for the network:

$$P_i = P_{G_i} - P_{L_i} = \sum_j Y_{ij} V_i V_j \cos(\delta_i - \delta_j - \gamma_{ij}). \tag{7.43}$$

$$Q_i = Q_{G_i} - Q_{L_i} = \sum_j Y_{ij} V_i V_j \sin(\delta_i - \delta_j - \gamma_{ij}). \tag{7.44}$$

Generally speaking, our objective in this section is to solve for the bus voltage magnitudes V_i and the phase angles δ_i when the power generations and loads are specified. For a power system with N buses, there are $2N$ number of power flow equations. At each bus, there are six variables: P_{Gi}, Q_{Gi}, P_{Li}, Q_{Li}, V_i, and δ_i. Depending on the nature of the bus, four of these variables will be specified at each bus, leaving two unknown variables at each bus. We will end up with $2N$ unknown variables related by $2N$ equations 7.43 and 7.44, and our aim in the rest of this section is to develop algorithms for solving this problem.

Let us consider a purely load bus first, that is, with $P_{Gi} = Q_{Gi} = 0$. In this case, the loads P_{Li} and Q_{Li} are assumed to be known either from measurements or from load estimates, and the bus voltage variables V_i and δ_i are the unknown variables. Purely load busses with no generation support are called **PQ busses** in power flow studies because both real-power injection P_i and reactive power Q_i have been specified at these busses.

Typically, every generator in the system consists of two types of internal controls, one for maintaining the real power output of the generator and the other for regulating the bus voltage magnitude. In power flow studies, we usually assume that both these control mechanisms are operating perfectly and so the real power output P_{Gi} and V_i are maintained at their specified values. Again, the load variables P_{Li} and Q_{Li} are also assumed to be known. This leaves the generator reactive output Q_{Gi} and the voltage phase angle δ_i as the two unknown variables for the bus. In terms of injections, the real power injection P_i and the bus voltage V_i are then the specified variables; thus, the generator busses are normally denoted **PV busses** in power flow studies.

In reality, the generator voltage control for keeping the bus voltage magnitude at a specified value becomes inactive when the control is pushed to the extremes, such as when the reactive output of the generator becomes either too high or too low. This voltage control limitation of the generator can be represented in power flow studies by keeping track of the reactive output Q_{Gi}. When the reactive generation Q_{Gi} becomes larger than a prespecified maximum value of $Q_{Gi,\,\max}$ or goes lower than a prespecified minimum value $Q_{Gi,\,\min}$, the reactive output is assumed to be fixed at the limiting value $Q_{Gi,\,\max}$ or $Q_{Gi,\,\min}$, respectively, and the voltage control is disabled in the formulation; that is, the reactive power Q_{Gi} becomes a known variable, either at $Q_{Gi,\,\max}$ or $Q_{Gi,\,\min}$, and the voltage V_i then becomes the unknown variable for bus i. In power flow terminology, we say that the generator at bus i has "reached its reactive limits" and, hence, bus i has changed from a PV bus to a PQ bus. Owing to space limitations, we will not discuss generator reactive limits in any more detail in this section.

In addition to PQ busses and PV busses, we also need to introduce the notion of a **slack bus** in the power flow formulation. Note that power conservation demands that the real power generated from all the generators in the network must equal the sum of the total real power loads and the line losses on the transmission network:

$$\sum_i \boldsymbol{P}_{G_i} = \sum_i \boldsymbol{P}_{L_i} + \sum_i \sum_j \boldsymbol{P}_{\text{losses}_{ij}}. \tag{7.45}$$

The line losses associated with any transmission line in turn depend on the line resistance and the line current magnitude. As stated earlier, one of the main objectives of power flow studies is to compute the line currents, and as such, the line current values are not known at the beginning of a power flow computation. Therefore, we do not know the actual values for the line losses in the transmission network. Looking at equation 7.45, we need to assume that at least of one of the variables P_{Gi} or P_{Li} should be a free variable for satisfying the real power conservation. Traditionally, we assume that one of the generations is a "slack" variable, and such a generator bus is denoted the slack bus. At the slack bus, we specify both the voltage V_i and the angle δ_i. The power injections P_i and Q_i are the unknown variables. Again, by tradition, we set the voltage at slack bus to be the rated voltage or at 1 pu and the phase angle to be at zero.

Like in standard textbooks, slack bus is defined in this section to be the first bus in the network with $V_1 = 1$ and the angle $\delta_1 = 0$. Assuming the number of generators to be N_G, the busses 2 through $N_G + 1$ are set to be the PV busses. The remaining buses $N_G + 2$ through N are then the PQ busses.

Gauss-Seidel Algorithm

Let us consider a set of simultaneous linear equations of the form $\underline{A}\underline{x} = \underline{b}$, where $\underline{A}$ is an $n \times n$ matrix and $\underline{x}$ and $\underline{b}$ are $n \times 1$ vectors. Clearly, there exists a unique solution to the problem when the matrix $\underline{A}$ is invertible, and the solution is given by $\underline{x} = \underline{A}^{-1}\underline{b}$. When the matrix size is very large, it may not be possible to compute the inverse of the matrix $\underline{A}$ for finding the solution; there exist other numerical techniques. **Gauss-Seidel algorithm** is one such classical algorithm that tries to arrive at the solution $\underline{x} = \underline{A}^{-1}\underline{b}$ iteratively by starting from an approximate initial condition of $\underline{x}^0$. The iteration for the solution $\underline{x}^{k+1}$ from the previous iterate $\underline{x}^k$ proceeds as follows.

$$x_i^{k+1} = \frac{1}{a_{ii}}\left(b_i - \sum_{j<i} a_{ij}x_j^{k+1} - \sum_{j>i} a_{ij}x_j^k\right) \text{ for } i = 1, 2, \ldots, n \tag{7.46}$$

Here, a_{ij} denotes the *i*th or *j*th entry of the matrix $\underline{A}$ as usual. It can be shown that the iterative solution $\underline{x}^k$ converges to the exact solution $\underline{A}^{-1}\underline{b}$ for any initial condition $\underline{x}^0$, provided the matrix $\underline{A}$ satisfies certain "diagonal dominance" properties. The details are limited here to save space, and they can be found in standard numerical analysis textbooks.

In the previous section, we formulated the power flow problem as a set of simultaneous nonlinear equations of 7.42 and as such, it is not obvious how the Gauss-Seidel algorithm can be applied for solving these equations. The trick here is to visualize the power balance equations to be arising from the network admittance equations $\underline{\boldsymbol{Y}}_{\text{bus}}\ \underline{\boldsymbol{V}}_{\text{bus}} = \underline{\boldsymbol{I}}_{\text{bus}}$. The matrix $\underline{\boldsymbol{Y}}_{\text{bus}}$ takes over the role of the matrix $\underline{A}$ in the linear equations. We will be solving for the bus voltage vector $\underline{\boldsymbol{V}}_{\text{bus}}$. The current injections $\underline{\boldsymbol{I}}_{\text{bus}}$ are not known per se. The current injections are in fact dependent on the bus voltages. As we see next, they can also be computed iteratively from the power injections $\boldsymbol{S_i}$ by using the relationship $\boldsymbol{I_i} = \boldsymbol{S_i}^*/\boldsymbol{V_i}^*$. For a PQ bus, the injection $\boldsymbol{S_i}$ is a specified variable and, hence, is known. For PV busses, only the real power injection P_i is known, while the reactive injection Q_i is evaluated first using the latest estimate of bus voltages $\underline{\boldsymbol{V}}_{\text{bus}}$.

An outline of the Gauss-Seidel algorithm for solving the power flow equations of 7.42 is presented next. Let us start with an initial condition for the bus voltages $\underline{\boldsymbol{V}}_{\text{bus}}^0$, and we would like to compute the iterate $\underline{\boldsymbol{V}}_{\text{bus}}^{k+1}$ from the previous iterate $\underline{\boldsymbol{V}}_{\text{bus}}^k$. Recall that bus 1 is a slack bus and, hence, $\boldsymbol{V}_1^k = 1\angle 0$ for all iterations. Also, busses 2 through $N_G + 1$ are PV busses; therefore we need to keep V_i^k at specified values $V_{i,\text{ specified}} = V_i^0$ for all iterations for the PV busses.

Gauss-Seidel Iterations

- Slack bus ($i = 1$): $\boldsymbol{V}_1^{k+1} = 1\angle 0$
- PV busses ($i = 2, \ldots, N_G + 1$):
  (1) Compute the reactive power generation at bus *i*.

$$\begin{aligned} Q_i^{k+1} &= \sum_{j<i} \boldsymbol{Y}_{ij}\boldsymbol{V}_i^k\boldsymbol{V}_j^{k+1}\sin\left(\delta_i^k - \delta_j^{k+1} - \gamma_{ij}\right) \\ &\quad + \sum_{j\geq i} \boldsymbol{Y}_{ij}\boldsymbol{V}_i^k\boldsymbol{V}_j^k\sin\left(\delta_i^k - \delta_j^k - \gamma_{ij}\right). \end{aligned} \tag{7.47}$$

  (2) Update the bus voltage phasor $\boldsymbol{V}_i^{k+1}$.

$$\boldsymbol{V}_i^{k+1} = \frac{1}{\boldsymbol{Y}_{ii}}\left(\frac{P_i - jQ_i^{k+1}}{\boldsymbol{V}_i^{k^*}} - \sum_{j<i}\boldsymbol{Y}_{ij}\boldsymbol{V}_j^{k+1} - \sum_{j>i}\boldsymbol{Y}_{ij}\boldsymbol{V}_j^k\right). \tag{7.48}$$

  (3) Normalize the magnitude $\boldsymbol{V}_i^{k+1}$ to be V_i^0.

$$\boldsymbol{V}_i^{k+1} = \frac{\boldsymbol{V}_i^{k+1}}{\boldsymbol{V}_i^{k+1}}\boldsymbol{V}_i^0. \tag{7.49}$$

- PQ busses ($i = N_G + 2, \ldots, N$):
  (4) Update the bus voltage phasor $\boldsymbol{V}_i^{k+1}$.

$$\boldsymbol{V}_i^{k+1} = \frac{1}{\boldsymbol{Y}_{ii}}\left(\frac{P_i - jQ_i}{\boldsymbol{V}_i^{k^*}} - \sum_{j<i}\boldsymbol{Y}_{ij}\boldsymbol{V}_j^{k+1} - \sum_{j>i}\boldsymbol{Y}_{ij}\boldsymbol{V}_j^k\right). \tag{7.50}$$

At the end of the $(k+1)$th iteration, we have the updated values of the bus voltages $\underline{\boldsymbol{V}}_{\text{bus}}^{k+1}$. The values of $\underline{\boldsymbol{V}}_{\text{bus}}^{k+1}$ can be compared with the previous set of values $\underline{\boldsymbol{V}}_{\text{bus}}^k$ to check whether the solution has converged.

For the power flow problems, the Gauss-Seidel algorithm has been known to converge even from poor initial conditions, which is one of its main strengths. The algorithm is typically used for "flat starts" when all the initial voltage magnitudes are set to be at their rated values ($V_i^0 = 1$ pu for all the PV busses), and the bus voltage angles are set to be zero ($\delta_i^0 = 0$ for all buses). The relative simplicity of the computations involved in each iteration step in equations 7.46 to 7.49 implies that the algorithm is very fast to implement. On the other hand, the error convergence rate is typically linear in the sense that the ratios of the error norm from one iteration to the previous iteration tend to be constant. Therefore, while the Gauss-Seidel algorithm can converge to the proximity of the actual solution in tens of iterations, it typically takes a large number of iterations to get to an accurate solution estimate.

Newton-Raphson Algorithm

Unlike the Gauss-Seidel algorithm, which was originally developed for solving simultaneous linear equations, the **Newton-Raphson** (NR) algorithm is specifically designed for solving nonlinear equations. The algorithm proceeds iteratively by linearizing the nonlinear equations into linear equations at each step and by solving the linearized equations exactly.

Suppose we want to solve the nonlinear equations $\underline{F}(\underline{x}) = \underline{0}$, where $\underline{x}$ is a $n \times 1$ vector and where $\underline{F} : \Re^n \rightarrow \Re^n$ is a smooth nonlinear function. We have been given an initial condition $\underline{x}^0$. Then, for computing the estimate $\underline{x}^{k+1}$ from x^k, we first linearize the functions $\underline{F}(\underline{x})$ at $\underline{x}^k$ as follows:

$$0 = \underline{F}(\underline{x}) \approx \underline{F}(\underline{x}^k) + \left.\frac{\partial \underline{F}}{\partial \underline{x}}\right|_{\underline{x}^k} \left(\underline{x} - \underline{x}^k\right). \tag{7.51}$$

The solution to the linearized equations 7.17 and 7.18 is defined as the iteration estimate $\underline{x}^{k+1}$:

$$\underline{x}^{k+1} = \underline{x}^k - \left(\left.\frac{\partial \underline{F}}{\partial \underline{x}}\right|_{\underline{x}^k}\right)^{-1} \underline{F}\left(\underline{x}^k\right). \tag{7.52}$$

Note that the linearization of equation 7.51 will be a good approximation if the estimate $\underline{x}^k$ is close to the true solution of $\underline{x}^*$ since $\underline{F}(\underline{x}^*) = 0$. The NR algorithm stated in equation 7.52 can be proved to converge to the true solution $\underline{x}^*$ when the initial condition $\underline{x}^0$ is sufficiently close to $\underline{x}^*$. On the other hand, for initial conditions away from $\underline{x}^*$, the approximation of equation 7.51 becomes poorly justified, and the iterations can quickly diverge away from $\underline{x}^*$. When the iterations converge, owing to the linearized nature of the algorithm, the norm of the error decreases to zero in a "quadratic" fashion. Roughly speaking, the ratios of the error norm from one iteration to the square of the error norm in the previous iteration tend to be a constant. An example would be that the error norms decrease from 0.1 in one iteration, to 0.01 in the next iteration, to 0.0001 in the following iteration. Therefore, given good initial conditions, the NR algorithm can typically get to an accurate solution estimate within a few iterations.

Let us apply the NR algorithm for solving the power flow equations 7.43 and 7.44. We will solve for the unknown variables among the bus voltage magnitudes V_i and angles δ_i first. That is, we define the vector $\underline{x}$ as consisting of all the PV and PQ bus angles and all the PQ bus voltages. PV bus voltages are known and, hence, they are not included in $\underline{x}$:

$$\underline{x} = \left(\delta_2, \ldots, \delta_{N_G+1}, \delta_{N_G+2}, \ldots, \delta_N, V_{N_G+2}, \ldots, V_N\right)^T. \tag{7.53}$$

The corresponding power flow equations are as follows:

$$\underline{F}(\underline{x}) = \begin{pmatrix} P_2 - p_2(\underline{x}) \\ \cdots\cdots\cdots \\ P_{N_G+1} - p_{N_G+1}(\underline{x}) \\ P_{N_G+2} - p_{N_G+2}(\underline{x}) \\ \cdots\cdots\cdots \\ P_N - p_N(\underline{x}) \\ Q_{N_G+2} - q_{N_G+2}(\underline{x}) \\ \cdots\cdots\cdots \\ Q_N - q_N(\underline{x}) \end{pmatrix}$$
$$= \begin{pmatrix} P_2 - \sum_j Y_{2,\,j} V_2 V_j \cos\left(\delta_2 - \delta_j - \gamma_{2,\,j}\right) \\ \cdots\cdots\cdots \\ P_{N_G+1} - \sum_j Y_{N_G+1,\,j} V_{N+1} V_j \cos\left(\delta_{N_G+1} - \delta_j - \gamma_{N_G+1,\,j}\right) \\ P_{N_G+2} - \sum_j Y_{N_G+2,\,j} V_{N+2} V_j \cos\left(\delta_{N_G+2} - \delta_j - \gamma_{N_G+2,\,j}\right) \\ \cdots\cdots\cdots \\ P_N - \sum_j Y_{N,\,j} V_N V_j \cos\left(\delta_N - \delta_j - \gamma_{N,\,j}\right) \\ Q_{N_G+2} - \sum_j Y_{N_G+2,\,j} V_{N+2} V_j \sin\left(\delta_{N_G+2} - \delta_j - \gamma_{N_G+2,\,j}\right) \\ \cdots\cdots\cdots \\ Q_N - \sum_j Y_{N,\,j} V_N V_j \sin\left(\delta_N - \delta_j - \gamma_{N,\,j}\right) \end{pmatrix}. \tag{7.54}$$

The entries of the $\underline{F}$ function in equation 7.54 are the differences between the specified power injections and the computed power injections from the current power flow solutions, and these are usually denoted as the **real** and **reactive power mismatches** at the different busses. In the power flow problem, we want to find a solution that makes the power mismatches in equation 7.54 equal zero.

Suppose an initial condition $\underline{x}^0$ has been specified. Then, the NR algorithm for solving the power flow equations 7.54 proceeds iteratively as follows.

Newton-Raphson Iterations

(1) Compute the power mismatches $\underline{F}(\underline{x}^k)$ for step k from equation 7.54. If the mismatches are within desired tolerance values, the iterations stop.

(2) Compute the power flow Jacobian:

$$\underline{J}^k = \left.\frac{\partial \underline{F}}{\partial \underline{x}}\right|_{\underline{x}^k}. \tag{7.55}$$

Owing to the nice structure of the equations in 7.54, explicit formulas can be derived for the entries of the Jacobian matrix, and the Jacobian for step k can be evaluated by substituting the current values of $\underline{x}^k$ into these formulas.

(3) Compute the correction factors $\Delta\underline{x}^k$ from equation 7.52 by solving a set of simultaneous linear equations:

$$\underline{J}^k \Delta\underline{x}^k = -\underline{F}\left(\underline{x}^k\right). \tag{7.56}$$

The Jacobian matrix $\underline{J}^k$ is extremely sparse even for very large power systems, which facilitates the solution of $\Delta\underline{x}^k$ in equation 7.55.

(4) Evaluate $\underline{x}^{k+1}$ from $\underline{x}^k$ by adding the correction factors $\Delta\underline{x}^k$:

$$\underline{x}^{k+1} = \underline{x}^k + \Delta\underline{x}^k. \tag{7.57}$$

As compared with the Gauss-Seidel algorithm, each iteration step in the NR algorithm is computationally much more intensive because of (a) evaluating the Jacobian and (b) solving the linear equations 7.55. On the other hand, the error convergence rate of the NR algorithm is spectacularly faster, and hence, the NR algorithm requires much fewer iterations to reach comparable solution accuracies. In usual practice, the Gauss-Seidel algorithm is used only for flat starts with poorly known initial conditions. In most other situations, the NR algorithm is the preferred choice.

Fast Decoupled Power Flow Algorithm

Both the Gauss-Seidel algorithm and the Newton-Raphson algorithm are general methods for solving linear and nonlinear equations respectively, and they were tailored toward solving the power flow problem. On the other hand, we study a specific method for power systems in this section called the **fast decoupled power flow algorithm**, which is a heuristic method that is derived by exploiting specific properties for a power system.

The fast decoupled power flow algorithm is essentially a highly simplified and approximated version of the Newton-Raphson algorithm of the previous subsection. We recall that the NR iteration steps are computation intensive because of evaluating $\underline{J}^k$ and solving the Jacobian equation 7.55. In this subsection, we will proceed to simplify this by replacing the iteration specific $\underline{J}^k$ with a constant matrix.

It is a well-known property of power systems that variations in the bus voltage magnitudes mostly affect the reactive power injections under nominal operating conditions. Similarly, the variations in the bus voltage phase angles mostly influence the real power injections. By idealizing this property, we assume that all the Jacobian entries of the form $\frac{\partial p_i}{\partial V_j}$ and $\frac{\partial q_i}{\partial \delta_j}$ are all identically zero. Next, if we assume that the bus voltage magnitudes are all close to one pu, and the voltage phase angle differences on the two ends of any transmission line are all close to zero, the NR algorithm greatly simplifies to the fast decoupled algorithm stated in equation 7.58.

Let us split the power flow state vector $\underline{x}$ in equation 7.53 into the voltage magnitude $\underline{V}$ and angle δ counterparts:

$$\underline{\delta} = (\delta_2, \ldots, \delta_{N_G+1}, \delta_{N_G+2}, \ldots, \delta_N)^T, \quad \underline{V} = (V_{N_G+2}, \ldots, V_N)^T. \tag{7.58}$$

Similarly, we separate the real and reactive power mismatches in equation 7.54:

$$\Delta\underline{P} = \begin{pmatrix} P_2 - p_2(\underline{x}) \\ \cdots\cdots\cdots \\ P_{N_G+1} - p_{N_G+1}(\underline{x}) \\ P_{N_G+2} - p_{N_G+2}(\underline{x}) \\ \cdots\cdots\cdots \\ P_N - p_N(\underline{x}) \end{pmatrix} \text{ and } \Delta\underline{Q} = \begin{pmatrix} Q_{N_G+2} - q_{N_G+2}(\underline{x}) \\ \cdots\cdots\cdots \\ Q_N - q_N(\underline{x}) \end{pmatrix}. \tag{7.59}$$

Suppose initial conditions for the voltage magnitude vector $\underline{V}^0$ and angle vector δ^0 have been specified. The fast decoupled algorithm then proceeds iteratively as follows.

Fast Decoupled Iterations

(1) Compute the real and reactive power mismatches $\Delta\underline{P}(\underline{x}^k)$ and $\Delta\underline{Q}(\underline{x}^k)$. If the mismatches are within desirable tolerance, the iterations end.

(2) Normalize the mismatches by dividing each entry by its respective bus voltage magnitude:

$$\Delta\underline{\tilde{P}}^k = \begin{pmatrix} \Delta P_2^k / V_2^k \\ \cdots\cdots\cdots \\ \Delta P_{N_G+1}^k / V_{N_G+1}^k \\ \Delta P_{N_G+2}^k / V_{N_G+2}^k \\ \cdots\cdots\cdots \\ \Delta P_N^k / V_N^k \end{pmatrix} \text{ and } \Delta\underline{\tilde{Q}}^k = \begin{pmatrix} \Delta Q_{N_G+2}^k / V_{N_G+2}^k \\ \cdots\cdots\cdots \\ \Delta Q_N^k / V_N^k \end{pmatrix}. \tag{7.60}$$

(3) Solve for the voltage magnitude and angle correction factors $\Delta\underline{V}^k$ and $\Delta\underline{\delta}^k$ by using the constant matrices $\overline{B}$ and $\overline{\overline{B}}$, which are extracted from the bus admittance matrix $\underline{\boldsymbol{Y}}_{\text{bus}}$:

$$\overline{B}\Delta\underline{\delta}^k = \Delta\underline{\tilde{P}}^k \text{ and } \overline{\overline{B}}\Delta\underline{V}^k = \Delta\underline{\tilde{Q}}^k. \tag{7.61}$$

Define $B_{ij} = \text{imag}(\boldsymbol{Y}_{ij})$. The matrices $\overline{B}$ and $\overline{\overline{B}}$ are constructed as follows:

$$\overline{B} = -\begin{bmatrix} B_{2,\,2} & \ldots & B_{2,\,N} \\ \ldots & \ldots & \ldots \\ B_{N,\,2} & \ldots & B_{N,\,N} \end{bmatrix} \text{ and } \overline{\overline{B}} = -\begin{bmatrix} B_{N_G+2,\,N_G+2} & \ldots & B_{N_G+2,\,N} \\ \ldots & \ldots & \ldots \\ B_{N,\,N_G+2} & \ldots & B_{N,\,N} \end{bmatrix} \tag{7.62}$$

(4) Update the voltage magnitude and angle vectors.

$$\underline{\delta}^{k+1} = \underline{\delta}^k + \Delta\underline{\delta}^k, \; \underline{V}^{k+1} = \underline{V}^k + \Delta\underline{V}^k. \tag{7.63}$$

By using the constant matrices $\overline{B}$ and $\overline{\overline{B}}$ in equation 7.60, the time taken for evaluating one iteration for the fast decoupled algorithm is considerably less than that of the Newton-Raphson algorithm. In repeated power flow runs of the same power system, the inverses of the matrices $\overline{B}$ and $\overline{\overline{B}}$ can directly be stored, which enables the implementation to be very fast. However, the convergence speed of the fast decoupled algorithm is not quadratic, and it takes considerably more iterations to converge to an accurate power flow solution. Fast decoupled algorithm is used in applications where quick approximate estimates of power flow solutions are required.

Direct Current Power Flow Algorithm

A further simplification of the fast decoupled algorithm is the highly approximate dc power flow algorithm, which completely transforms the nonlinear power flow equations into linear equations by using drastic assumptions. In addition to the assumptions used in deriving the fast decoupled method, we also assume that all the voltage magnitudes are at 1 pu and all the transmission lines are lossless.

With these assumptions, the voltage correction factors $\Delta \underline{V}^k$ become irrelevant in equation 7.60. Moreover, the angle variables can be solved explicitly by the linear equations:

$$\overline{B}\underline{\delta} = \underline{P}, \tag{7.64}$$

where $\underline{P}$ is the vector of bus power injections. The resulting solution for the bus voltage phase angles is called the **dc power flow model**. It gives approximate values for the phase angles across the power system. The phase angles can be used to approximate the real power flow on any transmission line by dividing the phase angle difference between the two ends of the transmission lines by the line reactance. The advantage of the dc power flow model is its extreme simplicity in finding a power flow solution. The limitations of the solution need to be kept in mind, however, in light of the drastic assumptions that were used to simplify the nonlinear power flow equations into linear equations.

7.3 Dynamic Analysis

The power system in practice is constantly undergoing changes because of such factors as changing loads, planned outages of equipment for maintenance or other disturbances (e.g., equipment failures, line faults, lightning strikes etc), or any number of other events that cause outages. During disturbances, the precise balance between generation and load is not maintained. These disturbances may lead to oscillations, and the system must be able to dampen these and reach a viable steady-state operating condition. Extremely fast electromagnetic transients, such as those that arise from lightning strikes or switching actions, are not considered from a system point of view, hence, the network models introduced in the previous sections are still valid. Dynamic models for generator units models still must be introduced to understand system response. Load dynamics are also important, particularly from large induction motors, but such details are beyond the scope here. This section focuses on the transient response of the system over fractions of a second to oscillations over several seconds and then up to slow dynamics that occur with voltage problems over several minutes.

7.3.1 Modeling

Electric Generators

To understand modeling generators for dynamic analysis, more details on the physical construction are needed. Most **generators** are three-phase synchronous machines, which means they are designed to operate at a constant frequency. The machine rotor is driven mechanically by the prime mover governing system to control power output and speed. Synchronous machine rotors can be classified as either **cylindrical** or **salient pole**. Cylindrical rotors have an even air gap at all points between the stator, i.e., the stationary part of the machine, and the rotor. This construction is used for machines that rotate at high speed, typically steam-driven generators. Steam generators generally are two-pole or four-pole machines and so rotate, in North America, at 1800 RPM or 3600 RPM to produce the desired 60 Hz signal. Hydro generators, conversely, may have numerous pole pairs, as it is more efficient to drive them at lower speeds. These generators have a salient pole construction that leads to a variable air gap between the stator and the rotor.

For modeling purposes, the pole construction is important because it represents the mechanical speed of rotations and also because the transfer of power from the rotor to the stator through mutual inductance depends on the size of the air gap (i.e., the reluctance of the air gap and, thus, the effective coupling). During disturbances, these variations are most evident, and the effective circuit inductances must be modeled accurately. In modern power system modeling for dynamic analysis, a rotating frame of reference is chosen to represent these effects. The circuit equations are then written in terms of direct and quadrature axes. For simplicity, the more involved rotating frame of reference models are not developed here but instead a simple model approximating the variable inductances is presented. To begin, there are primarily two sets of windings of concern:

- **Armature windings**: The windings on the stator are referred to as the armature windings. The armature is the source from which the power generated will be drawn. A voltage is induced in the armature from the rotation of the field generated by currents on the rotor. For purposes of modeling, the self-inductance, including leakage, and mutual inductance between phases of the armature windings describe the circuit performance as current flows from the terminals. The armature windings

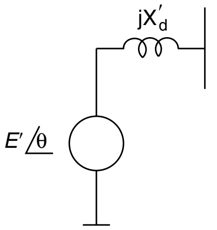

FIGURE 7.12 A Simple Model of a Synchronous Generator Armature for Dynamic Studies

are distributed in slots around the stator to produce a high-quality sinusoidal signal. Winding resistance may also be included but is small and often neglected in simple studies.

- **Field windings**: These windings reside on the rotor and provide the primary excitation for the machine. The windings are supplied with a dc current so that with rotation, they induce a voltage in the armature windings. The current is controlled by the exciter to provide the desired voltage across the armature windings. This current must be constrained to avoid overheating of the windings; the modeling of these limits and excitation of the control circuit are critical for analysis.

In addition, in salient pole machines, there are solid conducting bars in the pole faces called **damper windings**, or amortisseurs windings, that influence the effective inductance. These windings serve to damp out higher frequency oscillations. Similar effects are also seen in the cylindrical case through eddy current flows in the rotor even though damper windings may not be present. These details are not pursued further here.

The armature will be modeled as a voltage controlled by the rotor current behind a simple transient reactance as illustrated in Figure 7.12. The induced voltage $E'\angle\theta$, referred to as the voltage behind the reactance, is connected to the generator terminal through the transient reactance $x_d^{'}$, where the subscript indicates a direct axis quantity and the superscript a transient quantity.

To control the terminal voltage, the field current is controlled by the exciter, which in turn varies the voltage behind the reactance. A simple high gain exciter with limits can be modeled as in Figure 7.13. For the field circuit, there is a time constant associated with the winding inductance and resistance. Together, these describe the basic electromagnetic time constants for a simple generator model. There is often a supplementary stabilization control on large units referred to as a power system stabilizer (PSS). The interested reader is referred to the literature.

Mechanically, the generator is similar to a mass spring system with some frictional damping. If there is a net imbalance of torque acting on the rotor, then, neglecting damping, the machine will accelerate according to the well-known swing equations:

$$\frac{d\omega_m}{dt} = \dot{\omega}_m = \frac{1}{J}(T_m - T_e), \tag{7.65}$$

where J is the rotational inertia, T_m is the mechanical torque input, and T_e the electromagnetic torque that arises from producing an electric power output. Recall that power equals the torque times angular velocity, so multiplying both sides of equation 7.65 by ω_m yields:

$$\dot{\omega}_m\omega_m = \frac{1}{J}(P_m - P_e). \tag{7.66}$$

Typically, engineers normalize the machine inertia based on the machine rating and use the per unit inertia constant H as:

$$H = \frac{1}{2}\frac{J(\omega_m^{o})^2}{S_B}, \tag{7.67}$$

with ω_m^0 the synchronous mechanical speed. If in addition the speed and the real powers are expressed on a per unit basis, then substituting equation 7.67 into equation 7.66 gives:

$$\dot{\omega} = \frac{\omega_s}{2H}(P_m - P_e) \text{ or } \dot{\omega} = \frac{\pi f_s}{H}(P_m - P_e), \tag{7.68}$$

where $\dot{\omega}$ is now the acceleration relative to synchronous speed. The electrical power output is a function of the rotor angle θ, and so we need to write the simple differential equation that relates rotor angle to speed:

$$\dot{\theta} = \omega - \omega_s. \tag{7.69}$$

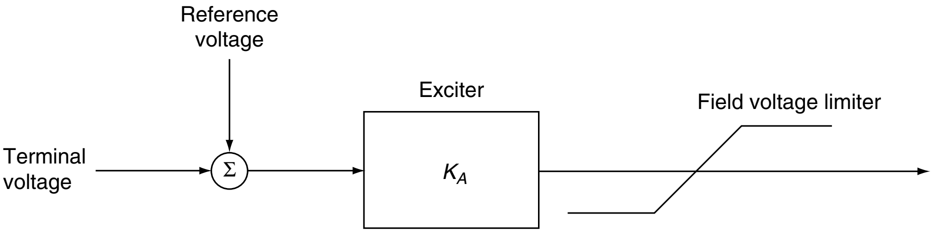

FIGURE 7.13 Basic Components of Simple Voltage Regulation and Excitation System

Thus, the mechanical equations can be expressed as a second-order dynamic system. In the next section, the analysis of this in a connected system is discussed.

7.3.2 Power System Stability Analysis

The power system is a nonlinear dynamic system consisting of generators, loads, and control devices, which are coupled together by the transmission network. The dynamic equations of the generator have been discussed in the previous section. The interactions of the generators with the loads and the control devices can result in diverse nonlinear phenomena. Specifically, we are interested in understanding whether the system response can return to an acceptable operating condition following disturbances. Normally, we distinguish between two types of disturbances in the power system context:

- **Minor disturbances** such as normal random load fluctuations, are denoted small-disturbances, and the ability of the power system to damp out such small disturbances is called **small-signal stability**. In the next section, we will learn that small-signal stability can be understood by computing the eigenvalues of the system Jacobian matrix that is evaluated at an equilibrium point.
- **Major disturbances**, such as transmission line trippings and generator outages, are denoted large disturbances, and the capability of the power system to return to acceptable operating conditions following a large disturbance is called the **transient stability**. In the following paragraphs, we will also study techniques for verifying the transient stability of a power system following a specific large disturbance.

Small-Signal Stability

Consider a nonlinear system described by the following ordinary differential equation:

$$\frac{d\underline{x}}{dt} = \underline{f}(\underline{x}),\ \underline{x} \in \Re^n,\ \underline{f}\colon \Re^n \to \Re^n,\ \underline{f} \text{ is smooth.} \qquad (7.70)$$

Suppose that $\underline{x}^*$ is an equilibrium point for the system. That is, $\underline{f}(\underline{x}^*) = \underline{0}$. We define the Jacobian matrix $\underline{A}$ for the equilibrium to be the matrix of partial derivatives $\frac{\partial f}{\partial \underline{x}}$ evaluated at $\underline{x}^*$. Then, classical analysis in nonlinear dynamical system theory tells us that the equilibrium $\underline{x}^*$ is locally stable if all the eigenvalues of the matrix $\underline{A}$ have negative real parts. Recall that the eigenvalues of a matrix $\underline{A}$ are defined as the solutions λ_i of the polynomial matrix characteristic equation det $(\lambda \underline{I}_n - \underline{A}) = 0$, where $\underline{I}_n$ denotes the n–X–n identity matrix. In addition, the equilibrium will be locally unstable if any one of the eigenvalues has a positive real part.

In the power system context, the concept of local stability is known as the small-signal stability or the small-disturbance stability. We will look at a simple power system example next for studying the concept in more detail.

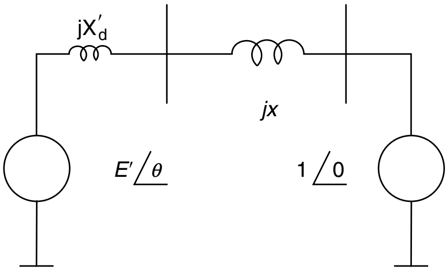

FIGURE 7.14 A Simple Power System

A single generator that is connected to an ideal generator bus through a transmission line is shown in Figure 7.14. The ideal generator maintains its bus voltage at 1 pu irrespective of the external dynamics and is referred to as an infinite bus. It also defines the reference angle for this power system, and the angle is set at zero. The other generator is represented by the classical machine model with a voltage source of $E'\angle\theta$ connected to the generator terminal through the transient reactance $x_d^{'}$. In the classical machine model, the internal induced voltage E' is assumed to remain constant, and the rotor angle θ follows the second-order swing equations as in equation 7.68 but here includes a damping component P_d:

$$\frac{2H}{\omega_s}\ddot{\theta} = P_m - P_e - P_d. \qquad (7.71)$$

This can be rewritten into the standard form of:

$$\begin{pmatrix} \dot{\theta} \\ \dot{\omega} \end{pmatrix} = \begin{pmatrix} \omega - \omega_s \\ \frac{\omega_s}{2H}(P_m - P_e - P_d) \end{pmatrix}. \qquad (7.72)$$

For the power system in Figure 7.14, the electrical power output P_e is easily calculated as:

$$P_e = \frac{E' \sin\theta}{x_d' + x} = P_{\max} \sin\theta, \qquad (7.73)$$

where $P_{\max} = E'/(x_d' + x)$ is a constant. The remaining term, the damping power P_d, is usually defined as $P_d = D(\omega' - \omega_s)$, where D is known as the damping constant for the generator, which is a positive constant. Substituting the entries for P_e and P_d into equation 7.72, we get the dynamic equations for the generator as:

$$\begin{pmatrix} \dot{\theta} \\ \dot{\omega} \end{pmatrix} = \begin{pmatrix} \omega - \omega_s \\ \frac{\omega_s}{2H}(P_m - P_{\max}\sin\theta - D(\omega - \omega_s)) \end{pmatrix}. \qquad (7.74)$$

The equilibrium points for equation 7.74 can be easily solved by setting the derivatives to be zero. The $(\theta^*, \omega_s)^T$ is an equilibrium point for this system if $P_m = P_{\max}\sin\theta^*$. The equilibrium points can be identified visually by plotting P_e and P_m as shown in Figure 7.15. The intersection of the

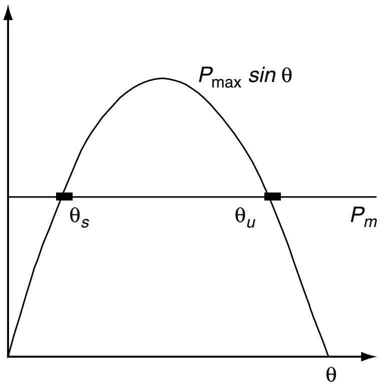

FIGURE 7.15 Plot of P_e and P_m

constant line P_m with the curve $P_{\max}\sin\theta$ highlighted by the black marks depict the two possible equilibrium points when $P_m < P_{\max}$. Let us denote the equilibrium point between 0 and $\pi/2$ by θ_s and the other equilibrium between $\pi/2$ and π by θ_u.

We will show that the equilibrium $(\theta_s, \omega_s)^T$ is small-signal stable, while the other equilibrium $(\theta_u, \omega_s)^T$ is small-signal unstable. For assessing the small-signal stability, we need to evaluate the Jacobian matrix $\underline{A}$ at the respective equilibrium point. The Jacobian is first derived as:

$$\frac{\partial \underline{f}}{\partial \underline{x}} = \begin{bmatrix} 0 & 1 \\ \frac{\omega_s}{2H}(-P_{\max}\cos\theta) & \frac{\omega_s}{2H}(-D) \end{bmatrix}. \tag{7.75}$$

The eigenvalues of the system matrix $\underline{A}$ can easily be computed at the equilibrium point $(\theta_s, \omega_s)^T$ as the solutions of the second-order polynomial:

$$\lambda^2 + \frac{\omega_s}{2H} D\lambda + \frac{\omega_s}{2H} P_{\max}\cos\theta_s = 0. \tag{7.76}$$

Since θ_s by definition lies between 0 and $\pi/2$, *cos* θ_s is positive. Therefore, the two roots of the characteristic equation 7.76 have negative real parts, and the equilibrium $(\theta_s, \omega_s)^T$ is small-signal stable. Therefore, the system will return to the equilibrium condition following any small perturbations away from this equilibrium point. On the other hand, when the equilibrium point $(\theta_u, \omega_s)^T$ is considered, note that cos θ_u is negative because θ_u lies between $\pi/2$ and π. Then, the characteristic equation 7.76 will have one positive real eigenvalue and one negative real eigenvalue when θ_s is replaced by θ_u. Therefore, the equilibrium $(\theta_u, \omega_s)^T$ is small-signal unstable.

Normally, the power system is operated only at the stable equilibrium point $(\theta_s, \omega_s)^T$. The unstable equilibrium point $(\theta_u, \omega_s)^T$ also plays an important role in determining the large disturbance response of the system that we study in the next subsection. Unlike this simple system, assessing the small-signal stability properties of a realistic large power system is an extremely challenging task computationally.

Transient Stability

Assume that the power system is operating at a small-signal stable equilibrium point. Suppose the system is suddenly subject to a large disturbance such as a line fault. Then, the power system protective relays will detect the fault, and they will isolate the faulty portion of the network by possibly tripping some lines. The occurrence of fault and the subsequent line trippings will cause the system response to move away from the equilibrium condition. After the fault has been cleared, the ability of the system to return to nominal equilibrium condition is called the **transient stability** for that fault scenario. We will study a transient stability example for the simple system in Figure 7.16.

Suppose we want to study the occurrence of a solid three-phase-to-ground fault at the middle point of the lower transmission line in Figure 7.16. We usually assume that the system is operating at a nominal equilibrium point before the fault occurs. For this prefault system, the effective transmission line reactance is $x/2$, since there are two transmission lines in parallel each with reactance x. The dynamic equations for the prefault system are then given by:

$$\begin{pmatrix} \dot\theta \\ \dot\omega \end{pmatrix} = \begin{pmatrix} \omega - \omega_s \\ \frac{\omega_s}{2H}\left(P_m - P_{\max}^{\text{pre}}\sin\theta - D(\omega - \omega_s)\right) \end{pmatrix}, \tag{7.77}$$

where $P_{\max}^{\text{pre}} = E'/x'_d + x/2$. The equilibrium points can be solved by setting the derivatives to zero in equation 7.77. Let us denote the stable equilibrium by $(\theta_s^{pre}, \omega_s)^T$ where θ_s^{pre} is the equilibrium solution of the rotor angle between 0 and $\pi/2$.

Next, let us say that the fault occurs at time t = 0. When the solid fault is present at the middle of the lower transmission line, the system in Figure 7.14 changes to the configuration shown in Figure 7.17.

The computation of the generator electrical power output P_e for the fault-on system in Figure 7.15 requires a little more work. Looking from the generator terminal bus, the effective Thevenin voltage is $1\angle 0[x/(\frac{x}{2}+x)] = \frac{1}{3}\angle 0$, which is $1/3\angle 0$. Next, the effective Thevenin reactance is the parallel equivalent of reactance x and the reactance $x/2$, which is $x/3$. Therefore, the electrical power P_e during the fault-on period is given by:

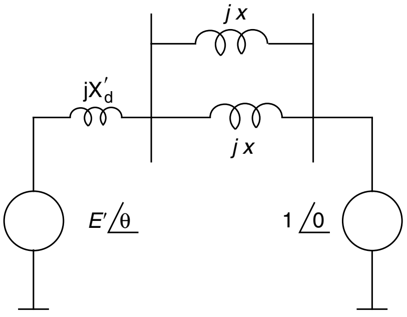

FIGURE 7.16 Prefault Power System

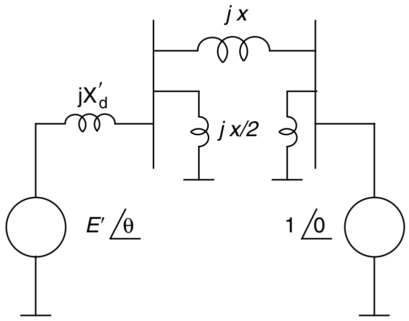

FIGURE 7.17 Fault-On Power System

$$P_e^{\text{fault}} = P_{\max}^{\text{fault}} \sin\theta = \frac{E'/3}{x_d' + x/3} \sin\theta. \tag{7.78}$$

The dynamic equations for the fault-on system are then given by:

$$\begin{pmatrix} \dot{\theta} \\ \dot{\omega} \end{pmatrix} = \begin{pmatrix} \omega - \omega_s \\ \frac{\omega_s}{2H}(P_m - P_{\max}^{\text{fault}} \sin\theta - D(\omega - \omega_s)) \end{pmatrix}. \tag{7.79}$$

Let us assume that the relays clear the fault at time $t = t_c$ by opening the lower transmission line at both the sending and receiving end. Then, the system configuration becomes as shown in Figure 7.14, and the dynamic equations for the postfault system are given by:

$$\begin{pmatrix} \dot{\theta} \\ \dot{\omega} \end{pmatrix} = \begin{pmatrix} \omega - \omega_s \\ \frac{\omega_s}{2H}(P_m - P_{\max}^{\text{post}} \sin\theta - D(\omega - \omega_s)) \end{pmatrix}, \tag{7.80}$$

where $P_{\max}^{\text{post}} = E'/xd' + x$. If the system settles down to the stable equilibrium of the postfault system of equation 7.80 after the fault is cleared, we say that the system is transient stable for the fault under study. To verify this numerically, we proceed as follows.

Transient Stability Study by Numerical Integration

(1) The system is at $(\theta_s^{\text{pre}}, \omega_s)$ before the fault occurs. Therefore, we start the simulation with $(\theta, \omega)^T = (\theta_s^{\text{pre}}, \omega_s)^T$ at time $t = 0$.

(2) During the fault-on period, the system dynamics is governed by equation 7.79, and the fault-on period is from time $t = 0$ through time $t = t_c$. Therefore, we integrate the equation 7.79 starting from the initial condition $(\theta_s^{\text{pre}}, \omega_s)^T$ at time $t = 0$ for a time period from $t = 0$ to $t = t_c$. Let us denote the system state at the end of fault-on period numerical integration at time $t = t_c$ by the clearing state $(\theta_c, \omega_c)^T$.

(3) At time $t = t_c$, the system equations change to the postfault equation 7.80. Therefore, we integrate the equation 7.80 starting from the clearing state $(\theta_c, \omega_c)^T$ at time $t = t_c$ for a period of several seconds to assess whether the system response converges to the stable equilibrium $(\theta_s^{\text{post}}, \omega_s)^T$. If the postfault response settles down to the nominal equilibrium, we can determine the system to be transient stable for the disturbance. If the postfault system response diverges away, the system is not transient stable.

The steps involved in the numerical integration procedure for a realistic large system are similar to the outline above for the simple system. The models are of very large dimensions for real-size power systems. Hence, the formulation of the prefault, fault-on, and postfault models becomes a nontrivial task, and the numerical integration becomes highly time-consuming.

Equal Area Criterion

To verify the transient stability, it is possible to derive analytical conditions for the power system in Figure 7.15. For simplicity, we assume that the damping constant $D = 0$ and that the fault clearing is instantaneous ($t_c = 0$). We recall that the dynamics of the prefault system are described by:

$$\frac{2H}{\omega_s} \ddot{\theta} = P_m - P_{\max}^{\text{pre}} \sin\theta, \tag{7.81}$$

where $P_{\max}^{\text{pre}} = E'/xd' + x/2$. Similarly, the equations for the postfault system are described by:

$$\frac{2H}{\omega_s} \ddot{\theta} = P_m - P_{\max}^{\text{post}} \sin\theta, \tag{7.82}$$

where $P_{\max}^{\text{post}} = E'/xd' + x$. Clearly, it follows that $P_{\max}^{\text{pre}} > P_{\max}^{\text{post}}$ because $x/2 < x$. Intuitively, more power can be transferred in the prefault configuration with two parallel lines compared to one transmission line present in the postfault configuration.

As stated earlier, the system is operating at the prefault equilibrium $(\theta_s^{\text{pre}}, \omega_s)^T$ before the fault occurs where $\sin\theta_s^{\text{pre}} = P_m/P_{\max}^{\text{pre}}$, and θ_s^{pre} lies between 0 and $\pi/2$. When the fault is cleared instantaneously at time $t = 0$, we would like to know whether the transient starting from $(\theta_s^{\text{pre}}, \omega_s)^T$ will settle to the postfault system equilibrium $(\theta_s^{\text{post}}, \omega_s)^T$ or whether it will diverge away. Convergence to $(\theta_s^{\text{post}}, \omega_s)^T$ or divergence implies transient stability or instability, respectively.

Let us start with the analysis. First, we note that $\theta_s^{\text{pre}} < \theta_s^{\text{post}}$ because $P_{\max}^{\text{pre}} > P_{\max}^{\text{post}}$. For visualization, let us plot P_e and P_m for the postfault system as shown in Figure 7.18.

The dynamics of the transient starting from $(\theta_s^{\text{pre}}, \omega_s)^T$ are governed by the second-order equation:

$$\frac{2H}{\omega_s} \ddot{\theta} = \frac{2H}{\omega_s} \dot{\omega} = P_m - P_{\max}^{\text{post}} \sin\theta. \tag{7.83}$$

Therefore, the sign of the term $P_m - P_{\max}^{\text{post}} \sin\theta$ determines whether the speed derivative $\dot{\omega}$ is positive or negative. Inspecting the plot Figure 7.18, we conclude that the rotor frequency ω increases whenever the rotor angle θ is below the P_m line because then $P_m - P_{\max}^{\text{post}} \sin\theta$ will be positive. Similarly, the

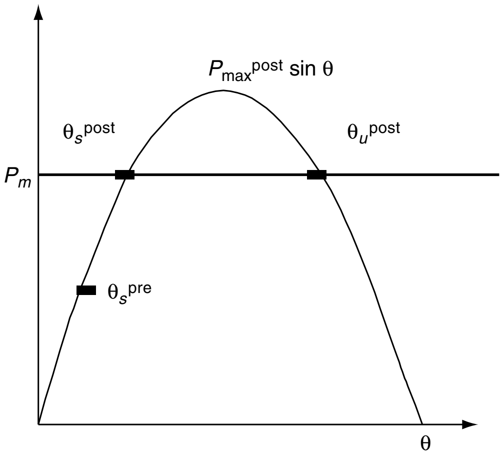

FIGURE 7.18 Power-Angle Curve for the Postfault System

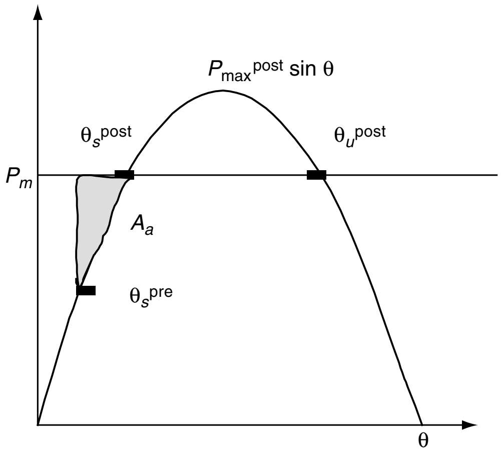

FIGURE 7.19 Acceleration Area for the Postfault System

rotor speed decreases in value when the angle θ is above the P_m line because then $P_m - P_{\max}^{\text{post}}\sin\theta$ will be negative.

Let us recall that the postfault system response starts at $(\theta_s^{\text{pre}}, \omega_s)^T$ at time $t = 0$. As noted earlier, the initial rotor angle θ_s^{pre} lies beneath the P_m line in Figure 7.18, hence, the speed ω increases from the initial value $\omega = \omega_s$ at time $t = 0$ as soon as the fault is cleared. When ω increases above ω_s, the rotor angle starts to increase from θ_s^{pre} because $\dot{\theta} = \omega - \omega_s$ for the machine dynamics. Therefore, the rotor angle moves up on the power-angle curve in Figure 7.18, and the rotor speed keeps increasing until the rotor angle reaches the value θ_s^{post} at the intersection point with the P_m line in Figure 7.18. Let us say that the angle θ takes time t_1 seconds to increase from the initial value θ_s^{pre} at time $t = 0$ to the value θ_s^{post}. During this time period from $t = 0$ to $t = t_1$, the speed ω has increased from ω_s to some higher value, such as ω_1. The dynamic state of the postfault system at time $t = t_1$ is then given by $(\theta_s^{\text{post}}, \omega_1)^T$. Note that even though the rotor angle θ equals θ_s^{post} at time $t = t_1$, the system is not in the equilibrium condition because the speed ω equals ω_1 at time t_1, and ω_1 is greater than the equilibrium speed value ω_s.

By construction, the speed value ω_1 is defined as follows by the dynamics of equation 7.83:

$$\omega_1 - \omega_s = \int_{t=0}^{t=t_1} \dot{\omega}dt = \int_{\theta_s^{pre}}^{\theta_s^{\text{post}}} \frac{\omega_s}{2H}\left(P_m - P_{\max}^{\text{post}}\sin\theta\right)d\theta = \frac{\omega_s}{2H}A_a, \qquad (7.84)$$

where A_a is the shaded area shown in Figure 7.19. Because the rotor acceleration $\ddot{\theta}$ has been positive during this time period from $t = 0$ to $t = t_1$, the angle has been accelerating in the area shown, and hence, the area A_a is called the **acceleration area**.

When the transient reaches $(\theta_s^{\text{post}}, \omega_1)^T$ at time $t = t_1$, the rotor angle keeps on increasing because $\dot{\theta} = \omega_1 - \omega_s > 0$ at time t_1. However, for time $t > t_1$, the rotor angle moves above the P_m line in Figure 7.18, and hence, the derivative of speed becomes negative. That is, the speed ω starts to decrease from the value ω1 as the time increases from $t = t_1$. Only after the speed ω has decreased below the synchronous speed ω_s can the rotor angle start to decrease. Until then, the rotor angle will keep increasing, and the rotor speed keeps decreasing as time increases from $t = t_1$.

Looking at the power-angle plot in Figure 7.19, the rotor angle stays above the P_m line only up to the unstable equilibrium value θ_u^{post}. If the rotor angle were to increase above θ_s^{post}, then the speed derivative $\dot{\omega}$ becomes positive again, and the speed will start to increase. In this case, there is no scope for speed ω to decrease to the synchronous speed ω_s, and transient instability results. Therefore, for any chance of transient stability, and for response to settle down around $(\theta_s^{\text{post}}, \omega_s)^T$, we need the speed ω to decrease below ω_s before the rotor angle reaches the critical value θ_u^{post}. Graphically, this implies that the maximum deceleration area $A_d^{\max}$ shown in Figure 7.20 needs to be larger than the acceleration area A_a shown in Figure 7.19.

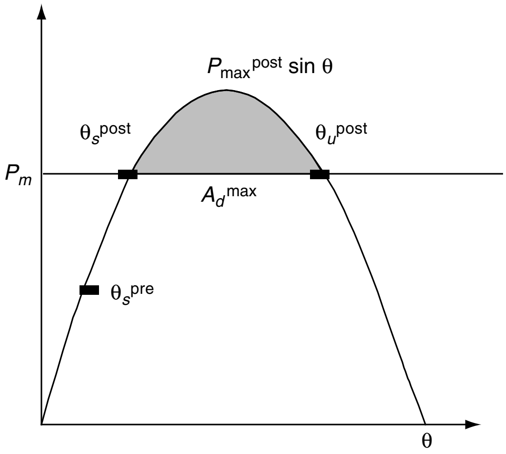

FIGURE 7.20 Maximum Deceleration Area for the Postfault System

When $A_d^{\max} > A_a$, as the rotor angle decelerates past θ_s^{post} from time $t = t_1$, the deceleration area will become equal to the accelaration area at some intermediate value of θ between θ_s^{post} and θ_u^{post} at some time of $t = t_2$. For time $t > t_2$, the speed ω falls below ω_s, and the rotor angle θ starts to decrease back toward θ_s^{post}. The alternating scenarios of rotor angle acceleration and deceleration will continue before the angle swings are damped out eventually by the rotor damping effects that have been ignored thus far. Therefore, we say that the system is transient stable whenever $A_d^{\max} > A_a$.

On the contrary, when $A_d^{\max} < A_a$, the rotor speed stays above ω_s, the rotor angle reaches θ_u^{post}. Then, the rotor speed starts to increase away from ω_s monotonously. In this case, the rotor speed never recovers below ω_s, and the rotor angle continuously keeps increasing. The transient diverges away, thus resulting in transient instability.

The analytical criterion presented in this section for the simple system can be extended to multimachine models using Lyapunov theory and based on the concepts of energy functions. Development of analytical criteria for checking the transient stability of large representative dynamic models remains a research area. Numerical integration procedures outlined in the previous sections are commonly used by the power industry for studying the transient stability properties of large power systems.

7.4 Conclusion

This chapter has introduced the readers to the basic concepts in power system analysis, namely modeling issues, power flow studies, and dynamic stability analysis. The concepts have been illustrated on simple power system representations. In real power systems, power-flow studies and system stability studies are routinely carried out for enduring the reliability and security of the electric grid separation. While the basic concepts here have been summarized in this chapter on simple examples, the real power systems are large-scale, nonlinear systems. The large interconnected nature of electric networks makes the computation aspects highly challenging. We have highlighted some of these issues in this section, and the readers are encouraged to refer to advanced power system analysis textbooks for additional details.

Power System Operation and Control

8.1 Introduction

The primary objective of power system operation is delivering power to consumers meeting strict tolerances on voltage magnitude and frequency. Accordingly, the operation control problems naturally divide into the control of voltage magnitudes or the **voltage control** issues and the control of system frequency or the **frequency control** problems. Because a power system is an interconnected, large system spread over a geographically wide network, operation of the large system is complex. The controls are built to exploit the inherent time-scale and structural properties of the system. In this chapter, we focus on the frequency control problem as an example of power system controls. In fact, the **automatic frequency control** in the North American electric power grid was the first instance of a successful implementation of a large-scale network-based control scheme.

The frequency control includes two subproblems. First, we need to determine optimal values of generations that minimize the total generation costs while meeting the load demands. This problem is denoted the **economic dispatch problem** and is discussed in Section 8.2.

It can be shown that differences between total active power that is generated and the total active power that is consumed lead to frequency drifting. Because the load fluctuations themselves are random, it is not possible to exactly match the total generation with the power consumption at all times. Therefore, the system frequency will tend to drift around on its own. In North American grids, there exists a central closed-loop controller that samples system-wide power flows and frequency to maintain the system frequency within tight tolerances while also maintaining economically dispatched generations. A brief introduction to the control called the **automatic generation control** or the **load frequency control** is presented in Section 8.3.

In addition to the topics in Sections 8.2 and 8.3, the voltage control problem is another important topic because it is a complex problem. It is mostly done by distributed automatic local controls in the North American grid. However, some European countries such as France do have automatic coordinated voltage control schemes for the large network.

The operation of the power system also has to meet regulations on security and reliability. Roughly speaking, the system is required to continue normal operation even with the loss of any one component. These studies are grouped under the framework of **power system security**, which is a broad topic in itself.

8.2 Generation Dispatch

A power system must generate sufficient power at all times to meet the load demand from the grid. The amount of load connected to the system varies significantly based on seasonal and time-of-day considerations. The cost of producing power at different generators also varies from plant to plant, depending on the efficiency of plant design and fuel costs at the generator location. Therefore, it is not economical to divide the required generation capacity arbitrarily among the available generators. The problem of determining how the total load requirement is to be divided among the generators in service is denoted the **generation dispatch** problem. This problem clearly optimizes the total generation costs in producing the required amount of active power. We discuss this problem first in Secton 8.2.1 under a classical formulation. Moreover, there are also active power losses involved in transmitting real power from generators to loads. Some generators, such as those near coal mines with low fuel costs, may incur large transmission losses in transferring the generated power to load centers. An optimization formulation that includes some simple consideration of transmission losses together with generation costs is presented in Section 8.2.2. Section 8.2.3 discusses a general framework for posing detailed optimization problems in the form of optimal power flow formulation.

8.2.1 Classical Lossless Generation Dispatch

The cost C of generating power P at a thermal plant can be roughly stated by the nonlinear function:

$$C(P) = \alpha + \beta P + \gamma P^2$$

Let us assume that there are N thermal generators in the system that share the total load demand of P_D. The economic dispatch problem tries to minimize the total generation costs for generating power at the N generators while meeting the load demand P_D. In the classical lossless formulation, we also assume that there are no transmission losses involved, which simplifies the optimization considerably. For the lossless case, the power conservation equation or the power balance equation is simply stated as:

$$\sum_{i=1}^{N} P_i = P_D,$$

where P_i denotes the power generated at plant i. Then, the economic dispatch reduces to the constrained optimization problem for minimizing the total generation cost C_T:

$$\underset{P_i}{\text{Min}} \quad C_T = \sum_{i=1}^{N} C_i(P_i),$$

$$\text{subject to} \sum_{i=1}^{N} P_i = P_D.$$

The problem can be easily solved using the Lagrangian formulation by defining the Lagrangian $L(P_1, P_2, \ldots, P_N, \lambda)$ as:

$$L(P_1, P_2, \ldots, P_N, \lambda) = \sum_{i=1}^{N} C_i(P_i) + \lambda\left(P_D - \sum_{i=1}^{N} P_i\right).$$

By setting the partial derivatives of the Lagrangian L with respect to P_i and λ equal to zero, the optimal solution can be described by the conditions:

$$IC_i = \frac{dC_i}{dP_i} = \lambda \text{ for } i = 1, 2, \ldots N, \tag{8.1}$$

and

$$\sum_{i=1}^{N} P_i = P_D. \tag{8.2}$$

In other words, the generation dispatch becomes optimal when the incremental generation costs IC_i become equal at all the generators. Since the generation cost C_i is a quadratic function of P_i, the incremental cost IC_i is a linear function of P_i. Therefore, the optimality problem reduces to solving $N + 1$ linear equations 8.1 and 8.2 stated above in terms of $N + 1$ unknown variables P_1 through P_N and λ. The unique solution is easily solved as:

$$\lambda = \frac{P_D + \sum_{i=1}^{N} \beta_i/2\gamma_i}{\sum_{i=1}^{N} 1/2\gamma_i} \text{ and } P_i = \frac{\lambda - \beta_i}{2\gamma_i}. \tag{8.3}$$

Thus far, we have considered no limits on the generation capacity at individual plants. In reality, there are lower and upper limits, $P_{\min,i}$ and $P_{\max,i}$, on the generation output P_i. These limits can be easily incorporated into the optimization problem above by appending the inequality constraints:

$$P_{\min,i} \leq P_i \leq P_{\max,i}, \tag{8.4}$$

with the conditions of equations 8.1 and 8.2. Since these equations are linear, the optimal solution can be computed by simply freezing P_i at either $P_{\min,i}$ or $P_{\max,I}$ whenever the limit is reached while finding the optimal solution. Details can be found in any standard textbook on power system analysis.

The discussion in this section has thus far been focused on thermal generation plants. The operation costs of a hydroelectric plant are fundamentally different because there are no fuel costs involved. Here, the concern is to maintain an adequate level of water storage while maintaining required water flow through the generator turbines. Clearly, the stored water capacity depends on water in-flow and out-flow rates, and these issues are typically studied over longer time horizons as compared to the dispatch of thermal power plants. The problem of coordinating the generation outputs of hydro generators and thermal plants for meeting load demands while minimizing generation costs is called the **hydrothermal coordination**. Again, the formulation and solution details can be found in standard power system textbooks.

8.2.2 Lossy Economic Dispatch

In the real system, there will always be transmission losses associated with sending power from the generation facilities to the load busses. In the previous section, these losses were ignored, which resulted in simple solutions for the generation dispatch problem. In this section, we modify the power balance equation 8.2 to include the power losses P_L. For a given set of generations P_i, the line losses have to be computed from the line currents, which in turn require solving the corresponding power flow equations. Such a problem of optimizing the total generation costs while solving nonlinear power flow equations is called the **optimal power flow formulation**, and it will be discussed in the next section. In this section, we approximate the total line losses P_L as a direct function of the generations P_i using the equation:

$$P_L = \sum_{i=1}^{N}\sum_{j=1}^{N} B_{ij}P_iP_j + \sum_{i=1}^{N} B_{i0}P_i + B_{00}. \tag{8.5}$$

Here, the term B_{00} is constant while the coefficients B_{ij} and B_{i0} summarize the quadratic and linear dependence of line losses P_L on the generations. Equation 8.5 is called the **B matrix loss formula**, and the B coefficients in equation 8.5 are called the **loss factors**. There exists a rich history in the literature on the computation of loss factors for a given economic dispatch problem.

In this section, let us address the economic dispatch problem when the losses are represented by equation 8.5. Then, the optimization changes to:

$$\underset{P_i}{\text{Min}}\ C_T = \sum_{i=1}^{N} C_i(P_i), \tag{8.6}$$

subject to:

$$\sum_{i=1}^{N} P_i = P_D + P_L(P_1,\ P_2,\ \dots P_N).$$

We redefine the Lagrangian $L(P_1, P_2, \dots, P_N, \lambda)$ as:

$$\begin{aligned} L(P_1,\ P_2,\ \dots,\ P_N, \lambda) &= \sum_{i=1}^{N} C_i(P_i) \\ &+ \lambda\left(P_D + P_L(P_1,\ P_2,\ \dots P_N) - \sum_{i=1}^{N} P_i\right). \end{aligned} \tag{8.7}$$

The optimal solution can be determined by solving these two equations:

$$IC_i = \frac{dC_i}{dP_i} = \lambda\left(1 - \frac{\partial P_L}{\partial P_i}\right) \text{ for } i = 1, 2, \dots N. \tag{8.8}$$

$$\sum_{i=1}^{N} P_i = P_D + P_L(P_1,\ P_2, \dots P_N). \tag{8.9}$$

Whereas equations 8.1 and 8.2 for the lossless case were linear in the variables P_i and λ, the equations 8.8 and 8.9 for the lossy case are quadratic. The solution from the lossless formulation provides an excellent initial condition, and the lossy economic dispatch solution can be computed by iterative solution strategies such as the Newton-Raphson algorithm discussed in the power system analysis chapter.

Equation 8.8 provides the relationship between the power generations P_i and the Lagrangian multiplier λ. That is, we can restate 8.8 as $\lambda = IC_i/(1 - \partial P_L/\partial P_i)$. The product term $1/(1 - \partial P_L/\partial P_i)$ denotes the penalty factor that is being multiplied to the incremental cost IC_i from the contribution of generation P_i to the line losses P_L.

Moreover, once the multiplier λ is specified, the power generations P_i can be uniquely determined from equation 8.8 since this equation is linear in P_i. Therefore, it follows that the optimal solution of the equations 8.8 and 8.9 essentially reduces to the problem of finding the Lagrangian multiplier λ. There exist excellent iterative techniques in the literature for finding the optimal solution by iterating on λ.

8.2.3 Optimal Power Flow Formulation

In previous subsection, we simplified the network power balance equations into a single power conservation equation by either ignoring the losses (equation 8.2) or by approximating the line losses (equation 8.9). However, in both earlier approaches, the network nature of the power transmission was completely ignored. In this section, we treat the power transmission in earnest by stating the power balance equations in full, which summarizes the transfer of power from the generators to the loads through the transmission network. The optimization itself has the same objective of minimizing the total cost of generation.

Let us assume that the system has N generators like before, and the total number of busses including generator and load busses is M. To simplify the notation, bus number 1 is assumed to be the slack bus. Busses 2 to N are the PV busses, and busses numbered $N + 1$ through M are PQ busses. The slack bus generation P_{GI} becomes a dependent variable, while the remaining generations P_{G2} through P_{GN} are the control variables for the minimization. Real and reactive loads are denoted by P_{Di} and Q_{Di}, respectively. Suppose the ith or jth entry $\boldsymbol{Y_{ij}}$ of the $\boldsymbol{Y}_{\mathbf{bus}}$ matrix has the magnitude Y_{ij} and the phase γ_{ij}.

The basic optimal power flow problem can then be stated as:

$$\underset{P_{G_i}}{\text{Min}}\, C_T = \sum_{i=1}^{N} C_i(P_{G_i}), \tag{8.10}$$

which is subject to the real power flow equations of:

$$P_i = P_{G_i} - P_{D_i} = \sum_{j} Y_{ij}V_iV_j\cos\left(\delta_i - \delta_j - \gamma_{ij}\right), \tag{8.11}$$

for $i = 2, \ldots, M$, and the reactive power flow equations of:

$$Q_i = Q_{G_i} - Q_{D_i} = \sum_j Y_{ij} V_i V_j \sin(\delta_i - \delta_j - \gamma_{ij}), \qquad (8.12)$$

for $i = N+1, \ldots, M$. The power flow variables, namely the bus voltages $V_{N+1}, \ldots, V_M$ and phase angles $\delta_2, \ldots, \delta_N$ become the dependent variables in the optimization procedure. In general, there may exist inequality constraints on the control variables as well as the state variables in the optimal power flow formulation.

The optimal power flow problem can be formally stated as:

$$\underset{u}{\text{Min}}\ f(x, u) \qquad (8.13)$$

$$\text{subject to} \quad g(x, u) = 0 \qquad (8.14)$$

$$\text{and} \quad h_i(x, u) \leq 0 \quad \text{for } i = 1, 2, \ldots, k. \qquad (8.15)$$

Here u denotes the optimization control variables, and x denotes the network state variables that are dependent on u through equation 8.14. The function *f(x, u)* is the objective function to be minimized. The equations 8.14 denote the equality constraints, and the number of equations of n in equation 8.14 matches the dimension of x. The equation 8.15 represents k different inequality constraints.

A solution to the general constrained optimization problem in equations 8.13 to 8.15 can be found by using the celebrated Kuhn-Tucker theorem. We first define a generalized Lagrangian $L(x, u, \lambda, \mu)$ for the problem as:

$$L(x, u, \lambda, \mu) = f(x, u) + \lambda^T g(x, u) + \mu^T h(x, u), \qquad (8.16)$$

where $\lambda \in \mathcal{R}^n$ and $\mu \in \mathcal{R}^k$. The Kuhn-Tucker theorem provides the conditions that must be satisfied at the optimal solution as:

$$\frac{\partial f}{\partial x} + \lambda^T \frac{\partial g}{\partial x} + \mu^T \frac{\partial h}{\partial x} = 0. \qquad (8.17)$$

$$\frac{\partial f}{\partial u} + \lambda^T \frac{\partial g}{\partial u} + \mu^T \frac{\partial h}{\partial u} = 0. \qquad (8.18)$$

$$g(x, u) = 0. \qquad (8.19)$$

$$\begin{aligned} &h_i(x, u)\mu_i = 0 \text{ with either } \mu_i = 0 \text{ and} \\ &h_i(x, u) < 0 \text{ or } \mu_i > 0 \text{ and } h_i(x, u) = 0. \end{aligned} \qquad (8.20)$$

Therefore, the optimal power flow problem becomes the solution of equations 8.17 through 8.20. In large-scale power system formulations, it is very difficult to find an exact solution to the Kuhn-Tucker conditions. It is quite often sufficient to find a suboptimal solution using heuristic optimization algorithms. In recent history, excellent progress has been made in the development of such heuristic algorithms.

8.3 Frequency Control

The power system load is continually undergoing changes as individual loads fluctuate while others are energized or de-energized. Generation must precisely match these changes to maintain system frequency, a function called **load frequency control** (LFC), and at the same time must follow an appropriate economic dispatch of the units as discussed in the previous section. Together, these functions are referred to as **automatic generation control** (AGC). Accordingly, all modern power systems have centralized control centers that run software called **Energy Management Systems** (EMS) that, in addition to other functions, monitor frequency and generator outputs. Units that are on AGC will receive raise and lower signals to adjust their set points.

8.3.1 AGC

Ensuring the power balance is commonly referred to as regulation and can be sensed by changes in the system frequency. If load (including losses) exceeds the generation input, then energy must be leaving the system over time. This energy will be drawn from the kinetic energy stored in the rotating masses of the generators. Hence, the generators will begin to rotate more slowly and the system frequency will decrease. Conversely, if generation input exceeds the load, then frequency will increase. It is the responsibility of the governor on a generator to sense these speed deviations and adjust the power input (say through the opening or closing of valves on a steam unit) as appropriate.

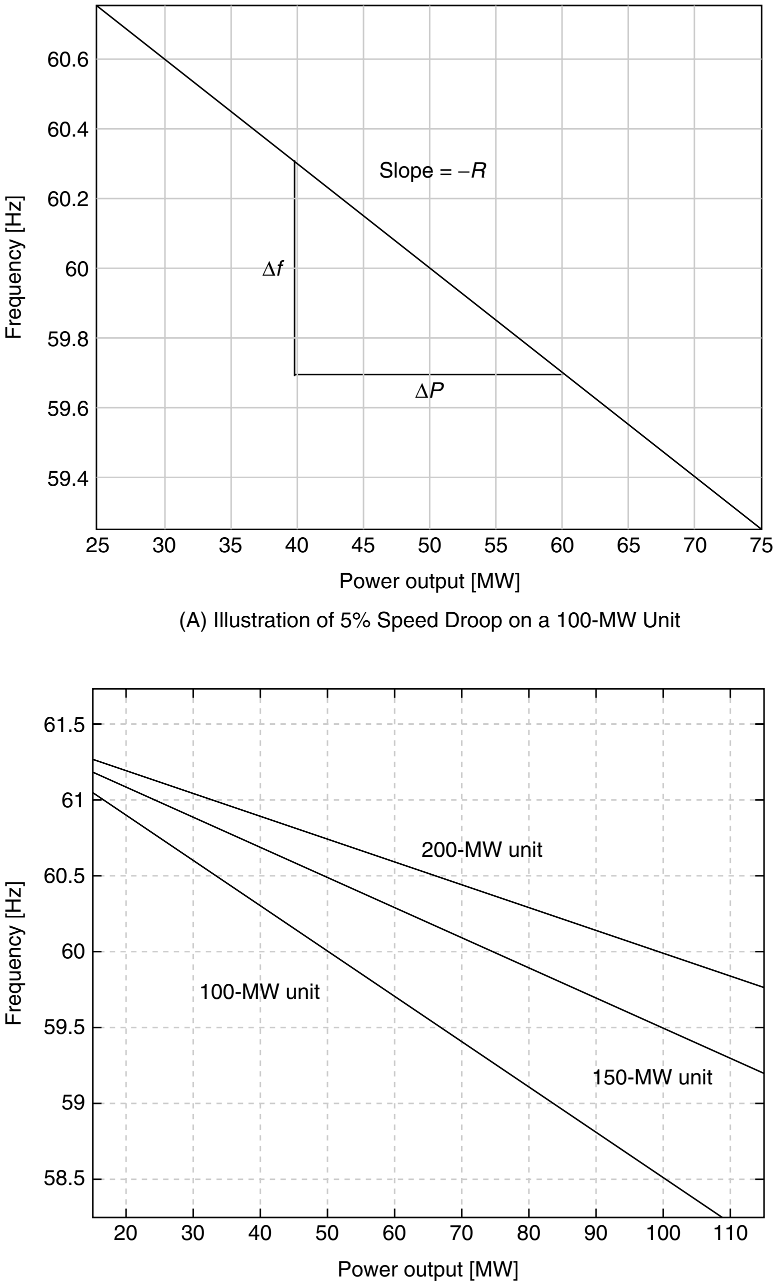
Specifically, the governor will change the power input in proportion to the speed deviation. This is referred to as the **droop** or **speed regulation**, *R*, and can be expressed as:

$$\Delta P = -\frac{1}{R}\Delta f, \qquad (8.21)$$

where Δf is the change in frequency and where ΔP is the resulting change in power input. The R is measured in hertz per megawatts or alternatively as a percentage of the rated capacity of a unit. Typical droops in practice are on the order of 5 to 10%. If no further action is taken, the system will then operate at this new frequency.

Figure 8.1(A) illustrates a standard scenario. Assume a simple system with a nominal frequency of 60 Hz and a 100 MW unit is operating with a 5% droop. The regulation constant is calculated to be $R = 0.05(60/100) = 0.03\,\text{Hz/MW}$. If the generator unit senses a drop in frequency of 0.6 Hz, then this corresponds to a 20 MW increase in power output. In addition to governor actions, many loads are frequency sensitive (e.g., motors). For these loads, the load will decrease as the frequency drops so that the needed increase from the generators is less. This can be expressed as:

$$\Delta P = -\left(\frac{1}{R} + D\right)\Delta f, \qquad (8.22)$$



(A) Illustration of 5% Speed Droop on a 100-MW Unit

(B) Illustration of Three Units with 5% Droop

FIGURE 8.1 Speed Droop Characteristics

where *D* is the damping. Thus, the effective droop is slightly less (i.e., the frequency drop will be less) when load damping is considered. This load damping is often approximated as a 1% decrease in load for every 1% decrease in frequency.

Now, as would normally be true, if there are several generators interconnected and on regulation, then each will see the same frequency change (after any initial transients die out) and respond. Assuming the same percentage droop on each unit, the load will be picked up according to the relative capacities. This is depicted in Figure 8.1(B) with units of 100 MW, 150 MW and 200 MW, respectively, all operating with a 5% droop. Analytically, with *R* on a per unit basis, we can express this for *n* units as:

$$\Delta P = -\left(\frac{1}{R_1} + \frac{1}{R_2} + \cdots + \frac{1}{R_n} + D\right)\Delta f. \qquad (8.23)$$

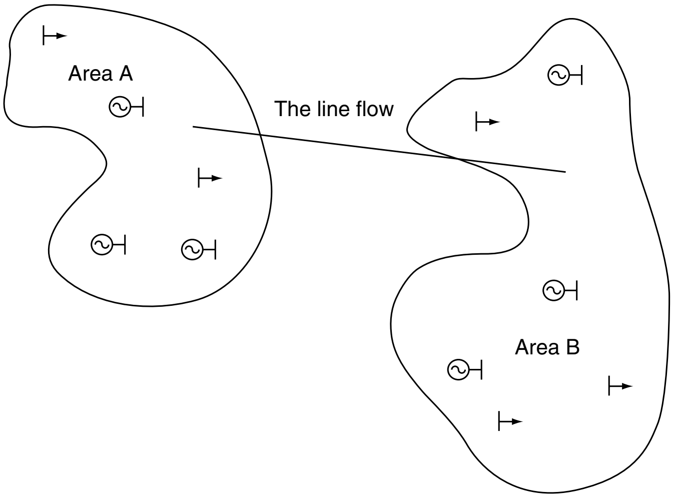


FIGURE 8.2 Multiple Control Areas Interconnected by Tie Lines

The control system as described in the previous paragraphs suffers from a serious drawback. Frequency will never return to the nominal (i.e., desired point). Supplemental control is needed to make the appropriate adjustments. One may think of this as adjusting for the initial loss of rotating kinetic energy when the load change first occurred by modifying the generator set points. This action must be coordinated among the units.

An additional issue arises in the coordination for this supplemental control. With relatively few exceptions (e.g., some islands), utilities are interconnected with their neighboring systems. Not only does this provide additional security and reliability in the case of outages, but it allows for more economic operation by judicious energy trades. Still, the utilities must coordinate their operation to maintain energy schedules and meet demand. If a load change occurs in a neighboring system, both systems will see the frequency change and respond. There is no difference from the viewpoint of the generator between the loads in the different areas. Clearly, each utility wishes only to supply loads for which it is responsible and will receive compensation.

Systems are generally broken into separate control areas reflecting the different responsibilities of the utilities as shown in Figure 8.2. The flow on tie lines between these control areas is monitored. The generator set point adjustments are made to maintain these scheduled tie flows. Note that while the first function of AGC is load following, these adjustments to generator set points may over time lead the units away from the most economic dispatch. Thus, the supplemental control may include additional adjustments for economic operation of the units. As summarized in the block diagram of Figure 8.3, the supplemental control serves several functions, including the following:

- Restoration of the nominal frequency
- Maintenance of the scheduled interchanges
- Provision for the economic dispatch of units

The coordination among areas is achieved by defining the so-called **area control error** (ACE) as a measure of the needed adjustments to the generator set points. Let the following be true:

$$\mathrm{ACE} = \Delta P_{Tie} - 10\beta_f \Delta f, \tag{8.24}$$

where ΔP_{Tie} is the deviation in the tie line from the scheduled exchange and $\beta_f \Delta f$ is called the frequency bias, which is by tradition negative and measured in MW/0.1 Hz (thus, the multiplier 10 in equation 8.4). If the ACE for an area is

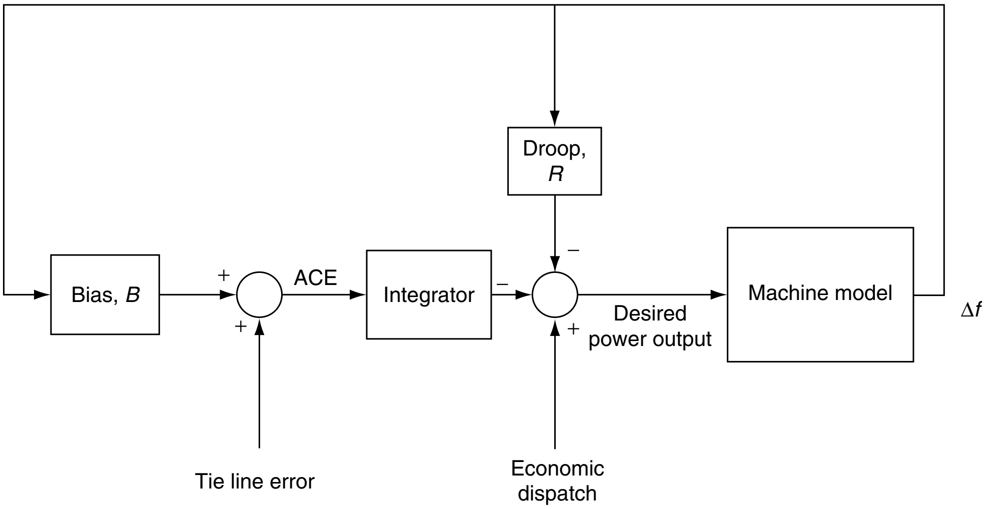

FIGURE 8.3 Block Diagram of AGC System

negative, then the area generation is too small and the unit set points should be increased.

Considering the system of Figure 8.2, notice the effect of a sudden load increase in area A on the ACE in both areas A and B. First, the frequency in both areas will decrease and, accordingly, the power output for all regulated units will increase according to their respective droop settings. Since the load change occurs in area A, there will be an additional unscheduled in-flow from B. ACE in area A will have two negative terms: **schedule error** ΔP_{Tie} and the **frequency bias**, or control, error. Conversely, ACE in area B will have a positive schedule error but a negative frequency bias.

It may seem that ideally the ACE in B would be zero and that in A it would precisely match the load change; however, this is not practical or particularly necessary. Instead, the ACE is integrated over time, and this signal is used to determine the generator set points. Integrating the error ensures that the actual energy exchange between areas is precisely maintained over time. Since the control center must calculate the ACE after gathering data from the system, the set point controls are discrete. In North America, the AGC signals are fed to the units typically, about once every 2–4 sec. In many parts of the world, such frequent adjustment is considered excessive, and supplementary control signals are sent over much less frequent time intervals. In each country, regulating agencies determine the required performance of the AGC so that utilities do not "lean" too hard on their neighbors. For example, the traditional performance criteria in North America is that the ACE has to return to zero or its predisturbance level within 15 min following the start of the disturbance.

8.4 Conclusion: Contemporary Issues

The supplementary control system as described above reflects AGC operation more or less as it has existed since the advent of computer controls in the late 1960s. Recent moves to deregulate the power system and open up the system to competition greatly complicate the traditional control philosophy. In an open market, the load responsibilities are not so clearly defined or geographically restricted. For example, an independent generator may have a contract to serve a load in a neighboring control area, and this impacts the scheduled flows on the intertie. A number of methods have been proposed to facilitate this control, including the establishment of a separate market for a "load-following" service. Consumers would pay for this service along with their energy fee. No regions in the world have fully opened AGC control to market competition, but many incremental steps have been taken. So while the supply of energy has proven to be amenable to economic competition, the vagaries of control are more difficult to formulate as an open transparent market.

9.1 Fundamentals of Power System Protection

This chapter defines the power system faults, the role of protective relaying, and the basic concepts of relaying. The discussion is a rather general overview. More specific issues are discussed in several excellent textbooks (Horowitz and Phadke, 1992; Blackburn, 1998; Ungrad *et al.*, 1995).

9.1.1 Power System Faults

Power systems are built to allow continuous generation, transmission, and consumption of energy. Most of the power system operation is based on a three-phase system that operates in a balanced mode, often described with a set of symmetrical phasors of currents and voltages being equal in magnitude and having the phase shifts between phases equal to 120° (Blackburn, 1993). The voltages and current behave according to Kirchhoff's laws of the electrical circuits stating that the sum of all currents entering and leaving a network node is equal to zero, and the sum of all voltage drops and gains in a given loop is also equal to zero. In addition, the voltage and currents generate electric power that integrated over a period of time produce energy. For the three-phase systems, a variety of definitions for the delivered, consumed, or transmitted power may be established as follows: **instantaneous**, **average**, **active**, **reactive**, and **complex**. The power system consists of components that are put together with a goal of matching each other regarding the power ratings, dielectric insulation levels, galvanic isolation, and number of other design goals. In the normal operating conditions, currents, voltages, power, and energy are matched to meet the design constraints.

As such, the system is capable of sustaining a variety of environmental and operating impacts that resemble normal operating conditions.

The abnormal operating conditions that the system may experience are rare but do happen. They include lightning striking the transmission lines during severe weather storms, excessive loading and environmental conditions, deterioration or breakdown of the equipment insulation, and intrusions by humans and/or animals. As a result, power systems may experience occasional faults. The **faults** may be defined as events that have contributed to a violation of the design limits for the power system components regarding insulation, galvanic isolation, voltage and current level, power rating, and other such requirements. The faults occur randomly and may be associated with any component of the power system. As a result, the power component experiences an exceptional stress, and unless disconnected or de-energized, the component may be damaged beyond repair. In general, the longer the duration of a fault, the larger is the damage. The fault conditions may affect the overall power system operation since the faulted component needs to be removed, which in turn may contribute to violation of the stability and/or loading limits. Last, but not least, the faults may present a life threat to humans and animals since the damage caused by the faults may reduce safety limits otherwise satisfied for normal operating conditions. Protective relaying was introduced in practice as early as the first power systems were invented to make sure that faults are detected and damaged components are taken out of service quickly.

To facilitate graphic representation of different types of faults, circuit diagrams shown in Figure 9.1 are used. The example is related to the faults on transmission lines and covers eleven types of most common transmission line ground and/or phase faults. To facilitate the presentation, multiple fault types are shown on the same diagram.

The rest of the discussion in this section describes the basic power system components and how different power system components are used to facilitate implementation of the protection concept. The basic requirements for the protection system solution are outlined pointing out the most critical implementation criteria.

9.1.2 Power System Components

The most basic **power system components** are generators, transformers, transmission lines, busses, and loads. They allow for power to be generated (generators), transformed from one voltage level to another (transformers), transmitted from one location to another (transmission lines), distributed among a number of transmission lines and power transformers (busses), and used by consumers (loads). In the course of doing this, the power system components are being switched or connected in a variety of different configurations using circuit breakers and associated switches (Horowitz and Phadke, 1992; Blackburn, 1998; Ungrad *et al.*, 1995). The circuit breakers are capable of interrupting the flow of power at a high energy level and, hence, may also be used to disconnect the system components on an emergency basis, such as in the case when the component experiences a fault (Flurscheim, 1985). Because the power systems are built to cover a large geographical area, the power system components are scattered across the area and interconnected with transmission lines. The grouping of the components associated with generation, switching, transformation, or consumption are called **power plants** (generation and transformation), **substations** (transformation and switching), and **load centers** (switching, transformation, and consumption). In turn, the related monitoring, control, protection, and communication gear is also located at the mentioned facilities.

To facilitate the description of power systems, a graphical representation of the power system components as shown in Figure 9.2 is used. Such representation is called a **one-line diagram**. It is reducing the presentation complexity of the three-phase connections into a single-line connection. This is sufficiently detailed when the normal system operation is considered since the solutions of voltages and currents are symmetrical and one-line representations resemble very closely the single-phase system representation used to obtain the solution. The solution for the faulted systems requires more detailed three-phase representation, but the one-line diagram is still sufficient to discuss the basic relaying concepts. In that case, a detailed representation of the faults shown in Figure 9.1 is not used, but a single symbol representing all fault types is used instead.

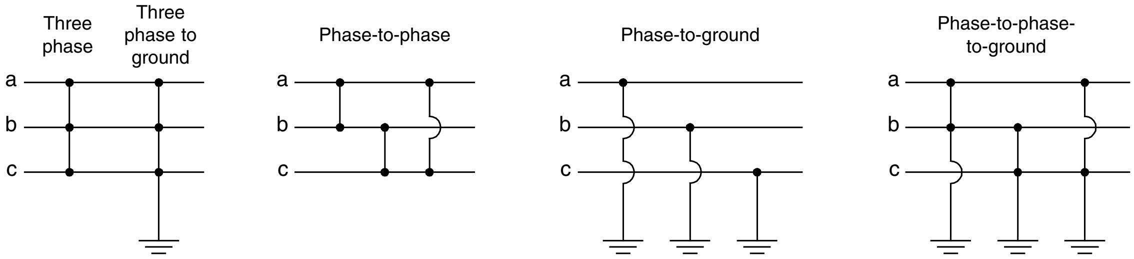

FIGURE 9.1 Eleven Types of Most Common Transmission Line Faults

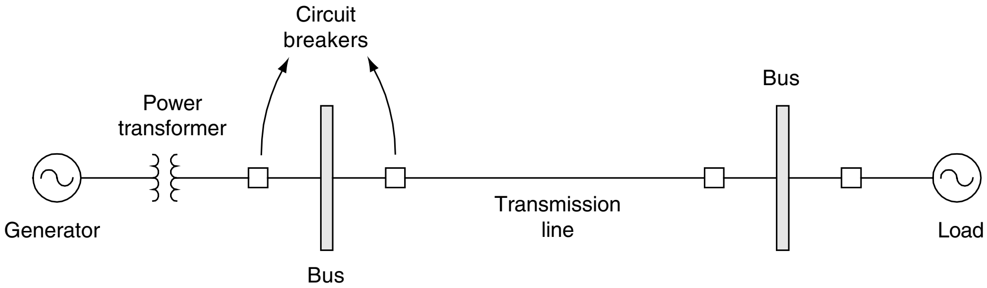

FIGURE 9.2 One-Line Representation of the Power System Components and Connection

The next level of detail is the **representation of the points** where the components merge, shown in Figure 9.2 as busses. A good example of such a point is a substation where a number of lines may come together, and a transformation of the voltage level may also take place. Figure 9.3 shows a one-line representation of a substation.

Substations come in a variety of configurations, and the one selected in Figure 9.3 is called a breaker-and-a-half. This configuration is used in high-voltage substations containing a number of transmission lines and transformers as well as different voltage levels and associated busses. This representation also includes circuit breakers and busses as the principal means of switching and/or connecting the power system components in a substation. The protective relaying role is to disconnect the components located or terminated in the substation when a fault occurs. In the case shown in Figure 9.3, the transmission line is connected to the rest of the system through two breakers marked up as "L," the bus is surrounded with several breakers connected to the bus and marked up as "B," and the power transformer is connected between the two voltage level busses with four breakers marked up as "T." In the common relaying terminology, all the breakers associated with a given relaying function are referred to as a **bay**, hence, the terminology exists of "protection bays" for a transmission line, a bus, and a transformer. It may be observed in the high-voltage substation example, given in Figure 9.3, that each breaker serves at least two protection bays. In Figure 9.3, each breaker box designated as "L" or "T" also acts as the breaker designated with "B." This property will be used later when introducing the concept of overlapping protection zones.

9.1.3 Relay Connections and Zones of Protection

Protective relays are devices that are connected to instrument transformers to receive input signals and to circuit breakers to issue control commands for opening or closing. In some instances, the relays are also connected to the communication channels to exchange information with other relays. The electronic relays always require a power supply, which is commonly provided through a connection to the station dc battery. Often, relays are connected to some auxiliary monitoring and control equipment to allow for coordination with other similar equipment and supervision by the operators. In the high-voltage power systems, relays are located in substations and, most frequently, in a control house. The connections to the instrument transformers and circuit breakers located in the substation switchyard are done through standard wiring originating from the substation switchyard and terminating in the control house.

To achieve effective protection solutions, the entire relaying problem is built around the concept of **relaying zones**. The zone is defined to include the power system component that

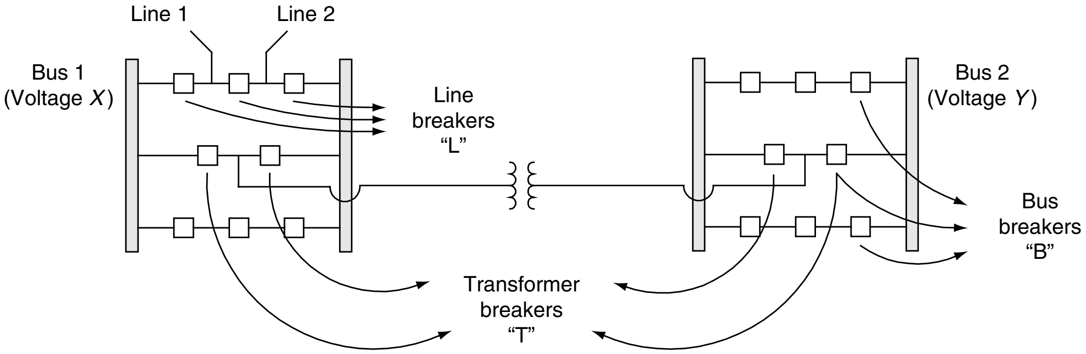

FIGURE 9.3 Breaker-and-a-Half Substation Connection

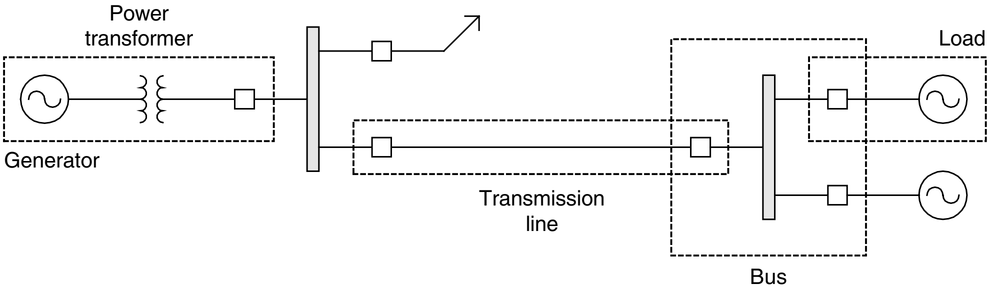

FIGURE 9.4 Allocation of Zones of Protection for Different Power System Components

has to be protected and include the circuit breakers needed to disconnect the component from the rest of the system. A typical allocation of protective relaying zones for the power system shown in Figure 9.2 is outlined in Figure 9.4.

Several points regarding the zone selection and allocation are important. First, the zones are selected to ensure that a multiple usage of the breakers associated with each power system component is achieved. Each circuit breaker may be serving at least two protection functions. This enables separation of the neighboring components in the case either one is faulted. At the same time, the number of breakers used to connect the components is minimized. By overlapping at least two zones of protection around each circuit breaker, it is important to make sure that there is no part of the power system left unprotected. This includes the short connection between circuit breakers or between circuit breakers and busses. Such an overlap is only possible if instrument transformers exist on both sides of the breaker, which is the case with so-called dead-tank breakers that have current transformers located in the breaker bushings.

Another important notion of the zones is to define a **backup coverage**. This is typical for the transmission line protection where multiple zones of protection are used for different sections of the transmission line. Figure 9.5 shows how the zones may be selected in case three zones of protection are used by each relay. The zones of protection are selected by determining the **settings** of the relay reach and the time associated with relay operation.

Each zone of protection is set to cover specific length of the transmission line, which is termed the **relay reach**. Typical selection of the zones in the transmission line protection is to cover 80 to 90% of the line in zone 1, 120–130% in zone 2, and 240–250% in zone 3. This protection is selected by locating a relay at a given line terminal and determining the length corresponding to the relay coverage as a percentage of the line length between the relay terminal and adjacent relay terminals. When doing this, the selected direction is down the transmission line starting from the terminal where the relay is located. The length of the transmission line originating from the location of the relay and ending at the next terminal is assumed to be 100%. The meaning of 120% is that the entire transmission line is covered as well as the additional 20% of the line originating from the adjacent terminal. The **times of operation** associated with zones are different: zone 1 operation is instantaneous, zone 2 is delayed to allow zone 1 relays to operate first, and zone 3 times allow the corresponding relays closer to the fault to operate first in either the zone 1 or zone 2. With this time-step approach selected for different zones of protection, the relays closest to the fault are allowed to operate first. If they fail to operate, the relays located at the remote terminals, that "see" the same fault in zone 2, will still disconnect the failed component. If zone 2 relay operation fails, relays located further away from the faulted line will operate next with the zone 3 settings. The advantage of this approach is a redundant coverage of each line section. They are also covered with multiple relay zones of the relay located on the adjacent lines, ensuring that the faulted component will be eventually removed even if the relay closest to the fault fails. The disadvantage is that each time a backup relay operates, a larger section of the system is removed from service because the relays operating in zone 2 (sometimes) or zone 3 (always) are connected to the circuit breakers that are remote from the ends of the transmission line experiencing the fault. In addition, the time to remove faulted sections from service increases as the

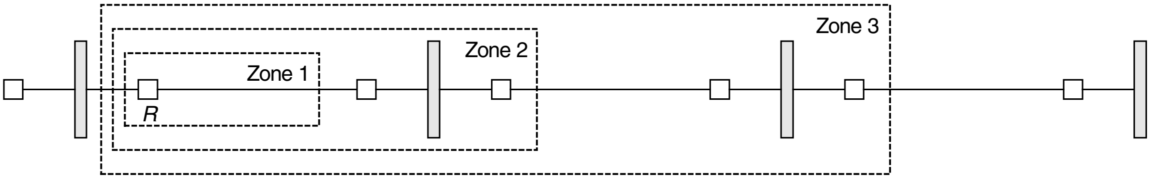

FIGURE 9.5 Selection of the Overlapping Zones for Transmission Line Protection

zone coverage responsible for the relay action increases due to the time delays associated with the zone 2 and zone 3 settings.

9.2 Relaying Systems, Principles, and Criteria of Operation

This section describes elements of a relaying system and defines the basic concept of a relaying scheme. In addition, the basic principles of protective relaying operation are discussed. More detailed discussions of each of the relaying solutions using the mentioned principles aimed at protecting different power system components are outlined in subsequent sections.

9.2.1 Components of a Relaying System

Each **relaying system** consists, as a minimum, of an instrument transformer, relay, and a circuit breaker. A typical connection for protection of high-voltage transmission lines using distance relays is shown in Figure 9.6.

In the case of Figure 9.6, since the relay measures the impedance (which is proportional to distance), both current and voltage instrument transformers are used. The relay is used to protect the transmission line, and it is connected to a circuit breaker at one end of the line. The other end of the line has another relay protecting the same line by operating the breaker at that end. In a case of a fault, both relays need to operate, causing the corresponding breakers to open and resulting in the transmission line being removed from service.

The role of **instrument transformers** is to provide galvanic isolation and transformation of the signal energy levels between the relay connected to the secondary side and the voltages and currents connected to the primary side. The original current and voltage signal levels experienced at the terminals of the power system components are typically much higher than the levels used at the input of a relay. To accommodate the needed transformation, instrument transformers with different ratios are used (IEEE, 1996; Ungrad, 1995). Next, a brief discussion of the options and characteristics of most typical instrument transformer types is given.

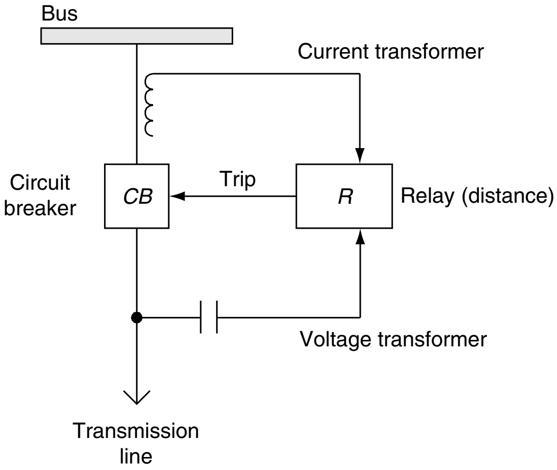

FIGURE 9.6 Protective Relaying System Consisting of Instrument Transformers, a Relay, and a Breaker

Current Transformer

Current transformers (CTs) are used to reduce the current levels from thousands of amperes down to a standard output of either 5 A or 1 A for normal operation. During faults, the current levels at the transformer terminals can go up several orders of magnitude. Most of the current transformers in use today are simple magnetically coupled iron-core transformers. They are input/output devices operating with a hysteresis of the magnetic circuit and, as such, are prone to saturation. The selection of instrument transformers is critical for ensuring a correct protective relaying operation. They need to be sized appropriately to prevent saturation. If there is no saturation, instrument transformers will operate in a linear region, and their basic function may be represented via a simple turns ratio. Even though this is an ideal situation, it can be assumed to be true for computing simple relaying interfacing requirements. If a remanent magnetism is present in an instrument transformer core, then the hysteresis may affect the time needed to saturate next time the transformer gets exposed to excessive fault signals. The current transformers come as free-standing solutions or as a part of the circuit breaker or power transformer design. If they come preinstalled with the power system apparatus, they are located in the bushings of that piece of equipment.

Voltage Transformer

Voltage transformers come in two basic solutions: **potential transformer** (PT) with iron-core construction and **capacitor coupling** voltage transformers (CVTs) that use a capacitor coupling principle to lower the voltage level first and then use the iron-core transformer to get further reduction in voltage. Both transformer types are typically free-standing. PTs are used frequently to measure voltages at substation busses, whereas CVTs may be used for the same measurement purpose on individual transmission lines. Since the voltage levels in the power system range well beyond kilovolt values, the transformers are used to bring the voltages down to an acceptable level used by protective relays. They come in standard solutions regarding the secondary voltage, typically 69.3 V or 120 V, depending if either the line-to-ground or line-to-line quantity is measured respectively. In an ideal case, both types of instrument transformers are assumed to be operating as voltage dividers, and the transformation is proportional to their turns ratio. In practice, both designs may experience specific deviations from the ideal case. In PTs, this may manifest as a nonlinear behavior caused by the effects of the hysteresis. In CVTs, the abnormalities include various ringing effects at the output when a voltage is collapsed at the input due to a close-in fault as well as impacts of the stray capacitances in the inductive transformer, which may affect the frequency response.

Relays

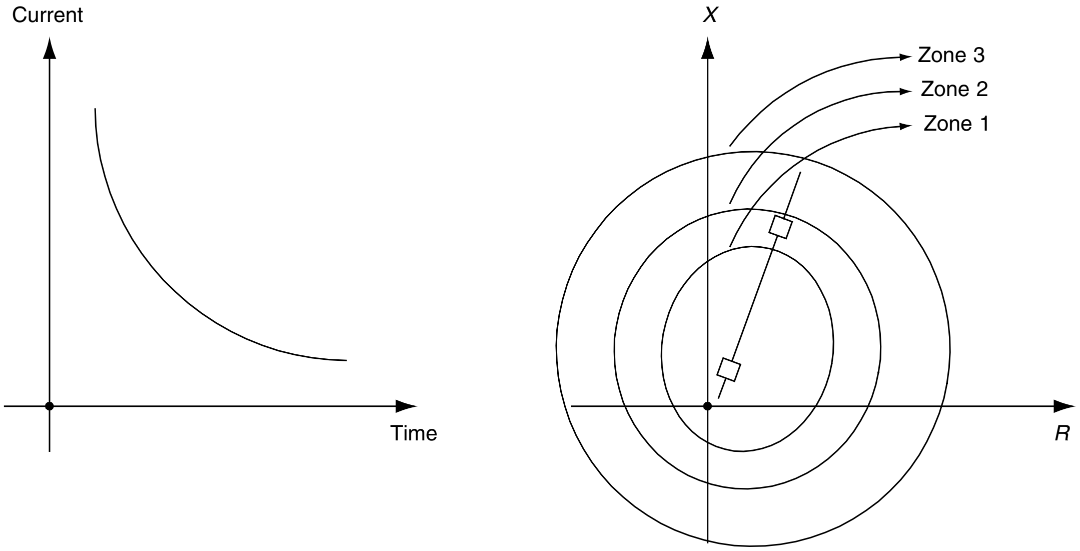
Another component shown in Figure 9.6 is the **relay** itself. Relays are controllers that measure input quantities and compare them to thresholds, commonly called relay settings, which in turn define operating characteristics. The relay characteristics may be quite different depending on the relaying quantity used and the relaying principle employed. A few different **operating characteristics** of various relays are shown in Figure 9.7. The first one is for the relay operating using an overcurrent principle with an inverse time-delay applied for different levels of input current. The second one is used by transmission line relays that operate using an impedance (distance) principle with the time-step zone implementation.

Further discussion of the specific relaying principles will be given later. In general, the relay action is based on a comparison between the measured quantity and the operating characteristic. Once the characteristic thresholds **(settings)** are exceeded, the relay assumes that this is caused by the faults affecting the measuring quantity, and it issues a command to operate associated circuit breaker(s). This action is commonly termed as a **relay tripping**, meaning opening a circuit breaker.

The relays may come in different designs and implementation technologies. The number of different designs at the early days when the relaying was invented was rather small, and the main technology was the electromechanical one. Today's design options are much wider with a number of different relay implementation approaches being possible. This is all due to a great flexibility of the microprocessor-based technology almost exclusively used to build relays today. Since the microprocessor-based relays use very low-level voltage signal at inputs to the signal measurement circuitry, all these relays have **auxiliary transformers** at the front-end to scale down the input signal levels even further from what is available at the secondary of an instrument transformer. To accommodate specific needs and provide different levels of the relay input quantities, some of the relay designs come with multiple connections of the auxiliary transformers called **taps**. Selecting appropriate tap determines a specific turns ratio for the auxiliary transformer that allows more precise selection of the specific level of the relay input signal. Besides the voltage and/or current signals as inputs and trip signals as outputs, the relays have a number of input/output connections aimed at other functions: coordination with other relays, communication with relays and operators, and monitoring. For an electronic relay, a connection to the power supply also exists.

Circuit Breaker

The last component in the basic relaying system is the **circuit breaker**. The breakers allow interruption of the current flow, which is needed if the fault is detected and a tripping command is issued by the relay. Circuit breakers operate based on different principles associated with physical means of interrupting the flow of power (Flurscheim, 1985). As a result, vacuum, air-blast, and oil-field breakers are commonly used depending on the voltage level and required speed of operation. All breakers try to detect the zero crossing of the current and interrupt the flow at that time since the energy level to be



(A) Overcurrent for Inverse-Time Relay

(B) Distance (Impedance) for Three Zone MHO Relay

FIGURE 9.7 Typical Relay-Operating Characteristic

interrupted is at a minimum. The breakers often do not succeed in making the interruption during the first attempt and, as a result, several cycles of the fundamental frequency current signal may be needed to completely interrupt the current flow. This affects the **speed of the breaker operation**. The fastest breakers used at the high-voltage levels are one-cycle breakers, whereas a typical breaker used at the lower voltage levels may take 20 to 50 cycles to open. Circuit breakers are initiated by the relays to disconnect the power system component in the case a fault is present on the component. In the case of the transmission line faults, many faults are temporary in nature. To distinguish between permanent and temporary faults on transmission lines, the concept of **breaker autoreclosing** is used. It assumes that once the breaker is tripped (opened) by the relay, it will stay open for a while, and then it will automatically reclose. This action allows the relays to verify if the fault is still present and, if so, to trip the breaker again. In the case the fault has disappeared, the relays will not act, and the transmission line will stay in service. The autoreclosing function may be implemented quite differently depending on the particular needs. The main options are to have a single or multiple reclosing attempts and to operate either a single pole or all three poles of the breaker. Circuit breakers are also quite often equipped with auxiliary relays called **breaker failure** (BF) relays. If the breaker fails to open when called upon, the BF relay will initiate operation of other circuit breakers that will disconnect the faulted element, quite often at the expense of disconnecting some additional healthy components. This may be observed in Figure 9.3: once a transmission line relay operates the two breakers in the transmission line bay and one of the breakers fails to operate, the BF relay will disconnect all the breakers on the bus side where the failed breaker is connected, making sure the faulted line is disconnected from the bus.

9.2.2 Basic Relaying Principles

When considering protection of the most common power system components, namely generators, power transformers, transmission lines, busses, and motors, only a few basic relaying principles are used. They include **overcurrent**, **distance**, **directional**, and **differential**. In the case of transmission line relaying, communication channels may also be used to provide exchange of information between relays located at two ends of the line. The following discussion is aimed at explaining the generic properties of the above-mentioned relaying principles. Many other relaying principles are also in use today. The details may be found in a number of excellent references on the subject (Horowitz and Phadke, 1992; Blackburn, 1998; Ungrad *et al.*, 1995; Blackburn, 1993).

Overcurrent protection is based on a very simple premise that in most instances of a fault, the level of fault current dramatically increases from the prefault value. If one establishes a threshold well above the nominal load current, as soon as the current exceeds the threshold, it may be assumed that a fault has occurred and a trip signal may be issued. The relay based on this principle is called an **instantaneous overcurrent relay**, and it is in wide use for protection of radial low-voltage distribution lines, ground protection of high-voltage transmission lines, and protection of machines (motors and generators). The main issue in applying this relaying principle is to understand the behavior of the fault current well, in particular when compared to the variation in the load current caused by significant changes in the connected load. A typical example where it may become difficult to distinguish the fault levels from the normal operating levels is the overcurrent protection of distribution lines with heavy fluctuations of the load. To accommodate the mentioned difficulty, a variety of overcurrent protection applications are developed using the basic principle as described previously combined with a **time delay**. One approach is to provide a fixed time delay, and in some instances, the time delay is proportional to the current level. One possible relationship is an inverse one where the time delay is small for high currents and long for smaller ones. The example shown earlier in Figure 9.7 describes an inverse time characteristic, which may also be a very or extremely inverse type. Further variations of the overcurrent relay are associated with the use of the **directional element**, which is discussed later. The issues of coordinating overcurrent relays and protecting various segments of a distribution line are also discussed later.

Distance relaying belongs to the principle of **ratio comparison**. The ratio is between the voltage and current, which in turn produces **impedance**. The impedance is proportional to the distance in transmission lines, hence the “distance relaying” designation for the principle. This principle is primarily used for protection of high-voltage transmission lines. In this case, the overcurrent principle cannot easily cope with the change in the direction of the flow of power, simultaneous with variations in the level of the current flow, which is common in the transmission but not so common in the radial distribution lines. Computing the impedance in a three-phase system is a bit involved because each type of fault produces a different impedance expression (Lewis, 1947). Because of these differences the settings of a distance relay need to be selected to distinguish between the ground and phase faults. In addition, fault resistance may create problems for distance measurements because the value of the fault resistance may be difficult to predict. It is particularly challenging for distance relays to measure correct fault impedance when a current in-feed from the other end of the line creates an unknown voltage drop on the fault resistance. This may contribute to erroneous computation of the impedance, called apparent impedence, “seen” by the relay located at one end of the line and using the current and voltage measurement just from that end. Once the impedance is computed, it is compared to the settings that define the operating characteristic of a relay. Based on the comparison, a decision is made if a fault has occurred and, if so, in what **zone**. As mentioned earlier, the

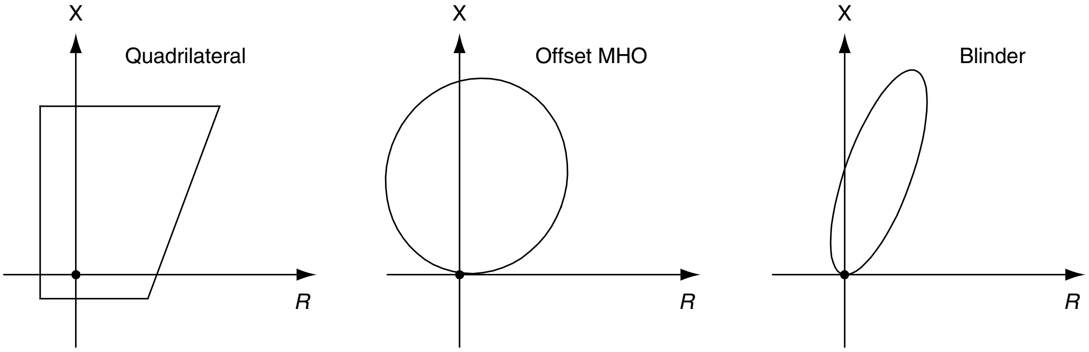


FIGURE 9.8 Operating Characteristics of a Distance Relay

impedance relay may be set to recognize multiple zones of protection. Due to variety of application reasons, the operating characteristics of a distance relay may have different shapes, the quadrilateral and MHO being the most common. The different operating characteristic shapes are shown in Figure 9.8 (Blackburn, 1998). The characteristics dictate relay performance for specific application conditions, such as the changes in the loading levels, different values of fault resistance, effects of power swings, presence of mutual coupling, and reversals of fault direction.

Distance relays may be used to protect a transmission line by taking the input measurements from only one end of the line. Another approach is to connect two distance relays to perform the relaying as a system by exchanging the data between the relays from two ends through a communication link. In this case, it is important to decide what information gets exchanged and how is it used. The logic that describes the approach is called a **relaying scheme**. Most common relaying schemes are based on the signals sent by the relay from one end causing either blocking and unblocking or facilitating and accelerating of the trip from the relay at the other end. In all of the mentioned applications, **directionality** of a distance relay is an important feature. It will be discussed in more detail later on.

As an example of the relaying scheme operation, Figure 9.9 shows relaying zones used for implementation of a blocking scheme. The zones for each relay are **forward overreaching** (FO) and **backward reverse** (BR). The FO setting is selected so that the relay can "see" the faults occurring in a forward direction, looking from the relay position toward the adjacent line terminal and beyond. The BR setting is selected so that the relay can "see" the faults occurring in the backward direction, causing a reversal of the power flow. If the relay *R*1 (at location A) has "seen" the fault (at location *X*1) in zone FO behind the relay *R*2 positioned at the other end (at location B) of the line, the relay is blocked by relay *R*2 from operating. Relay *R*2 has "seen" the fault at location *X*1 in a BR zone and, hence, can "tell" the relay *R*1 not to trip by sending a blocking signal. Should a fault occur in between the two relays (location *X*2), the blocking signal is not sent, and both relays operate instantaneously since both relays "see" the fault in zone FO and neither in zone BR.

A relaying concept widely used for protection of busses, generators, power transformers, and transmission lines is the **current differential**. It assumes that the currents entering and leaving the power system component are measured and compared to each other. If the input and output currents are the same, then it means that the protected component is "healthy," and no relaying action is taken. If the current comparison indicates that there is a deference, which means that a difference is caused by a fault, the relay action is called upon. The difference has to be significant enough to be attributed to a fault since some normal operating conditions and inaccuracies in the instrument transformers may also indicate a difference that is not attributed to a fault. More discussion about the

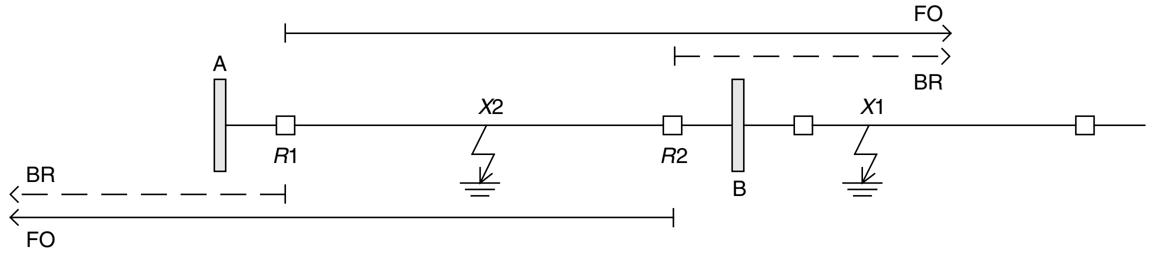

FIGURE 9.9 The Blocking Principle of Relaying with Fault Directionality Discrimination

criteria for establishing the type and level of the difference that are typical for a fault event are presented at a later time when this relaying principle is discussed in more detail. In the case of a differential protection of transmission lines, the measured quantities need to be sent over a communication channel to compute the difference. Since the speed and reliability of communication channels may play a role in the overall performance of the concept, slightly different philosophy is established regarding the type of measurements taken and the comparison criteria for the transmission lines versus other, more local, applications.

Directionality of a relay operation is quite important in many applications. It is established based on the angle of the fault current with the respect to the line voltage. It can be established for current alone or for impedance. In the latter case, the directionality is detected by looking at the angle between the reference voltages and fault current. In the impedance plane, the directionality is detected by the quadrant where the impedance falls. Whether the calculated fault impedance is in a forward (first-quadrant) or reverse (third-quadrant) zone determines the directions of the fault. Typically, the zone associated with the reverse direction is called a **reverse zone** and is numbered in a sequence after the **forward zones** are numbered first. The directionality may also be based on the power calculation, which in turn determines the direction of the power flow to/from a given power system component. Besides being used for implementation of the transmission line relaying schemes, directionality is quite important when applying overcurrent principle and is often used when implementing various approaches to ground protection.

9.2.3 Criteria for Operation

A number of different criteria for operation may be established, but the three most common ones are **speed**, **dependability/security**, and **selectivity** (WD G5, 1997a, b). All the criteria need to be combined in a sound engineering solution to produce the desirable performance, but for the sake of clarity, each of the criteria is now discussed separately.

Speed

The **speed** of operation is the most critical protective relay operating criterion. The relays have to be fast enough to allow clearing of a fault in the minimum time needed to ensure reliable and safe power system operation. The minimum operating time of a relay is achieved when the relay operates without any intentional time delay settings. Such an example is the time of operation of a distance relay in a direct (instantaneous) trip in Zone 1. The operating time may vary from the theoretical minimum possible to the time that a practical solution of a relaying algorithm may take to produce a decision. The operating time is dependent on the algorithm and technology used to implement the relay design. Because the relays respond to the fault transients, the relay operating time may vary slightly for the same relay if subjected to the transients coming from different types of fault. The minimum acceptable operating time is often established to make sure that the relay will operate fast enough to meet other time-critical criteria. For the transmission line protection example, the overall time budget for clearing faults in a system is expressed based on the number of cycles of the fundamental frequency voltage and current signals. This time is computed from the worst-case fault type persisting and potentially causing an instability in the overall power system. To prevent the instability from occurring, the fault needs to be cleared well before this critical time is reached, hence the definition of the minimum **fault clearance** time. The relay operating time is only a portion of this time-budget allocation. The rest is related to the operation of circuit breakers and a possible multiple reclosing action that needs to be taken. The consideration also includes the breaker failure action taken in the case a breaker fails to open and other breakers get involved in clearing the fault. The relay operating time is a pretty critical criterion even though it is allocated a very small portion of the mentioned fault-clearing time-budget criteria. As an example, the expected average operating time of transmission line relays in zone 1 is around one to two fundamental frequency cycles, where one cycle duration is 16.666 ms.

Dependability/Security

Another important operating criterion for protective relays is dependability/security. It is often mentioned as a pair since dependability and security are selected in a trade-off mode. **Dependability** is defined as the relay ability to respond to a fault by recognizing it each time it occurs. **Security** is defined as an ability of a relay not to act if a disturbance is not a fault. In almost all the relay approaches used today, the relays are selected with a bias toward dependability or security in such a way that one affects the other. A more dependable approach will cause the relays to **overtrip**, the term used to designate that the relay *will* operate whenever there is a fault but at the expense of possibly tripping even for nonfault events. The security emphasis will cause relays ***not* to trip** for nofault conditions but at a risk of not operating correctly when the fault occurs. The mentioned trade-off when selecting the relaying approach is made by choosing different types of relaying schemes and related settings to support one or the other aspect of the relay operation.

Selectivity

One criterion often used to describe how reliable a relaying scheme is relates to the relay ability to differentiate between a variety of operating options it is designed for. This criterion is called relay selectivity. It may be attributed to the relay accuracy, relay settings, or, in some instances, the measuring capabilities of the relay. In all cases, it designates how well the relay has recognized the fault conditions that it is designed or set to operate for. An example of the selectivity problem is an inability of a relay to correctly decide if it should operate in zone 1 or zone 2 for a fault that occurs in the region close to the set point between the zones. In this case, the relay operation may be termed as "overreaching" or "underreaching," depending if the relay has mistaken that the fault was inside of the selected zone while it was actually outside and vice versa.

9.3 Protection of Transmission Lines

The protection of transmission lines varies in the principle used and the implementation approaches taken, depending on the voltage level. The main principles and associated implementation issues are discussed for the following most frequent transmission line protective relaying cases: overcurrent protection of distribution radial feeders, distance protection of transmission lines and associated relaying schemes, and differential protection of transmission lines. Detailed treatment of the subject may be found in an excellent recent IEEE survey of the subject (IEEE, 1999).

9.3.1 Overcurrent Protection of Distribution Feeders

Protection of distribution feeders is most adequately accomplished using the overcurrent relaying principle. In a radial configuration of the feeder, shown in Figure 9.10, the fault current distribution is such that the fault currents are the highest for the faults closest to the source and the current decays as the fault gets farther away from the source. This property allows the use of the fault current magnitudes as the main criterion for the relaying action. The **overcurrent relaying** principle is combined with the inverse-time operating characteristic, as shown in Figure 9.11, and this represents the relaying solution for radial distribution feeders in most cases. The **inverse-time property** designates the relationship between the current magnitude and the relay operating time (the higher the fault current magnitude, the shorter the relay operation time). Further discussion is related to the setting procedures for the overcurrent relays with inverse-time characteristics.

To embark on determination of **relay settings**, the following data have to be made available for an overcurrent relay either through a calculation or through simple selection of design options: time dial, tap (pick-up setting), and operating characteristic type; current transformer ratio for each relay location; and extreme (minimum and maximum) short circuit values for fault currents. The mentioned data applied to the relaying system shown in Figure 9.10 are provided in Table 9.1. The values are determined only for relays *R*2 and *R*3 as an example. Similar approaches will yield corresponding values for relay *R*1.

The next step is to establish the criteria for **setting coordination**. The criteria selected as examples for relays *R*3 and *R*2 shown in Figure 9.10 are as these rules state:

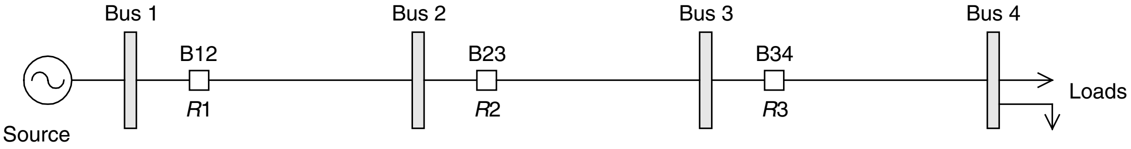

FIGURE 9.10 Protection of a Radial Distribution Feeder

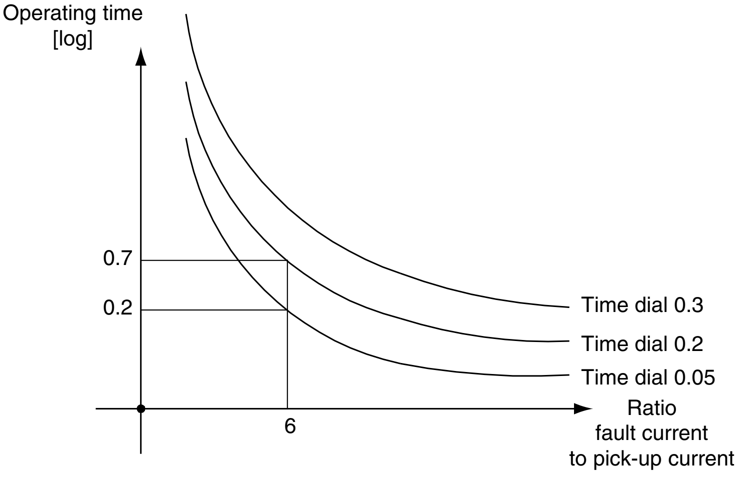

FIGURE 9.11 Inverse-Time Operating Characteristic of an Overcurrent Relay

TABLE 9.1 Data Needed for Setting Determination for the Case in Figure 9.10

	Bus/relay	
Max and min fault current [A]	*R*2	*R*3
Max fault current	306	200
Min fault current	250	156
CT ratio	50:5	50:5
Pick-up setting	5	5
Time-dial setting	0.2	0.05

1. *R*2 must pick up for a value exceeding one-third of the minimum fault current (rule of thumb) seen by relay *R*3 (assuming this value will never be below the maximum load current)
2. *R*2 must pick up for the maximum fault current seen by *R*3 but no sooner than 0.5 sec (rule of thumb) after *R*3 should have picked up for that current.

Based on the mentioned criteria and data provided in Table 9.1, the following are the setting calculation steps.

Step 1: Settings for Relay *R*3

The relay has to operate for all currents above 156 A. For reliability, one-third of the minimum fault current is selected. This yields a primary fault current of 156/3 = 52 A. Based on this, a CT ratio of 50/5 = 10 is selected. This yields a secondary current of 52/10 = 5.2 A. To match this, the relay tap (pick-up value) is selected to be 5.0 A. To ensure the fastest tripping for faults downstream from relay *R*3, the time dial of 0.05 is selected (see Figure 9.11).

Step 2: Settings for Relay *R*2

- Selection of CT ratio and relay tap
  The relay *R*2 must act as a backup for relay *R*3, and, hence, it has to operate for the smallest fault current seen by relay *R*3, which is 156 A. Therefore, the selection of the CT ratio and relay tap is the same for relay *R*2 as it was for relay *R*3.
- Time dial selection
  Based on the rule 2, relay *R*2 acting as a backup for relay *R*3 has to operate 0.5 sec after relay *R*3 should have operated. This means that relay *R*2 has to have a delay of 0.5 sec for the highest fault current seen by relay *R*3 to meet the above mentioned criteria. Let us assume that the highest fault current seen by relay *R*3 is at location next to breaker B34 looking downstream from breaker B34, and this current is equal to 306 A. In that case, the primary fault current is equal to 306/10 = 30.6 A. The selected relay tap setting will produce a pick-up current of 30.6/5 = 6.12 A. From Figure 9.11, the time delay corresponding to this pick-up value is 0.2 sec. Hence, if relay *R*3 fails to operate, the relay *R*2 will operate as a backup with a time delay of 0.2 sec + 0.5 sec = 0.7 sec. According to Figure 9.11, the time delay of 0.7 sec requires the selection of time dial of 0.2. It also becomes obvious that selection of a smaller current for calculation of the time delay of relay *R*3 will not allow the criteria in rule 2 to be met.

The overcurrent relaying of distribution feeders is a very reliable relaying principle as long as the time coordination can be achieved for the selected levels of fault current as well as the given circuit breaker operating times and instrument transformer ratios. The problems start occurring if the feeder loading changes significantly during a given period of time and/or the level of fault currents are rather small. This may affect a proper selection of settings that will accommodate a wide-range fluctuation in the load and fault currents. Some other, less likely, phenomena that may affect the relaying performance are as follows: current transformer saturation, selection of inadequate auxiliary transformer taps, and large variation in the circuit breaker opening times.

9.3.2 Distance Protection of Transmission Lines

As explained earlier, the distance protection principle is based on calculation of the impedance "seen" by the relay. This impedance is defined as the **apparent impedance** of the protected line calculated using the voltages and currents measured at the relaying point. Once the impedance is calculated, it is compared to the relay **operating characteristic**. If identified as falling into one of the zones, the impedance is considered as corresponding to a fault; as a result, the relay issues a **trip**. The concept of the impedance being proportional to the length of the transmission line and the idea of using the relay settings to correspond to the line length lead to the reason for calling this relaying principle **distance relaying**.

To illustrate the process of selecting distance relay **settings**, a simple network configuration, with data given in Table 9.2, is considered in Figure 9.12. Table 9.2 also contains additional information about the instrument transformer ratios.

The setting selection and coordination for the example given in Figure 9.12 can be formulated as follows.

Step 1: Determination of Maximum Load Current and Selection of CT and CVT Ratios

From the data given in Table 9.2, the maximum load current is computed as:

TABLE 9.2 Data Needed for Calculation of Settings for a Distance Relay

	Line impedance	
Data	Line 1–2	Line 2–3
Line impedance	$1.0 + j1.0$	$1.0 + j1.0$
Max load current	50 MVA	50 MVA
Line length	50 miles	50 miles
Line voltages	138 kV	138 kV

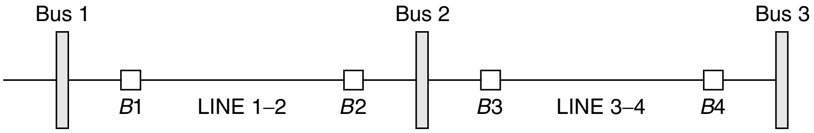

FIGURE 9.12 A Sample System for Distance Relaying Application

$$\frac{50(10^6)}{(\sqrt{3})(138)(10^3)} = 418.4\ \text{A} \tag{9.1}$$

The CT ratio is 400/5 = 80, which produces about 5 A in the secondary winding. If one assumes that the CVT secondary phase-to-ground voltage needs to be close to 69 V, then computing the actual primary voltage and selecting the ratio to produce the secondary voltage close to 69 V allows one to calculate the CVT ratio. The primary phase-to-ground voltage is equal to $138\sqrt{3}(10,000) = 79.67(10,000)$ V. If we allow the secondary voltage to be 69.3 V, then the CVT ratio can be selected as $79.67(10,000)/69.3 = 1150/1$.

Step 2: Determination of the Secondary Impedance "Seen" by the Relay

The CT and CVT ratios are used to compute the impedance as follows:

$$\frac{V_p/1150}{I_p/80} = \frac{V_p}{I_p}(0.07) = Z_{\text{line}}(0.07). \tag{9.2}$$

Therefore, the secondary impedance "seen" by the relay is for both lines equal to $0.07 + j0.07$.

Step 3: Computation of Apparent Impedance

Apparent impedance is the impedance of the relay seen under specific loading conditions. If we select the power factor of 0.8 lagging for the selected CT and CVT ratios as well as the selected fault current, the apparent impedance is equal to:

$$Z_{\text{load}} = \frac{69.3}{418.4\left(\frac{5}{400}\right)}(0.8 + j0.6) = 10.6 + 8.0. \tag{9.3}$$

Step 4: Selection of Zone Settings

Finally, the zone settings can now be selected by multiplying each zone's impedance by a safety factor. This factor is arbitrarily determined to be 0.8 for zone 1 and 1.2 for zone 2. As a result, the following settings for zone 1 and zone 2, respectively, are calculated as:

$$\begin{aligned} &\text{Zone 1} \quad 0.8(0.007 + j0.7) = (0.056 + 0.56)\Omega \\ &\text{Zone 2} \quad 1.2(0.007 + j0.7) = (0.084 + 0.84)\Omega. \end{aligned} \tag{9.4}$$

Distance relaying of transmission lines is not free from inherent limitations and application ambiguities. The most relevant inherent limitation is the influence of the current in-feed from the other end as described earlier. The other source of possible error is the fault resistance, which cannot be measured online. Therefore, it has to be assumed at the time of the relay setting computation, when a value different from what is actually present during the fault may be picked up. The anticipated value of the fault resistance is selected arbitrarily and may be a cause for a gross error when computing the impedance for a ground fault. Yet another source of error is the mutual coupling between adjacent transmission line or phases, which if significant, can adversely affect relay operation if not taken adequately into account when computing the fault impedance. The distance relaying becomes particularly difficult and sometimes unreliable if applied to some special protection case, such as multiterminal lines, lines with series compensation, very short lines, and parallel lines. In all of the cases, selecting relay settings is quite involved and prone to errors due to some arbitrary assumptions about the value of the fault impedance.

9.3.3 Directional Relaying Schemes for High-Voltage Transmission Lines

Due to the inherent shortcoming of distance relays not being able to recognize the effect of the current in-feed from the other end of the line and because of this possibly leading to a wrong decision, the concept of a relaying scheme is developed. The concept assumes that the relays at the two ends of a transmission line will coordinate their actions by exchanging the information that they detect for the same fault. To be able to perform the coordination, the relays have to use a **communication channel** to exchange the information. In an earlier discussion, illustrated in Figure 9.9, one of the principles for scheme protection of transmission lines was explained. A more comprehensive summary is given now.

The choices among basic relaying scheme principles are influenced by two factors: the **approach** in using the communication channels and the **type** of information sent over the channel. Regarding the approach for using the channels, one option is for the channels to be active during a fault, which means sending the information all the time and making sure that the communication did not fail. The other option is for the communication channels to be activated only when a command is to be transmitted and not being activated during other intervals or cases related to the fault. Regarding the type of information sent, the channels are used for issuing either a

TABLE 9.3 Summary of Basic Characteristics of Most Common Relaying Schemes

Scheme type (Directional Comparison)	The use of communication channel	Type of signal sent
Blocking	Blocking a signal (use of power line carrier)	Block
Unblocking	Sending either block or unblock signal all the time (use of frequency shift keying channel)	Block/unblock
Overreaching transfer trip Underreaching transfer trip	Sending a trip signal (use of audio tones)	Trip/guard

blocking or a tripping signal. In the case a **blocking signal** is issued, the relay from one end, after making a decision about a fault, sends a blocking signal to the other relay. If a **trip signal** is used, the relay that first detects the fault sends a signal to the other end. This will make the other relay perform a trip action immediately after it has detected a fault as well. Additional consideration in selecting the scheme relates to the type of **detectors** used in the relays for making the decisions about the existence of a fault and the location of the fault with the respect to the zones. Specific choices in setting up the zones are made for each scheme operation. Typical choices for the detector types are overcurrent and/or directional, with the zone I and / or zone II settings being involved in the decision making. A summary of the above considerations is given in Table 9.3.

As with any other relaying approach, the scheme implementations also have different performance criteria established. If one takes the dependability/security criterion (WG D5, 1997; WG, 1981) as the guiding factor in making the decisions, then the property of the various relaying scheme solutions can be classified as follows:

1. **Blocking/unblocking:** The blocking solution tends to provide higher dependability than security. Failure to establish a blocking signal from a remote end can result in overtripping for external faults. The unblocking solution offers a good compromise of both high dependability (channel not required to trip) and high security (blocking is continuous).
2. **Transfer trip (overreaching/underreaching):** The transfer trip solution offers higher security than dependability. A failure to receive the channel signal results in a failure to trip for internal faults. The transfer trip systems require extra logic for internal-trip operation at a local terminal when the remote terminal breaker is open or for a "weak infeed" when the fault contribution is too low to send a trip signal. This is not a problem with blocking and unblocking systems.

The options for scheme protection implementation are much more involved than what has been discussed here. Further details may be found in Blackburn (1993, 1998).

9.3.4 Differential Relaying of High-Voltage Transmission Lines

In the cases when the above-mentioned relaying schemes are not sufficiently effective, a differential scheme may be used to protect high-voltage (HV) transmission lines. In this type of relaying, the measurements from two (or multiple) ends of a transmission line are compared. Transmitting the measurement from one end to the other enables the comparison. The decision to trip is made once the comparison indicates a significant difference between the measurements taken at the transmission line end(s).

The main reason for introducing differential relaying is the ability to provide **100% protection** of transmission lines; at the same time, the influence of the rest of the system is minimal. The scheme has primarily been used for high-voltage transmission lines that have a strategic importance or have some difficult application requirements such as series compensation or multiterminal configuration. The use of a **communication system** is needed for implementation of this approach. This may be considered a disadvantage due to the increased cost and possibility for the channel malfunctioning.

The classification of the existing approaches can be based on two main **design properties**: the type of the communication **media** used and the type of the **measurements** compared. The communication media most commonly used are metallic wire, also known as pilot-wire; leased telephone lines; microwave radio; and fiber-optic cables. The measurements typically used for the scheme are composite values obtained by combining several signal measurements at a given end (IEEE, 1999) and sample-by-sample values of the phase currents (IEEE, 1999). A summary of the most common approaches for the differential relaying principle for transmission lines is given in Table 9.4.

In the past, the most common approach was to use metallic wire to compare the sequence values. The sequence values are a particular representation of the three-phase original values obtained through a symmetrical component transformation (Blackburn, 1993). Due to a number of practical problems caused by the ground potential rise and limited length of the physical wire experienced with the metallic wire use, these schemes have been substituted by other approaches where different media such as fiber-optic or microwave links are used. Most recently, as the wideband communication channels have become more affordable, the differential schemes are being implemented using either dedicated fiber-optic cables or a high-speed leased wideband communication system.

9.4 Protection of Power Transformers

For power transformers, the **current differential** relaying principle is the most common one used. In addition, other types of protection are implemented, such as a sudden pressure relay on the units with large ratings. As much as the current

TABLE 9.4 Summary of Most Common Differential Relaying Principles

Differential principle	Signals used for comparison	Properties
Pilot-wire	Three-phase currents converted into sequence voltage	Use of sequence filters due to direct use of wires prone to transients caused by interference
Phase comparison	Three-phase currents converted into a single current waveform	Composite waveform converted into binary string used for phase comparison
Segregated phase comparison	Phase currents in each phase directly compared at two ends	Currents converted into square waves used for phase comparison
Current differential	Samples of each current transmitted to the other end for comparison	Currents from both ends directly compared
Composite–waveform differential	Each current converted into sequence current and a combined composite signal is transmitted	Composite signals from both ends directly compared

differential relaying has been a powerful approach in the past, it has some inherent limitations that pose difficulties for special applications or practical design considerations. Further discussion concentrates on the mentioned limitations and their impact on the current differential approaches. The other relaying principles applied for protecting power transformers are not discussed here. Further details can be found in references (Horowitz and Phadke, 1992; Blackburn, 1998; Ungrad *et al.*, 1995).

9.4.1 Operating Conditions: Misleading Behavior of Differential Current

Power transformers are energy storage devices that experience transient behavior of the terminal conditions when the stored energy is abruptly changed. Such conditions may be seen during transformer energization, energization of a parallel transformer, removal of a nearby external fault, and a sudden increase in the terminal voltage. The following is a discussion of the mentioned phenomena and the impact they have on the terminal currents.

Energizing a transformer causes a transient behavior of the currents at the transformer primary due to so-called **magnetizing inrush** current. As a voltage is applied on an unloaded transformer, the nonlinear nature of the magnetizing inductance of the transformer causes the magnetizing current to experience an initial value as high as 8–30 times the full-load current, which may appear to the differential scheme as a difference caused by a fault. An example of the harmonic inrush wave shape for the magnetizing current is given in Figure 9.13. Fortunately, the inrush current has a rich harmonic content, which can be used as the basis for distinguishing between the high currents caused by a fault and the ones caused by the inrush. Since the magnetizing inrush is a function of both the prior history of remanent magnetism as well as the type of the transformer connection, selecting the scheme for recognizing proper levels of the harmonics needs to be carried out carefully.

Similar transient behavior of the primary current is seen in a transformer connected in parallel to a transformer that is being energized. The change in the magnetizing current is affecting the primary current of the parallel transformer due to an inrush created on the transformer being energized. This phenomenon is called **sympathetic inrush**. Sudden removal of an external fault and a sudden increase in the transformer voltage also cause the inrush phenomenon, again well recognized by an occurrence of particular harmonics in the primary current.

9.4.2 Implementation Impacts Causing Misleading Behavior of Differential Currents

The current differential relayed for power transformer applications may be affected by practical implementation constraints.

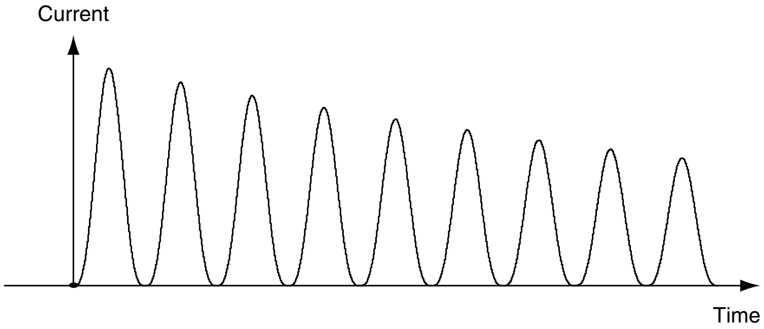

FIGURE 9.13 Magnetizing Inrush Affecting Primary Current

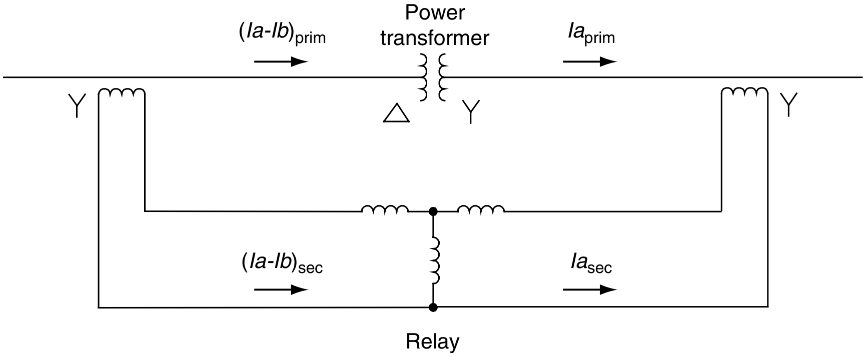

FIGURE 9.14 Phase Mismatch

One of the common problems is to have a mismatch between ratios of the instrument transformers located at the two power transformer terminals. This is called a **ratio mismatch**, and it is corrected by selecting appropriate taps on the auxiliary transformers located at the inputs of the transformer differential relay. Yet another obstacle may be a **phase mismatch**, where the instrument transformer connection may cause a phase shift between the two currents seen at the transformer terminals. This is because the connection of the power transformer may introduce a phase shift, and if the instrument transformer does not correct for this, a phase mismatch will occur at the terminals of the instrument transformer. The phase mismatch is illustrated in Figure 9.14, where the currents in the relaying circuit are not correctly selected. The mismatch can be avoided if the instrument transformer at the Y side of the power transformer is of a Δ type.

Besides the mentioned constraints, other constraints include the mismatch due to a changing tap position on the load tap changer as well as the mismatch caused by the errors in current transformers located at two terminals.

9.4.3 Current Differential Relaying Solutions

The straightforward solution for differential relaying is to take a difference of currents I_1 and I_2 at two ends and compare it to a threshold I_T as shown in equation:

$$|(I_1 - I_2)| \geq I_T. \tag{9.5}$$

This solution will have a problem to accommodate an error due to a mismatch discussed earlier. Hence, a different equation may be used to make sure that a higher error is allowed for higher current levels:

$$|(I_1 - I_2)| \geq \frac{|(I_1 - I_2)|}{2}. \tag{9.6}$$

Finally, to distinguish the case of the inrush condition mentioned earlier, a harmonic restraint scheme is used as represented by equation:

$$|(I_1 - I_2)| \geq k \cdot \frac{|(I_1 - I_2)|}{2}. \tag{9.7}$$

This type of operating characteristic will recognize that the current difference is caused by an event that is not an internal fault, and it will block the relay from operating. The criterion for recognizing a nonfault event is the presence of a particular harmonic content in the differential current. This knowledge is used to restrain the relay operation by relating the factor k to the presence of the harmonic content, hence the "harmonic restraint" terminology.

9.5 Protection of Synchronous Generators

Synchronous generators are commonly used in high-voltage power systems to generate electric power. They are also protected using the **current differential** relaying principle. In addition, the generators require a number of other special operating conditions to be met. This leads to the use of a score of other relaying principles. This section reviews some basic requirements for generator protection and discusses the basic relaying principles used. A much more comprehensive coverage of the subject may be found in an IEEE Tutorial (1995).

9.5.1 Requirements for Synchronous Generator Protection

Generators need to be protected from the **internal faults** as well as the abnormal operating conditions. Since generators consist of two parts, namely the **stator** and the **rotor**, protection of both is required. The stator is protected from both phase and ground faults, while the rotor is protected against ground faults and loss of field excitation. Due to the particular conditions required for the synchronous machine to operate, a number of operating conditions that represent either a power system disturbance or operational hazard need to be avoided. The conditions associated with **network disturbances** are overvoltage or undervoltage, unbalanced currents, network frequency deviation, and subsynchronous oscillations. The conditions of **hazardous operation** are loss of prime mover (better known as generator motoring), inadvertent energization causing a nonsynchronized connection, overload, out-of-step or loss of synchronism, and operation at unallowed frequencies.

9.5.2 Protection Principles Used for Synchronous Generators

The **current differential** protection principle is most commonly used to protect against phase faults on the **stator**, which are the most common faults. Other conditions require other principles to be used. The loss of field and the ground protection of the rotor are quite complex and depend on the type of the grounding and current sensing arrangement used. This subject is well beyond the basic considerations and is treated in a variety of specialized literature (IEEE, 1995). Protection from the **abnormal** generator operating **condition** requires the use of relaying principles based on detection of the changes in voltage, current, power, or frequency. A reverse power relay is used to protect against loss of a prime mover known as generator motoring, which is a dangerous condition since it can cause damage of the turbine and turbine blades. In addition, synchronous generators should not be subjected to an overvoltage. With normal operation near the knee of the iron saturation curve, small overvoltages result in excessive flux densities and abnormal flux patterns, which can cause extensive structural damage in the machine. A relaying principle based on the ratio between voltage and frequency, called a volt-per-hertz principle, is used to detect this condition. An inadvertent connection of the generator to the power system not meeting the synchronization requirements can also cause damage. The overcurrent relaying principle in combination with the reverse power principle are used to detect such conditions. The overload conditions as well as over- and under-frequency operations can cause damage from overheating, and thermal relays in combination with frequency relays are used. Undervoltage and overvoltage protections are used for detecting loss of synchronism and overvoltage conditions.

9.6 Bus Protection

Protecting **substation busses** is a very important task because operation of the entire substation depends on availability of the busses. The bus faults are rare, but in the open-air substations, they occasionally happen. They have to be cleared very fast due to high-fault current flow that can damage the bus. This section briefly discusses the requirements and basic principles used for bus protection. Detailed treatment of the subject is given in several classical references (Horowitz and Phadke, 1992; Blackburn, 1998; Ungrad *et al.*, 1995).

9.6.1 Requirements for Bus Protection

High-voltage substations typically have at least two busses: one at one voltage level and the other at a different voltage level with power transformer(s) connecting them. In high-voltage substations, the breaker-and-a-half arrangement, shown earlier in Figure 9.3, is used to provide a redundant bus connection at each voltage level. In addition, in some substation arrangements, there is a provision for separating one portion of the bus from another, allowing for independent operation of the two segments. All of those configurations are important when defining the bus protection requirements (Blackburn, 1998).

The first and foremost requirement for bus protection is **the speed of relay operation**. There are several important reasons for that all relate to the fact that the fault currents are pretty high. First, the **current transformers** used to measure the currents may get **saturated**; hence, a fast operation will allow for the relaying decision to be made before this happens. Next, due to the high currents, the equipment damage caused by a sustained fault may be pretty severe. Hence, the need to accomplish an isolation of the faulted bus from the rest of the system in the shortest time possible is paramount. Last, but not least, due to the various possibilities in reconfiguring busses, it is very important that the bus protection scheme is developed and implemented in a flexible way. It needs to allow for various parts of the bus to be isolated for maintenance purposes related to the breakers on the connected lines, and yet the protection for the rest of the bus needs to stay intact.

9.6.2 Protection Principles Used for Bus Protection

The most common bus protection principle is the **current differential approach**. All connections to the bus are monitored through current transformers to detect current imbalance. If an internal bus fault occurs, the balance between incoming and outgoing currents is drastically disturbed, and that becomes a criterion for tripping the bus breakers and isolating the bus from the rest of the system. This relaying principle would be very simple to implement if there were no problems with **CT saturation**. Due to high-fault currents, one of the CTs may see extraordinary high currents during a close-in external fault. This may cause the CT to saturate, making it very difficult to distinguish if the CT was saturated due to high currents from an internal or external fault. If **air-gap** or **air-core** CTs are used, the saturation may not be an issue, and the current differential relaying is easily applied. This solution is more costly and is used far less frequently than the solution using standard iron-core CTs.

To cope with the CT saturation, two types of relaying solutions are most commonly used (Blackburn, 1998). The first one is a **multirestraint current differential**, and the other one is a **high-impedance voltage differential**. The multirestraint current differential scheme provides the restraint winding connection to each circuit that is a major source of the fault current. These schemes are designed to restrain correctly for heavy faults just outside the differential zone, with maximum offset current, as long as the CTs do not saturate for the maximum symmetrical current. These schemes are more difficult to apply and require use of auxiliary CTs to match the current transformer ratios. The high-impedance voltage differential principle uses a property that CTs, when loaded with high impedance, will be forced to take the error differential current, and, hence, this current will not flow through the relay operating coil. This principle translates the current differential sensitivity problem is to the voltage differential sensitivity probem for distinguishing the close-in faults from the bus faults. The voltage differential scheme is easier to implement since the worst case voltage for external faults can be determined much more precisely knowing the open voltage of the CT.

9.7 Protection of Induction Motors

Induction motors are a very common type of load. The main behavioral patterns of the induction motor are representative of the patterns of many loads; their operation depends on the conditions of the network that is supplying the power as well as the **loading conditions**. This section gives a brief discussion on the most important relaying requirements as well as the most common relaying principles that apply to the induction motor protection. Further details can be found in (Horowitz and Phadke, 1992; Blackburn, 1998; Ungrad *et al.*, 1995).

9.7.1 Requirements for Induction Motor Protection

The requirements may be divided in three categories: **protecting the motor from faults**, **avoiding thermal damage**, and **sustaining abnormal operating conditions**. The protection from faults has to detect both phase and ground faults. The thermal damage may come from an overload or locked rotor and has to be detected by correlating the rise in the temperature to the occurrence of the excessive currents. The abnormal operating conditions that need to be detected are unbalanced operation, under voltage or overvoltage, reversed phases, high-speed reclosing, unusual ambient temperature, voltage and incomplete starting sequence.

The protection principle used has to differentiate the causes of problems that may result in a damage to the motor. Once the causes are detected and linked to potential problems, the motor needs to be quickly disconnected to avoid any damage.

9.7.2 Protection Principles Used for Induction Motor Protection

The most common relaying principles used for induction motor protection are the **overcurrent protection** and **thermal protection**. The overcurrent protection needs to be properly set to differentiate between various changes in the currents caused either by faults or excessive starting conditions. A variety of current-based principles can be used to implement different protection tasks that fit the motor design properties. Both the phase and ground overcurrents, as well as the differential current relays, are commonly used for detecting the phase and ground faults. The thermal relays are available in several forms: a "**replica**" **type**, where the motor-heating characteristics are approximated closely with a bimetallic element behavior; resistance temperature detectors embedded in the motor winding; and relays that operate on a combination of current and temperature changes.

Electric Power Quality

Gerald T. Heydt
*Department of Electrical Engineering,
Arizona State University,
Tempe, Arizona, USA*

10.1 Definition

There is no single acceptable definition of the term **electric power quality**. The term generally applies to the goodness of the electric power supply, its voltage regulation, its frequency, voltage wave shape, current wave shape, level of impulses and noise, and the absence of momentary outages. Some engineers include reliability considerations in electric power quality studies, some consider electromagnetic compatibility, and some perform generation supply studies. Narrower definitions of electric power quality generally focus on the bus voltage wave shape.

Electric power quality studies generally span the entire electrical system, but the main points of emphasis are in the primary and secondary distribution systems. This is the case because loads generally cause distortion of bus voltage wave shape, and this distortion is mainly noted near the source of the difficulty—namely near the load—in the secondary distribution system. Because the primary distribution system is closely coupled to the secondary system and the load, which is sometimes served directly by the primary distribution system, the primary network is also a point of focus. Transmission and generation systems are also studied in certain types of power quality evaluation and analyses. Table 10.1 shows the main points in electric power quality.

10.2 Types of Disturbances

There are two main classes of electric power quality disturbances: the **steady-state disturbance** that lasts for a long period of time (and is often periodic) and the **transient**. The latter generally exists for a few milliseconds, and then decays to zero. Controversy surrounds which is more important, and a case could be made for either type of disturbance being more problematic as far as cost. The steady-state type of disturbance is generally less evident in its appearance, often at lower voltage and current levels, and less harmful to the operation of the system. Because steady-state phenomena last for a long period of time, the integrated effects of active power losses (low or high voltage) and inaccurate timing signals may be quite costly. Transient effects tend to be higher level in amplitude and are often quite apparent in harmful effects as well as occasionally spectacular in cost (e.g., causing loss of a manufactured product or causing long-term outages). The cost of transient power quality problems has been estimated in the 100 million to 3 billion dollar range annually in the United States. Table 10.2 lists some types of steady-state and transient power quality problems. The transient problems are often termed **events**.

10.3 Measurement of Electric Power Quality

Many indices have been developed for the specification of electric power quality. A few are listed in Table 10.3. The most widely used index of power quality is the total harmonic distortion, which is an index that compares the intensity of harmonic signals in voltages and currents to the fundamental component. The main indices are as follows:

TABLE 10.1 Electric Power Quality Considerations

Consideration	Focus	Comments
Region of analysis	• Distribution systems • Points of utilization of electric power • Transmission systems • Electromagnetic compatibility	The main region of analysis is the primary and secondary distribution system. This is where nonsinusoidal waves are most prevalent and of greatest amplitude.
Types of problems	• Harmonics • Momentary outages and low voltages (sags)	There is a controversy concerning whether momentary low voltages (sags) or harmonics are the most problematic in terms of cost of the problem.
Analysis methods	• Circuit analysis programs • Harmonic power flow studies • Focused studies on particular events using circuit theory to obtain solution • Pspice	A range of commercial software is available for both smaller and larger studies. Many software tools are linked to elaborate graphics. Most methods are data intensive and approximate.
Mitigation techniques	• Filters • Capacitors • Problematic loads • Higher pulse order (e.g., twelve-pulse rather than six-pulse systems)	Mitigation techniques are often customized to the particular problem and application. In general, higher pulse order systems give much less problem than single-phase and six-pulse, three-phase systems.

TABLE 10.2 Power Quality Problems

Type	Problem	Appearance	Causes
Transient system problems	Impulses (surges, pulses)	High-voltage impulse for a short time, typically in the microsecond to 1 ms range	• Lightning • Switching surges • Rejection of inductive loads
	Momentary outages	Collapse of ac supply voltage for up to a few (e.g., 20) cycles	Circuit breaker operations
	Phase shift	Sinusoidal supply voltage proportional to a sine function whose phase angle suddenly shifts by an angle φ	Faults
	Sags (low voltage)	Momentary low voltage caused by faults in the supply	Faults
	Ringing	Damped sinusoidal voltages impressed on the ac wave	Capacitor switching
Steady-state system problems	Harmonics	Integer multiples of the ac supply frequency (e.g., 60 Hz) of (usually) lower amplitude signals impressed on the power frequency wave	• Nonlinear loads • Adjustable speed drives • Rectifiers • Inverters • Fluorescent lamps
	Voltage notches	Momentary low voltages of duration much shorter than one cycle caused by commutated loads	Adjustable speed drives
	Noise	Noise impressed on the power frequency	• Static discharge and corona • Arc furnaces
	Radio frequency	High-frequency (e.g., $f > 500\,\text{kHz}$) sinusoidal signals of typically low amplitude impressed on the power frequency	Radio transmitters
	Interharmonics and fractional harmonics	Components of noninteger multiples of the power frequency	• Cycloconverters • Kramer drives • Certain types of adjustable speed drives

- **Power factor**: The relationship of power factor to the IEEE Standard 519-1992, especially with regard to the failure of the power factor to register harmful and undesirable effects of high-frequency harmonics in power distribution systems, is well known. Many electric utilities have limits to the power factor of consumer loads, but there may not be a clear definition of power factor for the nonsinusoidal case. In particular, many electric utilities

TABLE 10.3 Voltage Measurement

Instrument	Configuration	Application considerations
Potential transformer (PT)	Energized at full line potential on the high side and typically in the 100-V range on the low side	• Bandwidth of the PT • Safety (e.g., upon failure of the PT) • Turns ratio, accuracy
Voltmeters	Energized directly or through a probe	• Isolation from the line • Bandwidth • True RMS reading questioned • Accuracy
Voltage divider	Energized at full line potential at the upper resistor; resistive voltage divider used to give low voltage at the low end of the string	• Safety (e.g., opening of low end of string) • Heat loss
Capacitively coupled voltage transformer	Capacitive voltage divider energized at full line potential at upper end; instrument transformer used to obtain some isolation	• Bandwidth • Resonance of the capacitors and transformer • Accuracy • Frequency dependence

do not distinguish between displacement of the power factor (i.e., the cosine between the voltage and current phasors at the fundamental frequency) and the power factor defined in Table 10.4. The term **true power factor** has been used by some to refer to $P/|V||I|$, but the IEEE Standard 100 used the term **power factor** for this ratio, and this simpler term is used in this chapter.

- **Total harmonic distortion**: The use of the total harmonic distortion (THD) is perhaps the most widespread power quality index, and many electric utilities have adopted a THD-based measure of the limits of customer load currents.
- ***K*-factor**: Explanation of the use of the *K*-factor to derate transformers that are expected to carry nonsinusoidal load currents has been used, and an alternative calculation of this index in the time domain has been shown.
- **Flicker factor**: This flicker factor index has been used in connection with electric arc furnaces for the purpose of quantifying the load impact on the power system.

Perhaps the main application of power quality indices has been in guides, recommended practices, and standards. As an example, the IEEE Standard 519-1992 contains an often cited limit to harmonic load currents and voltages. The ANSI

TABLE 10.4 Common Power Quality Indices

Index	Definition	Main applications
Total harmonic distortion (THD)	$\left(\sqrt{\sum_{i=2}^{\infty} I_i}\right)/I_1$	General purpose; standards
Power factor (PF)	$P_{tot}/\lvert V_{\mathrm{rms}}\rvert\lvert I_{\mathrm{rms}}\rvert$	Potentially in revenue metering
Telephone influence factor	$\left(\sqrt{\sum_{i=2}^{\infty} w_i^2 I_i}\right)/I_{\mathrm{rms}}$	Audio circuit interference
C message index	$\left(\sqrt{\sum_{i=2}^{\infty} c_i^2 I_i}\right)/I_{\mathrm{rms}}$	Communications interference
IT product	$\sqrt{\sum_{i=1}^{\infty} w_i^2 I_i^2}$	Audio circuit interference, shunt capacitor stress
VT product	$\sqrt{\sum_{i=1}^{\infty} w_i^2 V_i^2}$	Voltage distortion index
K factor	$\left(\sum_{h=1}^{\infty} h^2 I_h^2\right)/\sum_{h=1}^{\infty} I_h^2$	Transformer derating
Crest factor	$V_{\mathrm{peak}}/V_{\mathrm{rms}}$	Dielectric stress
Unbalance factor	$\lvert V_-\rvert/\lvert V_+\rvert$	Three-phase circuit balance
Flicker factor	$\Delta V/\lvert V\rvert$	Incandescent lamp operation, bus voltage regulation, sufficiency of short circuit capacity
Total demand distortion (TDD)	THD*(fundamental current/circuit rating)	In IEEE Standard 519

Standard 368 contains a well-quoted guide on limits of the IT product. The Underwriters Laboratories applies the *K*-factor to the specification of transformers that carry nonsinusoidal load currents.

10.4 Instrumentation Considerations

Because power quality is often stated in terms of voltages and currents, the main instrumentation needed to assess power quality relates to bus voltages and line and load currents. In terms of voltages, usually bus voltages are measured using potential transformers because isolation from the power circuit is desirable and because power system voltages are usually too high to measure directly. Typical potential transformers are capable of bringing circuit voltages (e.g., in the 440–7200 V range for distribution circuits and up to 40 kV for subtransmission circuits) to about 110 V. These potential transformers must have the proper bandwidth to "see" the desired voltages to be instrumented (e.g., harmonic voltages), they must have the proper dynamic range to allow measurement of the voltage, and they must have isolation suitable for safety. Some voltage measurement instruments are listed in Table 10.3.

Current instrumentation is analogous to voltage measurement with the replacement of the current transformer for the potential transformer. Main considerations are appropriateness of the current ratio in the current transformer, isolation for safety, loading with the proper current transformer burden, and bandwidth and dynamic range of the current transformer. Table 10.5 shows some of the basic instruments used in current instrumentation.

Both current and voltage transformers are available in several grades. General purpose transformers are not generally usable for power quality measurements because the bandwidth of these devices is often not much larger than 60 Hz (in 60-Hz systems). Harmonics may be attenuated by the current or potential transformer, and this adds intolerable error to the measurement. Relaying grade current and relaying potential transformers are usually not much better because of limited bandwidth. Revenue meter grade current and voltage transformers are generally not designed for high bandwidth applications. Laboratory grade transformers are usually the best choice. Modern power quality instruments generally have companion current and voltage transformers for use with a given instrument, and the manual for the instrument will contain the bandwidth measurement of the transformers. It is noted that for many voltage and current instruments used in power quality tests, current and voltage transformers are the most costly components of the instrumentation system.

Modern power quality assessment often involves more than voltage and current measurement. The following are also part of the test regimen in most cases:

- Event measurement (i.e., measurement of three-phase voltages and currents, plus neutral ground voltage and neutral current versus time)
- On-board evaluation of harmonics (of voltages and currents, often plotted versus time)
- Measurement of active and reactive power
- Measurement of total harmonic distortion
- Measurement of active power loss in a system component
- Assessment of high-frequency effects
- Measurement of rise time
- Oscillograph capability (often written digitally to a disk for subsequent analysis and report writing)
- Energy measurement.

Table 10.6 illustrates a few of these capabilities in commercial instruments in use for power quality assessment.

TABLE 10.5 Current Instrumentation

Instrument	Configuration	Application considerations
Current transformer (CT)	Placed around the conductor to be instrumented	• Bandwidth • Safety • Operation with correct CT burden
Resistive shunt for current measurement	Resistor in series with load to be instrumented	• No ohmic isolation • Accuracy • Heating of the shunt
Ammeter	Placed in series with circuit to be instrumented	• Accuracy • Bandwidth • Safety—no ohmic isolation for circuit
Optical instruments	Rotation of plane of polarized light in a fiber-optic cable around or near the instrumented circuit	• Accuracy • Vibration sensitivity • Cost
Hall-effect device	Measurement of magnetic field near instrumented conductor	• Accuracy • Bandwidth • Vibration and mechanical placement sensitivity • Linearity

TABLE 10.6 Power Quality Assessment Instruments

Instrument	Typical capability	Bandwidth	Dynamic range
Digital fault recorder (DFR)	Measure three-phase voltage and current; perform basic analysis on these data; measure digital output	Typically to about 3000 Hz	At least 80 db, possibly 100 db
Power quality node	Commercialized event recorder for distribution system instrumentation and field rugged, and telephone interrogations	Typically to about 3000 Hz	About 80 db
Event recorder, digital oscilloscope	Oscilloscope functions, digital readout, basic analysis functions, signal triggers recording	Varies widely—possibly into the megahertz range	About 100 db

10.4.1 Advanced Instrumentation

In the preceding section, several basic voltage and current measurement instruments were discussed. Because power quality measurements are often demanding in bandwidth and dynamic range, several types of advanced instrumentation techniques have been studied and developed for this application. A few are listed in Table 10.7.

10.5 Analysis Techniques

The main analytical techniques for power quality studies are the following:

- Power flow studies
- Injection current analysis
- Simulation methods, such as Pspice and EMTP
- Direct circuit analysis

Power flow studies are software tools that rely on steady-state operation of the system to be studied. These software tools use input data such as load type, load level (P, Q), and circuit data (e.g., impedance, connection diagram). The output is typically all nodal voltages and all line currents at all frequencies.

Injection current analysis is the analysis of how currents injected into a system propagate. This is a simplified form of power flow study.

Power quality engineering may be taken to be a specialized branch of signal analysis. In this regard, there are many useful formulas that may be applied to solve problems. One particularly useful set of formulas is the ideal rectifier set of formulas shown in Table 10.8. Rectifier loads are a main source of harmonic load currents. The ideal rectifier formulas give the various interrelationships of voltage and current parameters for the idealized case of no rectifier power loss and very high dc side inductance. These formulas, while useful, should be used with caution because the assumptions made in arriving at these formulas are all idealizations. Note that the displacement factor is the cosine of the angle between fundamental voltage and fundamental current. The power factor is the ratio $P/V_{\text{rms}}I_{\text{rms}}$.

10.6 Nomenclature

c_h	C-message weight
CBEMA	Computer Business Equipment Manufacturers Association
CT	current transformer
DF	displacement factor
DPF	displacement power factor
EPRI	Electric Power Research Institute
IEC	International Electrotechnical Commission
IT	current—telephone influence factor product, read as IT product
I_h, V_h	harmonic components of current $i(t)$ and $v(t)$
K	K-factor
kIT	thousands of IT units
kVT	thousands of VT units

TABLE 10.7 Advanced and Unconventional Instrumentation for Electric Power Quality Assessment

Basic instrumentation technique	Basis	Application
Poeckels effect	Rotation of the plane of polarized light in a medium due to electric field strength	Wideband measurement of voltage
Faraday rotation effect	Rotation of the plane of polarized light in a medium due to magnetic field strength	Wideband measurement of current
Hall effect	Variation of the resistance of a material in a magnetic field	Wideband measurement of current
Global Positioning System (GPS) applications	Triangular spotting of four or more artificial earth satellites to obtain time and position of a receiver	Accurate time tagging of measurements, phasor measurements

SIGNAL PROCESSING

Yih-Fang Huang
Department of Electrical Engineering,
University of Notre Dame,
Notre Dame, Indiana, USA

This section includes seven chapters that address various topics of *Signal Processing*, written by leading experts on the respective topics. Signal processing is one of the most important and rapidly growing fields in Electrical Engineering. Over the last few decades, it has played an important role in many different fields in science and engineering.

Information is most effectively represented by electronic signals or optical signals. Both types of signals can then be processed conveniently by electronic devices and systems. In the second half of the twentieth century, the successes in semiconductor device fabrication and integrated circuits technologies continued to fuel the development of powerful signal processing tools that benefit further development of various technological fields.

The first chapter of this section provides an overview of basic principles of signals and systems. It presents important fundamental concepts in transforming time-domain signals into frequency domain signals (like Fourier transform and z-transform and their properties) and linear shit-invariant systems and their properties.

The presentation of Chapter 1 lays down a nice foundation for the discussion of digital filters, with some emphasis on finite impulse response (FIR) and infinite impulse response (IIR) filters. The FIR filter and IIR filters are two most commonly used digital filters and they are realizations of linear shift-invariant systems. Properties and applications of those filters are addressed.

Chapters 3 to 5 present principles of the processing of various forms of signals, namely, speech signals, image signals and multimedia signals. Each form of signals has specific properties and applications that require distinctive processing techniques.

Chapter 6 presents fundamental concepts of statistical signal processing, which is an important aspect of signal processing. It provides a brief summary of the principles of mathematical statistics on which signal detection and estimation are based. Signal detection and estimation are critical in extracting information from signals in communication and control systems.

The Section ends with a chapter that addresses issues related to implementation of signal processing algorithms. It is concerned with application-specific VLSI architecture, including programmable digital signal processors, and dedicated signal processors implemented with VLSI technology. It also provides a good survey of recent development in VLSI signal processing technologies.

On behalf of all the authors in this section, I thank you for your interests in signal processing and hope you enjoy reading these chapters.

Signals and Systems

Rashid Ansari and
Lucia Valbonesi
Department of Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, Illinois, USA

1.1 Introduction

Signal processing deals with operations performed on a signal with the intent of either modifying it in some desirable way or extracting useful information from it. Signal processing encompasses the theory, design, and practice of software and hardware for converting signals produced by different sources into a form that allows a more effective utilization of the signal content. The signals might be speech, music, image, video, multimedia data, biological signals, sensor data, telemetry, electrocardiograms, or seismic data. Typical objectives of processing include manipulation, enhancement, transmission, storage, visualization, detection, estimation, diagnosis, classification, segmentation, or interpretation. Signal processing finds applications in many areas, such as in telecommunications, consumer electronics, medical imaging and instrumentation, remote sensing, space research, oil exploration, radar, sonar, and biometrics (Anastassiou, 2001; Baillet *et al.*, 2001; Ebrahimi *et al.*, 2003; Hanzo *et al.*, 2000; Molina *et al.*, 2001; Ohm, 1999; Podilchuck and Delp, 2001; Strintzis and Malassiotis, 1999; Strobel *et al.*, 2001; Wang *et al.*, 2000; National Science Foundation, 1994). Mathematical foundations of signal processing are mainly drawn from transform theory, probability, statistical inference, optimization, and linear algebra.

The field of signal processing has grown phenomenally in the past years. This growth has been fueled by theoretical and algorithmic developments, technological advances in hardware and software, and ever widening applications that have generated an insatiable demand for signal processing tools. Theory and practice in a number of fields have been greatly influenced by signal processing (e.g., communications, controls, acoustics, music, seismology, medicine, and biomedical engineering).

Signal processing finds widespread use in everyday life, though the ubiquity of signal processing may not be evident to most users. Users may be familiar with JPEG, MPEG, and MP3 without recognizing that these tools are rooted in signal processing (Ansari and Memon, 2000; Wang *et al.*, 2000).

Recording of movies on a digital video disc (DVD), one of the most successful consumer electronics products, is made possible by compression techniques based on signal processing. DVD video is usually encoded from digital studio master tapes to MPEG-2 format, where MPEG refers to Moving Pictures Expert Group. The encoding process uses lossy compression that removes information that is either redundant or not readily perceptible by the human eye. The ultimate objective in compression is to reduce the bit rate for storage and transmission of video. The signal processing used here consists of applying suitable transforms to the data. Typically, a reduction in bit-rate requirements by a factor of 30 to 40 permits acceptable video quality.

The reduced memory requirements of audio coded in MP3 format has made it a popular vehicle for exchanging and storing music by individual users. MP3 refers to the MPEG Layer 3 audio compression format. Raw digital audio signals typically consist of 16-bit samples acquired at a sampling rate that is at least twice the bandwidth of the audio signal. In compact discs (CDs), a sampling rate of 44.1 kHz is used for each channel of stereo music. As a result, more than 1.4 Mbits is needed to represent just 1 second of music in raw CD recordings. By using MP3 audio coding, the storage requirement is reduced by a factor of 12 to 14 without significant loss in sound quality. This saving in storage is realized by using a signal processing tool, called a filter bank, in conjunction with exploiting the nature of perception of sound waves by the human ear.

In some applications, both speech and visual information may be jointly processed (Chen, 2001; Strobel *et al.*, 2001). This joint processing is referred to as multimedia or multimodal signal processing where data of multiple media like text, audio, images, and video are processed in an integrated manner, and interaction among the different media or modalities is investigated and exploited. Person recognition and authentication systems that have recently acquired increased importance in security and surveillance applications can be made more reliable by combining inputs from different modalities, such as voice and visual information.

Progress in the signal processing field has in recent years been largely driven by specific applications. Signal processing often figures in multidisciplinary research efforts. A noteworthy success in the application of signal processing has been in the fields of medicine and healthcare (Baillet *et al.*, 2001; Ebrahimi *et al.*, 2003). A number of imaging tools have been developed to aid diagnosis and recognition of disease. Computer tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) are being widely used. These imaging technologies are testimony to the success of multidisciplinary interaction among researchers in fields such as signal processing, medicine, biology, and physics. The multidisciplinary effort can be witnessed in the collaboration on new challenges in modeling and processing in the emerging modalities for medical imaging such as electro/magneto-encephalography (E/MEG) and electrical impedance tomography (EIT).

In this chapter, we provide an overview of signals and systems that is largely based on signal representation framework, linear system theory, and transform theory. We begin by describing some basic notions of **discrete-time** and **continuous-time** signals and systems. The emphasis is on discrete-time signals and systems, but notions for the two cases are presented in parallel. The exposition of the continuous-time case is deliberately brief because the similarity in the notions should be evident to the reader. The concepts of sampling and quantization that relate continuous- and discrete-time signals are briefly discussed toward the end of the chapter.

Fundamentals of discrete-time systems and properties such as linearity, time-invariance, causality, and stability are reviewed first. Frequency domain analysis of signals and Fourier transforms are then presented followed by a discussion of frequency-selective filtering. Basics of *z*-transforms are covered next with a discussion of the *z*-domain interpretation of system properties such as causality and stability. Operations of sampling and quantization are then presented. Finally, the discrete Fourier transform is presented, and its importance in implementing signal processing algorithms is described. Our discussion is confined to the description and processing of **deterministic signals**.

1.2 Signals

Notions of signals and systems are encountered in a wide variety of disciplines. **Signal processing** formalizes these notions in a unified framework. It enables us to deal with diverse phenomena whose behavior is captured in variations of functions that characterize the phenomena. Signals are an abstraction for representing these variations. The signal may represent amplitude changes in speech or audio, concentration of a solute, biologically generated voltages, temperature inside an engine, pressure in a urinary bladder, noise in a communication receiver, and other such variables.

A **signal** is a mathematical function of one or more independent variables that usually represent time and/or space. An example of a signal as a function of time is a speech signal that represents a variation of acoustic pressure with time. An example of a signal as a function of space is an **image**: it is a function of light intensity and color in two spatial coordinates.

Some signals may depend both on space and time. Examples are video signals or the measurements of temperature in a room that depend on the three spatial coordinates defining each point in the room and that also vary with time.

In this section, we focus on signals that are functions of a single independent variable, and we will generally refer to this variable as **time**.

The independent variable of a signal can be either continuous or discrete, depending on the set of values for which the function is defined. In the first case, the signal is **continuous-time**, and the function is defined over a continuum of values of the independent variable; in the second case, the signal is **discrete-time**, and the function is defined over a countable set of values of the independent variable.

To distinguish between continuous-time and discrete-time signals, we will denote the independent variable as t in the continuous-time case and n in the discrete-time case.

The amplitude of a signal may also assume either continuous or discrete set of values. Thus, the signals can be classified into four categories depending on the nature of their independent and dependent variables.

It is convenient to introduce some notation here: $\mathcal{Z}$ denotes the set of integers, $\mathcal{C}$ the set of complex numbers, and $\mathcal{R}$ the set of real numbers:

- **Continuous-time or analog signals**: A continuous-time or an analog signal x_c is a mapping $x_c\colon \mathcal{R} \to \mathcal{R}$, where the domain is $\mathcal{R}$ and the range is a subset of the real line. A continuous-time signal will be denoted as $x_c(t)$ and not x_c, using the engineering convention of attaching the time variable as argument. This may be a source of confusion at times, but this aspect is clarified later. An example of a continuous-time signal is a speech signal: the acoustic pressure assumes a continuum of values, and pressure is defined at values of the independent variable, time, on the entire real line. Figure 1.1 shows an example of a continuous-time or an analog signal.
- **Quantized continuous-time signals**: A quantized continuous-time (boxcar) signal is a special case of a continuous-time signal, where the range of the signal is finite or countably infinite (i.e. it is a function defined over a continuum of values of the independent variable, while the range of values the signal assumes is discrete). An example of a quantized continuous-time (boxcar) signal is the control signal of a switch. At every instant of time, the switch is either open or closed depending on the control signal: if it is positive, the switch is open, whereas if it is negative, the switch is closed. Figure 1.2 shows an example of the control signal.
- **Discrete-time or sampled data signals**: A discrete-time signal x is a mapping $x\colon \mathcal{Z} \to \mathcal{R}$, where the domain is $\mathcal{Z}$ and the range is a subset of the real line. A discrete-time signal will be denoted as $x[n]$, and not x, again using the engineering convention of attaching the time variable as argument. Note that the independent variable is integer-valued. Sampling a continuous-time signal at equally spaced instants is commonly used to produce a discrete-time signal. The distance, T, in time between two adjacent sampling instants is called the **sampling interval**, and its inverse is called **sampling frequency**. Upon sampling, $x[n] = x_c(nT)$.

  Figure 1.3 shows an example of a discrete-time signal. This is the sampled but not necessarily quantized version of the signal in Figure 1.1.
- **Digital signals**: A digital signal is a special case of a discrete-time signal, where the range of the signal is finite or countably infinite (i.e., it is a function defined over integer values of the independent variable and the range of values the signal assumes is also discrete).

  Figure 1.4 shows an example of a digital signal. This is the same signal shown in Figure 1.1, sampled and quantized. In this case, we note that the function assumes only integer values (i.e., it is discrete-valued).

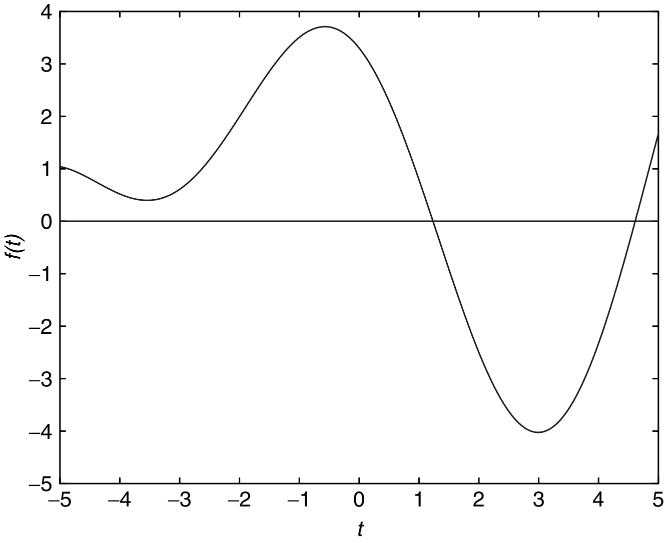

FIGURE 1.1 Example of **Continuous-Time** or **Analog Signal**. Both the independent and the dependent variables assume a continuum of values.

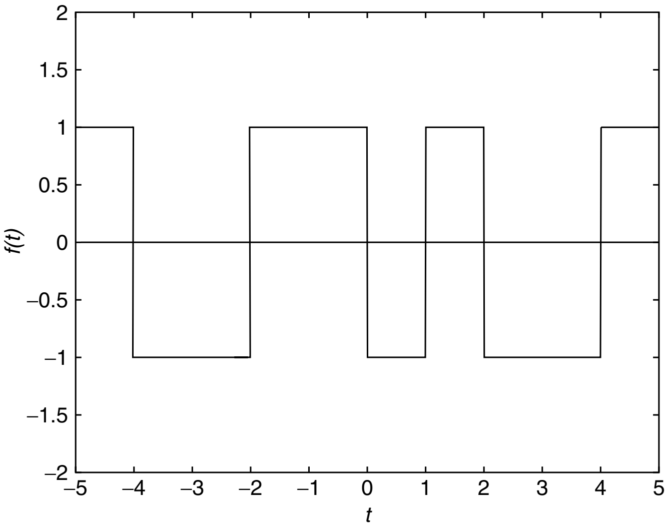

FIGURE 1.2 Example of **Quantized Continuous-Time (or Boxcar)** *Signal.* The independent variable is "continuous," whereas the dependent variable is "discrete".

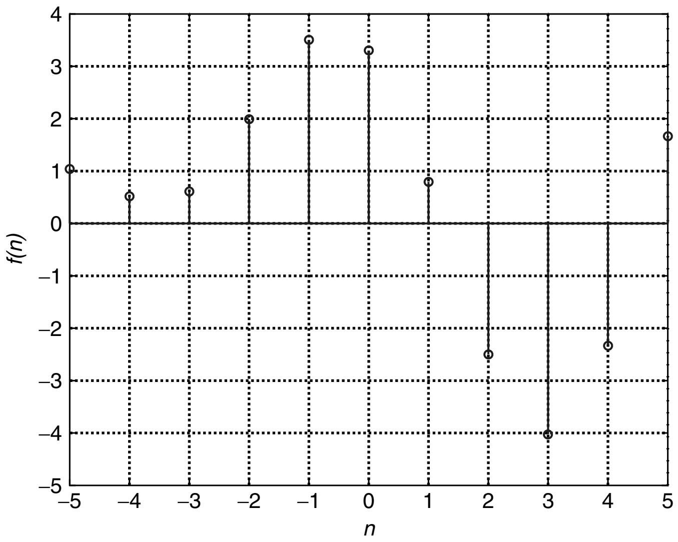

FIGURE 1.3 Example of a **Sampled Signal**. The independent variable is discrete, whereas the dependent variable is continuous.

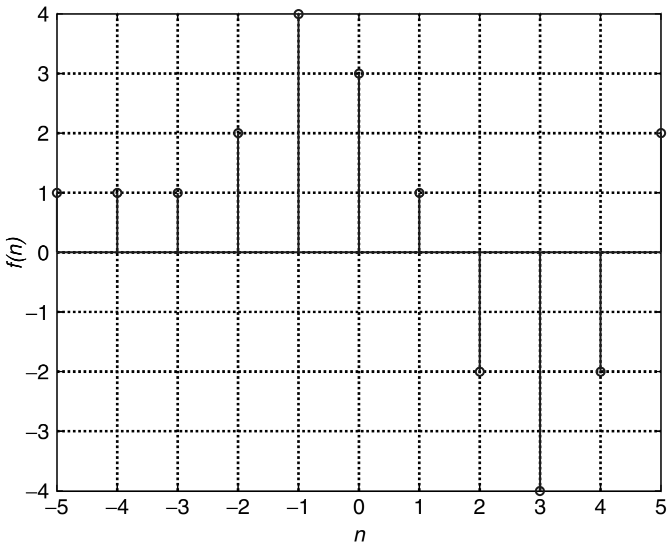

FIGURE 1.4 Example of **Digital Signal**. Both the independent and the dependent variables are discrete.

1.2.1 Basic Signals

Some basic signals are worthy of special attention because they play a particularly important role in the representation of other more general signals, either because other signals can be written as their weighted sum or integral or because they have useful properties. Signals in this category include the **unit sample** or **unit impulse**, the **unit step**, and the **exponential signal**. Another signal that plays an important role is a time-shifted version of a given signal. In the discrete-time case, this may be viewed as a transformation of a signal $x[n]$ given by $y = D_{n_0}x$ and defined by:

$$y[n] = D_{n_0}x[n] = x[n - n_0]. \tag{1.1}$$

In the case of a continuous-time signal $x_c(t)$, the time-shifted signal is defined as:

$$y_c(t) = D_{t_0}x(t) = x(t - t_0). \tag{1.2}$$

We will now define some common basic signals in continuous-time and discrete-time cases.

Unit Sample or Unit Impulse

The discrete **unit sample** or **unit impulse** is defined as:

$$\delta[n] = \begin{cases} 1, & n = 0. \\ 0, & n \neq 0. \end{cases} \tag{1.3}$$

The continuous-time counterpart of $\delta[n]$ is the unit impulse or the **Dirac delta-function** $\boldsymbol{\delta_c(t)}$. This function is zero-valued for $t \neq 0$ and $\int_{-\infty}^{\infty} \delta_c(t)dt = 1$.

The discrete-time and the continuous-time unit impulses are shown in Figure 1.5.

The unit impulse has the property that:

$$x[n_0] = \sum_{n=-\infty}^{\infty} x[n]\delta[n - n_0], \tag{1.4a}$$

$$x_c(t_0) = \int_{-\infty}^{\infty} x_c(t)\delta_c(t - t_0)dt. \tag{1.4b}$$

Moreover, every signal can be written as a weighted sum or integral of unit impulses:

$$x[n] = \sum_{k=-\infty}^{\infty} x[k]\delta[n - k]. \tag{1.5a}$$

$$x_c(t) = \int_{-\infty}^{\infty} x_c(\tau)\delta_c(t - \tau)d\tau. \tag{1.5b}$$

Unit Step

The **discrete-time unit step** is defined as:

$$u[n] = \begin{cases} 1, & n \geq 0. \\ 0, & n < 0. \end{cases} \tag{1.6}$$

The **continuous-time unit step** is defined as:

$$u_c(t) = \begin{cases} 1, & t \geq 0. \\ 0, & t < 0. \end{cases} \tag{1.7}$$

The discrete-time and the continuous-time unit steps are shown in Figure 1.6.

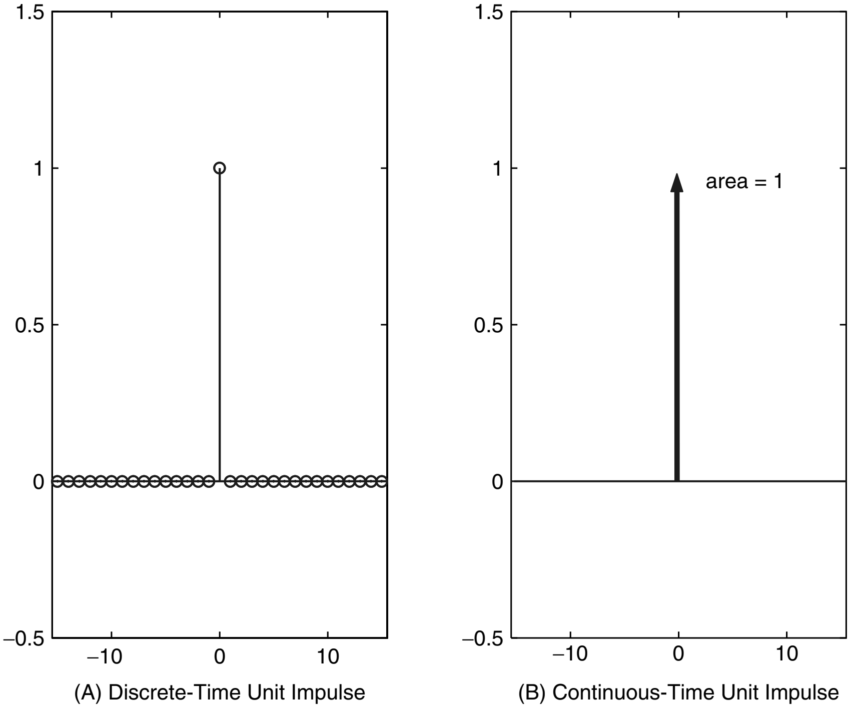

FIGURE 1.5 Discrete-Time and Continuous-Time Unit Impulses

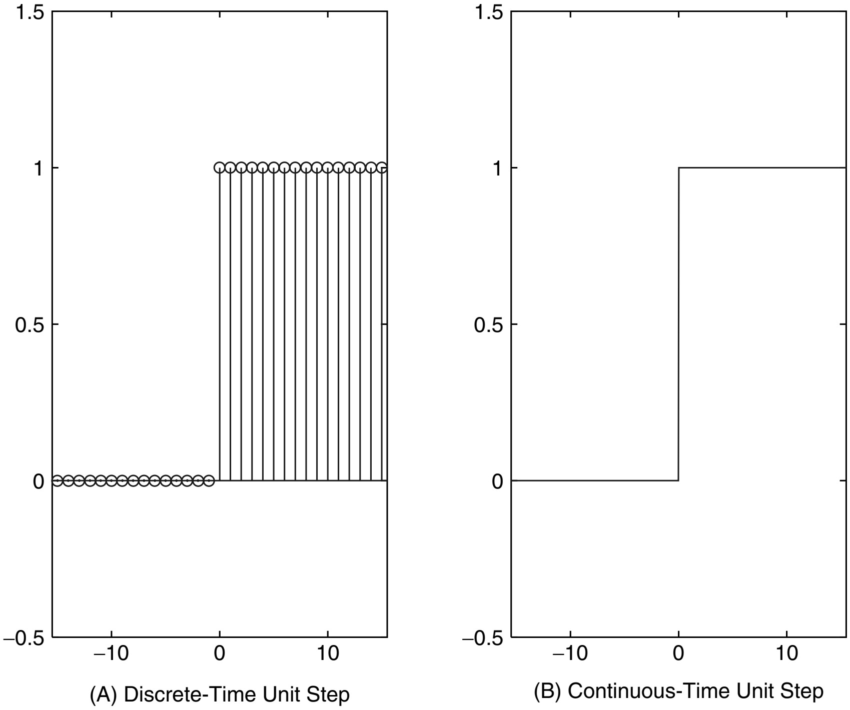

FIGURE 1.6 Discrete-Time and Continuous-Time Unit Steps

The unit impulse and the unit step functions are related by:

$$u[n] = \sum_{k=-\infty}^{n} \delta[k], \quad \delta[n] = u[n] - u[n-1]. \tag{1.8a}$$

$$u_c(t) = \int_{-\infty}^{t} \delta_c(\tau)dt, \quad \delta_c(t) = \frac{d}{dt}u_c(t). \tag{1.8b}$$

Exponential Signal

The continuous-time exponential signal is defined as:

$$f(t) = Ke^{st}, \tag{1.9}$$

where K is a constant, t is the independent variable, and s is in general a complex number with $s = \sigma + j\omega$.

When $\sigma = 0$ and $K = 1$, the real part of the signal is $\cos(\omega t)$, and the imaginary part is $\sin(\omega t)$.

Figure 1.7 shows the real part of complex exponential functions for different values of σ.

This is a periodic signal with period Δt given by:

$$\omega\Delta t = 2\pi, \tag{1.10}$$

from which we have:

$$\Delta t = \frac{2\pi}{\omega}. \tag{1.11}$$

The parameter ω is expressed in radians per second, and the *frequency* $f = \omega/2\pi$ is expressed in cycles per second or Hertz.

The role of the parameter σ is to amplify ($\sigma > 0$) or reduce ($\sigma < 0$) the amplitude of the signal when the independent variable increases.

In a similar way, the discrete-time exponential signal is defined as:

$$x[n] = Kz^n, \tag{1.12}$$

where K is a constant and z is in general a complex variable $z = \gamma e^{j\omega}$.

The discrete-time exponential signal is shown in Figure 1.8, with $z = 3/4$ and k = 1.

1.2.2 Signal Classification

Signals can be classified according to their support, energy, power, range bounds, and other characteristics. Here, we focus

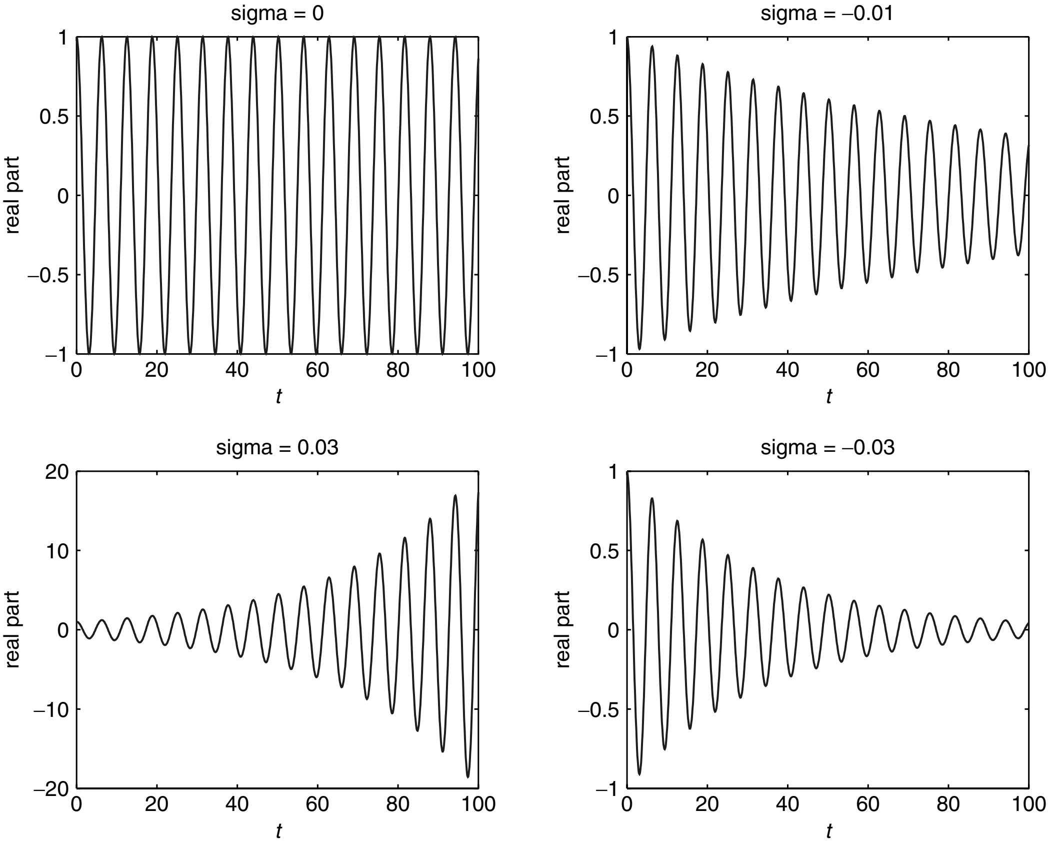

FIGURE 1.7 Real Part of the Complex Exponential Function for Different Values of the Parameter σ

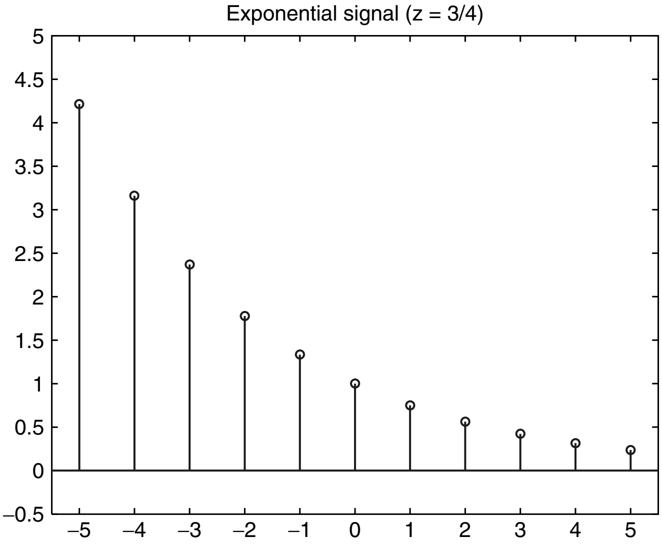

FIGURE 1.8 Discrete-Time Exponential Signal

on classification according to support. Support denotes the subset of the domain where the signal is nonzero (i.e., the extent of the independent variable or "time-axis" where the signal is nonzero). The nature of support bears a relation to types of convergence regions of the z-transform or Laplace transform of a signal as seen later.

Signal Duration

Signals can be classified according to their **duration** or support (i.e., the extent of domain over which the signal is nonzero).

- **Finite-extent signal**: A signal is of finite extent or finite duration if its support is bounded. In the discrete-time case, there exist integers, N_1 and N_2, such that the signal $x[n]$ satisfies the constraint:

$$x[n] = \begin{cases} 0, & n < N_1. \\ 0, & n > N_2. \end{cases} \tag{1.13}$$

  The corresponding requirement on a finite-extent continuous-time signal $x_c(t)$ is that there exist real numbers T_1 and T_2, such that:

$$x_c(t) = \begin{cases} 0, & t < T_1. \\ 0, & t > T_2. \end{cases} \tag{1.14}$$

- **Infinite-extent signal**. A signal is of infinite extent or infinite duration if its support is not bounded. Infinite-extent signals are further categorized into:
  (1) **Left-sided infinite-extent** signal: if there exists an integer N_1, such that $x[n] = 0$ for $n > N_1$
  (2) **Right-sided infinite-extent** signal: if there exists an integer N_2, such that $x[n] = 0$ for $n < N_2$
  (3) **Two-sided infinite-extent** signal: if the infinite-extent signal is neither left-sided no right sided

Causal Support

- **causal Signal**
  Causality is a system property that is described later in this chapter. For linear-time invariant systems, causality constrains the support of the system impulse response to non-negative values of the domain. The notion is extended to define a general "causal" signal. A discrete-time signal, $x[n]$, is causal if:

$$x[n] = 0, \quad n < 0. \tag{1.15}$$

  A continuous-time signal is causal if:

$$x_c(t) = 0, \quad t < 0. \tag{1.16}$$

  A signal is **noncausal** if it is *not* causal. An infinite-duration causal signal is a special case of an infinite-duration right-sided signal.
- **Anticausal Signal**
  A discrete-time signal is anticausal if:

$$x[n] = 0, \quad n > 0. \tag{1.17}$$

  A continuous-time signal is anticausal if:

$$x_c(t) = 0, \quad t > 0. \tag{1.18}$$

  An infinite-duration anticausal signal is a special case of a left-sided infinite-duration signal.

1.3 Systems

A **system** is an entity that transforms an **input signal** into an **output signal** according to a specified rule. Systems can be classified into **discrete-time systems** or **continuous-time systems** if the pair of input and output signals is discrete-time or continuous time, respectively, as shown in Figure 1.9. Systems can be hybrid (e.g., analog-to-digital converters) where the input is continuous-time and the output discrete-time.

A discrete-time or continuous-time input signal is denoted by $x[n]$ or $x_c(t)$, respectively, while the corresponding output signal is denoted as $y[n]$ or $y_c(t)$. The system (i.e., the transformation that maps that input signal into the output signal) is denoted by T so that $y[n] = T(x[n])$ or $y_c(t) = T(x_c(t))$. We will often refer to the system itself as T.

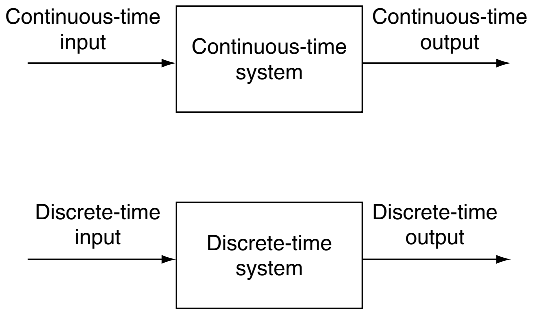

FIGURE 1.9 Continuous-Time and Discrete-Time Systems

Unfortunately the engineering notation here could be misleading. The relation $y_c(t) = T(x_c(t))$ does not mean that the output at instant t depends on the input only at time t. Rather, the equation should be understood in the mathematical sense of $y_c = T(x_c)$.

Time-Shift Operator

We had noted earlier that a signal that plays an important role in signal processing is a time-shifted version of a given signal. This signal can be viewed as the output of a **time-shifting system**. In the discrete-time case, this may be viewed as a transformation of a signal $x[n]$ given by $y = D_{n_0}x$ and defined by:

$$y[n] = D_{n_0}x[n] = x[n - n_0]. \tag{1.19}$$

In the case of a continuous-time signal $x_c(t)$, the time-shifted signal is as follows:

$$y_c(t) = D_{t_0}x_c(t) = x_c(t - t_0). \tag{1.20}$$

1.3.1 Common System Properties

To characterize system behavior, we need to impose some structure on a system. This structure takes the form of system properties that provide useful mathematical descriptions as well as insights into analysis and design of systems. We consider a few of these properties with a focus on linear shift-invariant systems.

Linearity

A **linear system** is one where the response (output) of a system to the sum of scaled stimuli (inputs) equals the sum of its scaled responses to each individual stimulus. Consider a discrete-time system T such that the output corresponding to an input $x_1[n]$ is $y_1[n] = T(x_1[n])$, and the output corresponding to an input $x_2[n]$ is $y_2[n] = T(x_2[n])$. The system is said to be *linear* if:

$$T(ax_1[n] + bx_2[n]) = ay_1[n] + by_2[n], \tag{1.21}$$

where a and b are **scalars** (real or complex numbers depending on the mapping T). The above rule can be extended to sum of a finite set of inputs by induction. We will assume that the system allows the extension of this property to a countably infinite sum of inputs.

Example

The system:

$$y[n] = \frac{1}{2}(x[n] + x[n-1]),$$

is linear, since:

$$y_1[n] = \frac{1}{2}(x_1[n] + x_1[n-1])$$

$$y_2[n] = \frac{1}{2}(x_2[n] + x_2[n-1])$$

$$\begin{aligned}
&\Rightarrow T(ax_1[n] + bx_2[n]) \\
&= \frac{1}{2}(ax_1[n] + bx_2[n] + ax_1[n-1] + bx_2[n-1]) \\
&= a\frac{1}{2}(x_1[n] + x_1[n-1]) + b\frac{1}{2}(x_2[n] + x_2[n-1]) \\
&= ay_1[n] + by_2[n].
\end{aligned}$$

Shift Invariance (or Time Invariance)

A **shift-invariant** or **time-invariant** system is one where the response of a system to a shifted version of an original input is the same as the shifted version of the system's response to the original input. Consider a discrete-time system T such that the output corresponding to an input $x[n]$ is $y[n] = T(x[n])$. The system T is **shift invariant** if:

$$T(x[n - n_0]) = y[n - n_0]. \tag{1.22}$$

Example

The system of the previous example with output given by:

$$y[n] = \frac{1}{2}(x[n] + x[n-1]),$$

is shift invariant. If the input to a system is $x_1[n] = x[n - n_0]$, then:

$$\begin{aligned}
y_1[n] &= \frac{1}{2}(x_1[n] + x_1[n-1]) \\
&= \frac{1}{2}(x[n - n_0] + x[n - n_0 - 1]) = y[n - n_0].
\end{aligned}$$

On the other hand, the system with output $y[n] = nx[n]$ is not shift invariant.

If $x_1[n] = x[n - n_0]$, then:

$$y_1[n] = nx_1[n] = nx[n - n_0] \neq y[n - n_0] = (n - n_0)x[n - n_0].$$

Causality and Stability

A discrete-time system T is **causal** if its output at any time instant depends only on the input samples at that time or prior to it. In other words, the output value $y[n_0]$ depends only on input samples $(x[n_0], x[n_0 - 1], x[n_0 - 2], \ldots)$ and not on future input samples $(x[n_0 + 1], x[n_0 + 2], \ldots)$.

Stability of a system is defined in many ways, but a common characterization is in terms of bounds on system response when the input range is confined to some specified bounds. A discrete-time system T is said to be **stable in the bounded-input**

bounded-output (BIBO) **sense** if, given any input $x[n]$ bounded for all n (i.e., $|x[n]| \leq B_1 < \infty$) the output is also bounded for all n (i.e., $|y[n]| \leq B_O < \infty$) for some B_O.

Examples

The system $y[n] = e^{x^2[n]}$ is BIBO stable. If $|x[n]| \leq 10 = B_I$, then $|y[n]| \leq e^{100} = B_O$.

The two systems with outputs $y[n] = nx[n]$ and $y[n] = \sum_{k=-\infty}^{\infty} x[n-k]$ are not BIBO stable because their outputs are not bounded (i.e., one cannot find a finite positive number B_O such that $|y[n]| \leq B_O$ for all n).

Invertibility

An **invertible system** is one in which an arbitrary input to the system can be uniquely inferred from the corresponding output of the system. The cascade of the system and its inverse, if it exists, is an identity system (i.e., the output of the cascade is identical to the input).

All properties so far were defined for discrete-time systems. Equivalent properties can be defined for continuous-time systems by requiring output to satisfy the following conditions, with notation analogous to that in the discrete-time case:

- **Linearity**: $T(ax_1(t) + bx_2(t)) = ay_1(t) + by_2(t)$.
- **Shift invariance**: $T(x(t - t_0)) = y(t - t_0)$.
- **Causality**: $y(t)$ is function of $x(\tau)$ for $-\infty < \tau \leq t$.
- **BIBO stability**: $|x(t)| \leq B_I$ for all $t \Rightarrow |y(t)| \leq B_O$ for all t.

1.3.2 Linear Shift-Invariant Systems

Linearity and shift invariance are often used in combination to model the behavior of practical systems. This chapter is largely devoted to developing descriptions and tools for the analysis and design of **linear shift-invariant** (LSI) **systems**. These are often referred to as linear time-invariant (LTI) systems because the independent variable is commonly **time**.

As pointed out before, a discrete-time signal can be expressed as a weighted sum of shifted discrete-time unit impulses. Similarly, a continuous-time signal can be expressed as the integral of weighted and shifted continuous-time unit impulses. This representation, together with system properties of linearity and shift invariance, allows us to create a practical and useful characterization of a system in terms of a function called the **impulse response** of the system.

To arrive at the characterization of a linear time-invariant discrete-time system in terms of its response to an impulse input, the input signal, $x[n]$, to a digital system is expressed as a weighted sum of discrete-time unit impulses:

$$x[n] = \sum_{k=-\infty}^{\infty} x[k]\delta[n-k]. \tag{1.23}$$

Here, a comment on the engineering notation is in order. Equation 1.23 should be understood as $x = \sum_{-\infty}^{\infty} x[k]D_k\delta$, so that $x[k]$ in this equation is a scalar and $\delta[n-k]$ is a discrete-time signal.

The output $y[n]$ for the input in equation 1.23 is expressed as:

$$y[n] = T(x[n]) = T\left(\sum_{k=-\infty}^{\infty} x[k]\delta[n-k]\right). \tag{1.24}$$

The linearity of the system allows us to rewrite equation 1.24 as:

$$y[n] = \sum_{k=-\infty}^{\infty} x[k]T(\delta[n-k]), \tag{1.25}$$

where we have assumed the system behavior allows us to extend the linearity property to the case of an infinite sum of inputs. Here, $T(\delta[n])$ denotes the output signal when a unit impulse is applied as input. This signal is called the impulse response of the system, and it is denoted by $h[n]$.

Next, we invoke the shift invariance property to assert that $T(\delta[n-k]) = h[n-k]$. The output signal can therefore be rewritten as:

$$y[n] = \sum_{k=-\infty}^{\infty} x[k]h[n-k]. \tag{1.26}$$

The last expression in equation 1.26 is called the **convolution sum** of the signals $x[n]$ and $h[n]$, which is denoted by $x[n] * h[n]$. The convolution sum of $h[n]$ and $x[n]$ can also be expressed as:

$$\begin{aligned} y[n] = x[n] * h[n] &= \sum_{k=-\infty}^{\infty} x[k]h[n-k] \\ &= \sum_{m=-\infty}^{\infty} x[n-m]h[m] = h[n] * x[n]. \end{aligned} \tag{1.27}$$

By proceeding in an analogous manner in the case of continuous-time systems, one arrives at equivalent relations. As pointed out before, each continuous-time signal can be written as the integral of weighted and shifted unit impulses:

$$x_c(t) = \int_{-\infty}^{\infty} x_c(\tau)\delta_c(t-\tau)d\tau. \tag{1.28}$$

We assume that $h_c(t)$ is the **impulse response** of the continuous-time system (i.e., it is the output of the system when a unit impulse is applied at the input).

By invoking linearity and shift invariance property of the system, the output signal $y(t)$ can be written as:

$$
\begin{aligned}
y_c(t) = T(x_c(t)) &= T(\int_{-\infty}^{\infty} x_c(\tau)\delta_c(t-\tau)d\tau) \\
&= \int_{-\infty}^{\infty} x_c(\tau)T(\delta_c(t-\tau))d\tau \qquad (1.29) \\
&= \int_{-\infty}^{\infty} x_c(\tau)h_c(t-\tau)d\tau = x_c(t) * h_c(t).
\end{aligned}
$$

Therefore, for a continuous-time system, the output signal is given by the convolution integral of the input signal and the system impulse response.

An important observation is that both discrete-time and continuous-time systems that are linear and time invariant are completely characterized by their impulse responses under suitable assumptions.

Example

An example of the convolution for two continuous-time signals is considered now. It illustrates the property that the duration of **convolved** signal is equal to the sum of the durations of the two signals that are convolved. For discrete-time convolution, the duration of the sum obtained as a convolution sum is equal to the sum of the durations of the signals less one.

Consider a signal $x_c(t)$:

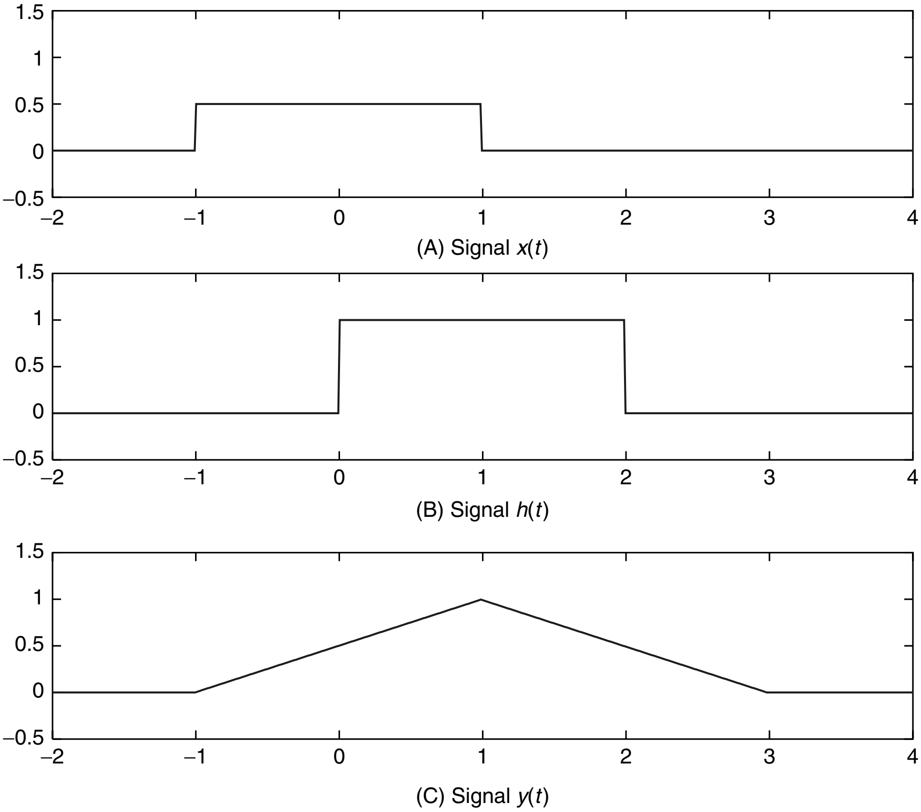
$$
x_c(t) = \begin{cases} 1/2, & -1 \le t \le 1, \\ 0, & \text{otherwise,} \end{cases}
$$

which is applied as input to a system with impulse response $h_c(t)$:

$$
h_c(t) = \begin{cases} 1, & 0 \le t \le 2 \\ 0, & \text{otherwise.} \end{cases}
$$

Figure 1.10 shows the two signals $x_c(t)$ and $h_c(t)$ and their convolution $y_c(t)$. We notice that the duration of the convolution signal is $L_y = L_x + L_h = 2 + 2 = 4$.

For discrete-time convolution, the duration of the signal obtained as a convolution sum is equal to the sum of the durations of the convolved signals less one. Let $x[n]$ and $h[n]$ be two finite-duration discrete-time signals such that $x[n] = 0$ for $n < N_1$ or $n > N_2 \ge N_1$, and $h[n] = 0$ for $n < M_1$ or $n > M_2 \ge M_1$. We assume that $x[N_1]$, $x[N_2]$, $h[M_1]$, and $h[M_2]$, are nonzero, so that the duration of $x[n]$ is $N = N_2 - N_1 + 1$ and the duration of $h[n]$ is $M = M_2 - M_1 + 1$. Then, the convolved signal $y[n] = x[n] * h[n]$ has duration $L = M + N - 1$. The signal $y[n]$ is zero for $n < L_1 = M_1 + N_1$ or $n > L_2 = M_2 + N_2$. Note that $L = L_2 - L_1 + 1$.



(A) Signal $x(t)$

(B) Signal $h(t)$

(C) Signal $y(t)$

FIGURE 1.10 Two signals and their convolution

To conclude this section, we list three properties of the convolution operator that are valid both in the continuous-time and in the discrete-time case. Their proofs follow directly from properties of the convolution sum and integral operators.

1. **Commutative property**: $x_1 * x_2 = x_2 * x_1$.
2. **Associative property**: $x_1 * [x_2 * x_3] = [x_1 * x_2] * x_3$.
3. **Distributive property**: $x_1 * [x_2 + x_3] = x_1 * x_2 + x_1 * x_3$.

In expressions 1 through 3, if x_1 is assumed to represent system input and x_2 and x_3 represent system impulse responses, then these have useful interpretations for an interconnected system. The associative property implies that a cascade connection of two LSI systems is equivalent to a single system with impulse response equal to the convolution of the two individual system impulse responses. The distributive property implies that a parallel connection of two LSI systems can be represented by a single system with impulse response equal to the sum of the two individual system impulse responses.

1.3.3 Properties of LSI Systems

An important observation is that both discrete-time and continuous-time systems that are **linear** and **time invariant** are completely characterized by their impulse responses. Other properties of LSI systems, such as causality, stability, and invertibility, can then be characterized in terms of a system's impulse response.

The characterization of the LSI system properties of causality, stability, and invertibility will first be examined for the case of discrete-time systems.

Causality

If a discrete-time system is causal, then the current output sample depends only on the current and past input samples and not on future samples. This definition is now examined in the case of an LSI system with an impulse response $h[n]$.

The output $y[n]$ of an LSI system can be expressed as:

$$\begin{aligned} y[n] = h[n] * x[n] &= \sum_{k=-\infty}^{\infty} x[n-k]h[k] \\ &= \ldots + x[n+2]h[-2] + x[n+1]h[-1] \\ &\quad + x[n]h[0] + x[n-1]h[1] + x[n-2]h[2] + \ldots . \end{aligned} \tag{1.30}$$

The expression of equation 1.30 immediately suggests the constraint on the impulse response of a causal LSI system. If the output is required to be independent of future samples of an arbitrary input, then the coefficients $h[-1], h[-2], \ldots$ in the convolution sum should each be equal to zero.

Therefore, an LSI system is causal if and only if $h[n] = 0$, $n < 0$.

BIBO Stability

A system was previously defined to be BIBO stable if a bounded input produces a bounded output. It will be shown that an LSI system is BIBO stable if and only if $\sum_{n=-\infty}^{\infty} |h[n]| < \infty$.

Proof

We first assume that $S_h = \sum_{n=-\infty}^{\infty} |h[n]| < \infty$. Now suppose the system input $x[n]$ is bounded (i.e., $|x[n]| < B_I$) for all n. The output satisfies:

$$|y[n]| \leq \sum_{k=-\infty}^{\infty} |x[n-k]||h[k]| \leq B_I \sum_{k=-\infty}^{\infty} |h[k]| = B_I S_h. \tag{1.31}$$

We conclude that $|y[n]| \leq B_O = B_I S_h$, and therefore the system is stable.

We now assume that the LSI system is BIBO stable with an impulse response that is not identically zero. Consider a bounded input $x[n]$ defined by:

$$x[n] = \begin{cases} B_I \frac{h^*[-n]}{|h[-n]|}, & h[n] \neq 0, \\ 0, & h[n] = 0, \end{cases} \tag{1.32}$$

where $h^*[n]$ is the complex conjugate of $h[n]$. The output $y[n]$ for $n = 0$ is given by:

$$|y[0]| = \sum_{k=-\infty}^{\infty} x[-k]h[k] = B_I \sum_{k=-\infty}^{\infty} |h[k]| = B_I S_h. \tag{1.33}$$

For the system to be stable, we require that $y[n]$ be bounded for all n. In particular, $|y[0]|$ above should be finite. This implies that $S_h = \sum_{n=-\infty}^{\infty} |h[n]| < \infty$.

Invertibility

Let an LSI system with impulse response $h[n]$ be invertible. It can then be shown that the inverse system is LSI. If the inverse system has impulse response $h^i[n]$, then $h[n] * h^i[n] = \delta[n]$.

In the case of continuous-time, we can obtain similar conditions on the impulse response, $h_c(t)$, of an LSI system as summarized here:

- An LSI system is causal $\Leftrightarrow h_c(t) = 0,\ t < 0$.
- An LSI system is BIBO stable $\Leftrightarrow \int_{-\infty}^{\infty} |h_c(t)| dt < \infty$.
- An Inverse system exists and has impulse response $h_c^i(t)$; then $h_c(t) * h_c^i(t) = \delta_c(t)$.

A special class of LSI systems commonly used in modeling and implementation is the class that is described by a linear constant-coefficient difference or differential equation in the case of discrete and continuous time, respectively. It should be pointed out that depending on the specified auxiliary (or "initial") conditions, a system described by a linear constant-coefficient difference or differential equation may not be LSI

(Oppenheim *et al.*, 1999; oppenheim and Willsky, 1997). We will assume that the auxiliary conditions are consistent with the LSI requirement. A condition of initial rest is assumed for the systems, so that we will be dealing only with linear shift-invariant systems described by the difference or differential equation.

The LSI systems can be further classified according to the duration of the impulse response. An LSI system is called **finite-duration impulse response** (FIR) if its impulse response has finite support. An **infinite-duration impulse response** (IIR) LSI system has an impulse response with infinite support. LSI systems are often referred to as filters in a generalized sense, though the term filters is commonly understood in terms of passing or rejecting signal content in a **frequency-selective** manner. Hence, the labels FIR and IIR filters are commonly used even when frequency selectivity is not the objective. We now consider frequency domain analysis of signals and systems.

1.4 Analysis in Frequency Domain

So far, we have examined discrete-time and continuous-time signals as well as LSI systems in the time domain. We now consider signal and LSI system descriptions in the frequency domain motivated by the fact that analysis and design may be more conveniently done in the frequency domain. Central to frequency-domain description and analysis is the fact that signals (and impulse responses) can be conveniently represented in terms of sinusoids and complex exponentials that are eigenfunctions of LSI systems.

Let T denote the system operator for an LSI system. We are interested in finding the eigenfunctions of this operator, that is the input signals $x[n]$ or $x(t)$, such that:

$$Tx = \lambda x, \tag{1.34}$$

where λ is a scalar. Equation 1.34 implies that for certain input signals x, the system output is a scaled version of the input. The scalar multiplier λ is called the **eigenvalue**.

It has already been mentioned that the **exponential signal** plays an important role in signal representation. We now consider the response of a linear shift-invariant system to an exponential signal applied as input.

We again focus on the discrete-time case first. Consider an LSI discrete-time system with impulse response $h[n]$. If the input to the system is $x[n] = e^{j\omega n}$ for $-\infty < n < \infty$, then the output signal is as written here:

$$\begin{aligned} y[n] &= \sum_{k=-\infty}^{\infty} x[n-k]h[k] = \sum_{k=-\infty}^{\infty} e^{j\omega(n-k)}h[k] \\ &= e^{j\omega n}\sum_{k=-\infty}^{\infty} e^{-j\omega k}h[k] = H(e^{j\omega})e^{j\omega n}. \end{aligned} \tag{1.35}$$

From equation 1.35, we observe that e^{jwn} is an eigenfunction of the linear shift invariant system. The LSI system output is equal to the input multiplied by a scalar factor $H(e^{j\omega})$, which is the eigenvalue given by:

$$H(e^{j\omega}) = \sum_{k=-\infty}^{\infty} e^{-j\omega k}h[k]. \tag{1.36}$$

The $H(e^{j\omega})$ represents the complex gain as a function of the frequency variable ω and is called the **frequency response** of the system and also the **discrete-time Fourier transform** (DTFT) of $h[n]$.

In general, the DTFT of a signal $x[n]$ is defined as:

$$X(e^{j\omega}) = \sum_{n=-\infty}^{\infty} e^{-j\omega n}x[n]. \tag{1.37}$$

The DTFT of a signal is a complex function that can be expressed as $|X(e^{j\omega})|e^{\phi(\omega)}$. Here $|X(e^{j\omega})|$ is the **magnitude**, and $\phi(\omega)$ is the **phase** of the DTFT. The magnitude $|X(e^{j\omega})|$ can be viewed as a measure of the strength of the signal content at different frequencies, and $\phi(\omega)$ represents the phase of the frequency components.

Example

Consider the computation of the DTFT of the rectangular window signal shown in Figure 1.11 and expressed as:

$$x[n] = \begin{cases} A, & -n_0 \leq n \leq n_0 \\ 0, & \text{otherwise.} \end{cases}$$

For $\omega = 0$, we note that $X(e^{j\omega}) = A(2n_0 + 1)$. For $\omega \neq 0$:

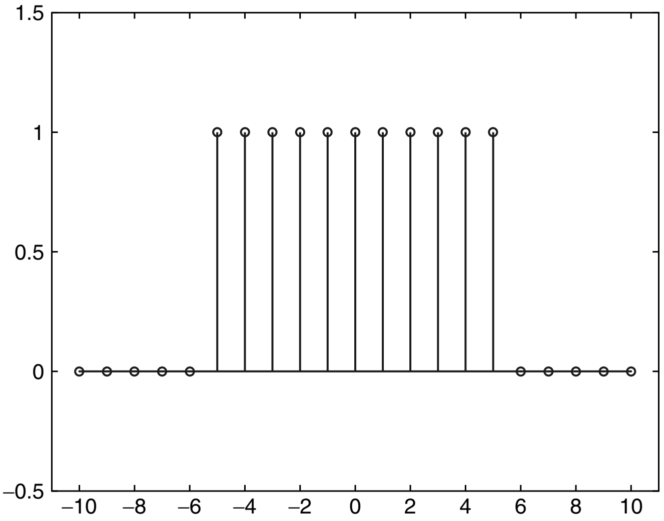


FIGURE 1.11 Rectangular Window

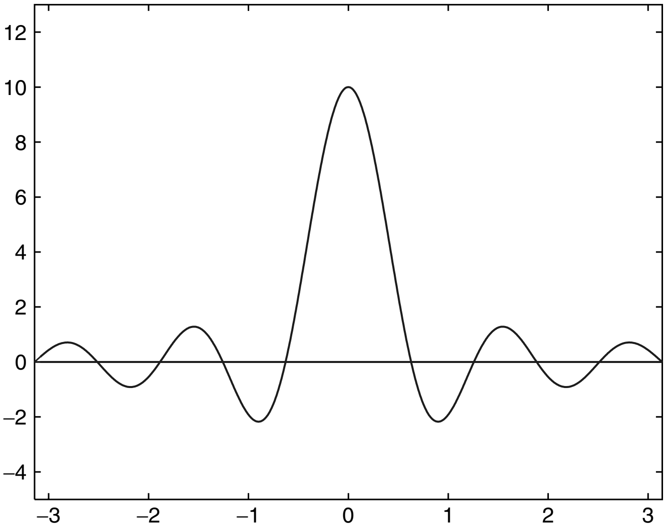

FIGURE 1.12 Discrete-Time Fourier Transform of the Rectangular Window.

$$X(e^{j\omega}) = \sum_{n=-\infty}^{\infty} x[n]e^{-j\omega n} = \sum_{n=-n_0}^{n=n_0} Ae^{-j\omega n}$$
$$= A\frac{e^{j\omega(n_0+1)} - e^{-j\omega n_0}}{e^{j\omega} - 1} = A\frac{\sin((2n_0+1)\omega/2)}{\sin(\omega/2)}.$$

The DTFT is shown in Figure 1.12.

1.4.1 Properties of the Discrete-Time Fourier Transform

The discrete-time Fourier transform (DTFT) was defined a complex series for an arbitrary discrete-time signal. The issue of its convergence is briefly examined. In the description here, a **sufficient condition** for the existence of DTFT is assumed. This is done by considering the signal $x[n]$ to be **absolutely summable** (i.e., $\sum_{n=-\infty}^{\infty} |x[n]| < \infty$). In this case:

$$|X(e^{j\omega})| = \left| \sum_{n=-\infty}^{\infty} e^{-j\omega n}x[k] \right| \leq \sum_{n=-\infty}^{\infty} |e^{-j\omega n}|\ |x[k]|$$
$$= \sum_{n=-\infty}^{\infty} |x[n]| < \infty.$$

Therefore, if the signal $x[n]$ is absolutely summable, the series converges and the DTFT exists.

Inverse DTFT

Given the DTFT of a signal, the signal can be recovered from it using the so-called inverse DTFT given by:

$$x[n] = \frac{1}{2\pi}\int_0^{2\pi} X(e^{j\omega})e^{j\omega n}d\omega. \qquad (1.38)$$

The validity of the above relation can be seen from:

$$\frac{1}{2\pi}\int_0^{2\pi} X(e^{j\omega})e^{j\omega n}d\omega = \frac{1}{2\pi}\int_0^{2\pi}\left(\sum_{m=-\infty}^{\infty} e^{-j\omega m}x[m]\right)e^{j\omega n}d\omega$$
$$= \sum_{n=-\infty}^{\infty} x[m]\frac{1}{2\pi}\int_0^{2\pi} e^{j\omega(n-m)}d\omega = \sum_{m=-\infty}^{\infty} x[m]\delta[n-m] = x[n],$$

where we have used the fact that:

$$\frac{1}{2\pi}\int_0^{2\pi} e^{j\omega(n-m)}d\omega = \begin{cases} 1, & n = m. \\ 0, & n \neq m. \end{cases}$$

Some useful properties of DTFT are now examined.

Periodicity

The DTFT is a periodic function in ω with period 2π, since:

$$X(e^{j(\omega+2\pi)}) = \sum_{n=-\infty}^{\infty} x[n]e^{-j(\omega+2\pi)n} = \sum_{n=-\infty}^{\infty} x[n]e^{-j\omega n}e^{-j2\pi n} = X(e^{j\omega}).$$

Linearity

A property that follows from the definition is that the DTFT of a linear combination of two or more signals is equal to the same linear combination of the DTFTs of each signal:

$$y[n] = ax_1[n] + bx_2[n] \Leftrightarrow Y(e^{j\omega}) = aX_1(e^{j\omega}) + bX_2(e^{j\omega}).$$

Symmetry of DTFT for Real Signals

If the signal $x[n]$ is real $(x[n] = x^*[n])$, then $X(e^{j\omega}) = X^*(e^{-j\omega})$. This follows from:

$$X(e^{-j\omega}) = \sum_{n=-\infty}^{\infty} x[n]e^{j\omega n}.$$
$$X^*(e^{-j\omega}) = \left(\sum_{n=-\infty}^{\infty} x[n]e^{j\omega n}\right)^* = \sum_{n=-\infty}^{\infty} x^*[n]e^{-j\omega n}$$
$$= \sum_{n=-\infty}^{\infty} x[n]e^{-j\omega n} = X(e^{j\omega}).$$

If $X(e^{j\omega}) = |X(e^{j\omega})|e^{\phi(\omega)}$, then $X^*(e^{-j\omega}) = |X(e^{-j\omega})|e^{\phi(-\omega)}$. Therefore, for real $x[n]$, the magnitude of the DTFT is an even function of ω and the phase of the DTFT is an odd function of ω.

Time Shift of Signals

A shift of the signal $x[n]$ in the time domain does not affect the magnitude of the DTFT but produces a phase shift that is linear in ω and in proportion to the time shift:

$$y[n] = x[n-n_0] \Leftrightarrow Y(e^{j\omega}) = X(e^{j\omega})e^{-j\omega n_0}.$$

This follows from:

$$Y(e^{j\omega}) = \sum_{n=-\infty}^{\infty} y[n]e^{-j\omega n} = \sum_{n=-\infty}^{\infty} x[n-n_0]e^{-j\omega n}$$

$$= e^{-j\omega n_0}\sum_{m=-\infty}^{\infty} x[m]e^{-j\omega n} = e^{-j\omega n_0}X(e^{j\omega}).$$

Convolution

The DTFT of the convolution sum of two signals $x_1[n]$ and $x_2[n]$ is the product of their DTFTs, $X_1(e^{j\omega})$ and $X_2(e^{j\omega})$. That is:

$$y[n] = x_1[n] * x_2[n] \Leftrightarrow Y(e^{j\omega}) = X_1(e^{j\omega})X_2(e^{j\omega}).$$

The DTFT of $y[n] = x_1[n] * x_2[n] = \sum_{k=-\infty}^{\infty} x_1[k]x_2[n-k]$ is given by:

$$Y(e^{j\omega}) = \sum_{n=-\infty}^{\infty} y[n]e^{-j\omega n} = \sum_{n=-\infty}^{\infty}\sum_{k=-\infty}^{\infty} x_1[k]x_2[n-k]e^{-j\omega n}$$

$$= \sum_{k=-\infty}^{\infty} x_1[k]e^{-j\omega k}\sum_{n=-\infty}^{\infty} x_2[n-k]e^{-j\omega(n-k)} = X_1(e^{j\omega})X_2(e^{j\omega}).$$

Modulation

A modulation of the signal in the time domain by a complex exponential signal corresponds to a shift in the frequency domain. That is:

$$y[n] = e^{j\omega_0 n}x[n] \Leftrightarrow Y(e^{j\omega}) = X(e^{j(\omega-\omega_0)}).$$

This is seen from:

$$Y(e^{j\omega}) = \sum_{n=-\infty}^{\infty} y[n]e^{-j\omega n} = \sum_{n=-\infty}^{\infty} x[n]e^{j\omega_0 n}e^{j\omega n}$$

$$= \sum_{n=-\infty}^{\infty} x[n]e^{-j(\omega-\omega_0)n} = X(e^{j(\omega-\omega_0)}).$$

Product of Signals

The DTFT of the product of two signals, $x_1[n]$ and $x_2[n]$ as well as the **periodic convolution** of the two DTFTs, $X_1(e^{j\omega})$ and $X_2(e^{j\omega})$, are shown on the right-hand side of the equation:

$$y[n] = x_1[n]x_2[n] \Leftrightarrow Y(e^{j\omega}) = \frac{1}{2\pi}\int_{-\pi}^{\pi} X_1(e^{j\theta})X_2(e^{j(\omega-\theta)})d\theta.$$

Computing the DTFT of the product:

$$Y(e^{j\omega}) = \sum_{n=-\infty}^{\infty} x_1[n]x_2[n]e^{-j\omega n} = \sum_{n=-\infty}^{\infty}\left[\frac{1}{2\pi}\int_{-\pi}^{\pi} X_1(e^{j\theta})e^{j\theta n}d\theta\right]x_2[n]e^{-j\omega n}$$

$$= \frac{1}{2\pi}\int_{-\pi}^{\pi} X_1(e^{j\theta})\left[\sum_{n=-\infty}^{\infty} x_2[n]e^{-jn(\omega-\theta)}\right]d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi} X_1(e^{j\theta})X_2(e^{j(\omega-\theta)})d\theta.$$

Parseval's Relation

The signal energy can equivalently be expressed in the time or in the frequency domain as:

$$\sum_{n=-\infty}^{\infty} |x[n]|^2 = \frac{1}{2\pi}\int_{-\pi}^{\pi} |X(e^{j\theta})|^2 d\theta.$$

Defining $x_1[n] = x[n]$, $x_2[n] = x^*[n]$ and $y[n] = x_1[n]x_2[n] = |x^2[n]|$ and then using the product relation, we obtain:

$$Y(e^{j0})\sum_{n=-\infty}^{\infty} x[n]x^*[n] = \sum_{n=-\infty}^{\infty} |x^2[n]|$$

$$= \frac{1}{2\pi}\int_{-\pi}^{\pi} X(e^{j\theta})X(e^{-j\theta})d\theta = \frac{1}{2\pi}\int_{-\pi}^{\pi} |X(e^{j\theta})|^2 d\theta.$$

For continuous-time signals, the Fourier transform and its inverse are given by:

$$X_c(j\Omega) = \int_{-\infty}^{\infty} x_c(t)e^{j\Omega t}, \qquad (1.39)$$

$$x_c(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} X_c(j\Omega)e^{j\Omega t}. \qquad (1.40)$$

Properties analogous to those for DTFT can be obtained for the continuous-time Fourier transform (CTFT), and these are summarized in Table 1.1. The subscript c used for continuous-time signals is dropped in the table.

1.4.2 Frequency Response of LSI System

An LSI system is characterized in the time domain by its impulse response. It can be equivalently characterized in the frequency domain by the system frequency response, which is the Fourier transform of the impulse response. We first examine the discrete-time case.

The frequency response of a discrete-time system is defined as the discrete-time Fourier transform (DTFT) of its impulse response $h[n]$, as shown in equation 1.36. If an input $x[n]$ is applied to the system, the output is the convolution sum $y[n] = x[n] * h[n]$. From the property of the DTFT of convolution sums discussed above, the DTFT, $Y(e^{j\omega})$, of the output,

TABLE 1.1 Properties of the Continuous-Time Fourier Transform

Property	Continuous-time signal	Continuous-time Fourier transform
Linearity	$y(t) = ax_1(t) + bx_2(t)$.	$Y(j\Omega) = aX_1(j\Omega) + bX_2(j\Omega)$.
Time shift	$y(t) = x(t - t_0)$.	$Y(j\Omega) = X(j\Omega)e^{-j\Omega t_0}$.
Frequency shift	$y(t) = x(t)e^{j\Omega_0 t}$.	$Y(j\Omega) = X(j(\Omega - \Omega_0))$.
Convolution	$y(t) = x_1(t) * x_2(t)$.	$Y(j\Omega) = X_1(j\Omega)X_2(j\Omega)$.
Product	$y(t) = x_1(t)x_2(t)$.	$Y(j\Omega) = X_1(j\Omega) * X_2(j\Omega) = \int_{-\infty}^{\infty} X_1(j\Theta)X_2(j(\Omega - \Theta))d\Theta$.
Area under $X(j\Omega)$		$\int_{-\infty}^{\infty} X(j\Omega) = x(0)$.
Parseval's relation		$\int_{-\infty}^{\infty} \lvert x(t)\rvert^2 dt = \int_{-\infty}^{\infty} \lvert X(j\Omega)\rvert^2 d\Omega$.
Conjugate function	$y(t) = x^*(t)$.	$Y(j\Omega) = X^*(-j\Omega)$.
Real part	$Re[x(t)]$	$\frac{1}{2}[X(j\Omega) + X^*(-j\Omega)]$.
Imaginary part	$Im[x(t)]$	$\frac{1}{2j}[X(j\Omega) - X^*(-j\Omega)]$.

$y[n]$, is the product of the DTFTs $H(e^{j\omega})$ and $X(e^{j\omega})$ of $h[n]$ and $x[n]$, respectively:

$$Y(e^{j\omega}) = H(e^{j\omega})X(e^{j\omega}). \tag{1.41}$$

If the DTFTs are expressed in terms of magnitude and phase, (i.e., $Y(e^{j\omega}) = |Y(e^{j\omega})|e^{j\phi_Y(\omega)}$, $X(e^{j\omega}) = |X(e^{j\omega})|e^{j\phi_x(\omega)}$, and $H(e^{j\omega}) = |H(e^{j\omega})|e^{j\phi_H(\omega)}$, then the following two equation apply:

$$\left|Y(e^{j\omega})\right| = \left|H(e^{j\omega})\right|.\left|X(e^{j\omega})\right|. \tag{1.42}$$

$$\phi_Y(\omega) = \phi_H(\omega) + \phi_X(\omega). \tag{1.43}$$

The $\left|H(e^{j\omega})\right|$ and $\phi_H(\omega)$ are referred to as the magnitude response and the phase response of the system, respectively. In equations 1.42 and 1.43, the system magnitude response represents the gain or attenuation that the input signal content at frequency ω experiences when the system maps it to the output. The system phase response represents the corresponding phase shift at frequency ω.

If the system magnitude response, $\left|H(e^{j\omega})\right|$, is unity, then the system is said to ideally pass the input signal content at frequency ω_0 to the output. The set of all such frequencies is called the **passband** of the system. If $\left|H(e^{j\omega_0})\right|$ is zero, then the system is said to ideally stop the input signal content at frequency ω_0 from appearing at the output. The set of all such frequencies is called the **stopband** of the system.

If the set of all frequencies $|\omega| \leq \pi$ is partitioned into passbands and stopbands, then the system is called an ideal filter that passes or stops the signal content in a **frequency-selective** manner. A filter is said to be ideal low-pass if its frequency response is the following:

$$H(e^{j\omega}) = \begin{cases} 1, & |\omega| < \omega_c. \\ 0, & |\omega_c| < |\omega| \leq \pi. \end{cases} \tag{1.44}$$

The filter passes all low-frequency input content in the passband $|\omega| < \omega_c$ and stops all high-frequency input content in the stopband $|\omega_c| < |\omega| \leq \pi$. The impulse response of the ideal low-pass filter can be computed as the inverse DTFT of $H(e^{j\omega})$:

$$h[n] = \begin{cases} \omega_c/\pi, & n = 0. \\ \sin \omega_c n/\pi n, & n \neq 0. \end{cases} \tag{1.45}$$

This filter can be shown to be unstable in the BIBO sense.

A practical low-pass filter can only approximate the ideal low-pass response. In practice, filters have passband magnitude within a tolerance of unity and have stopband magnitude within a tolerance of zero. When practical filters are specified, transition bands are allowed between adjacent passbands and stopbands so that the magnitude response in the transition bands may swing between the allowed passband and stopband magnitudes. The impulse response $h[n]$ of a practical filter can vary depending on given filter specifications. The task of determining $h[n]$ to satisfy the specifications is called **filter design.**

The frequency response of a continuous-time LSI system is the continuous-time Fourier transform $H_c(j\Omega)$ of the impulse response $h_c(t)$:

$$H_c(j\Omega) = \int_{-\infty}^{\infty} h_c(t)e^{j\Omega t}, \tag{1.46}$$

$$h_c(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} H_c(j\Omega)e^{j\Omega t}. \tag{1.47}$$

Frequency response of continuous-time filters is specified for frequencies over the range $-\infty < \Omega < \infty$.

1.5 The *z*-Transform and Laplace Transform

Fourier transforms are useful, but they exist for a restricted class of signals. They can be generalized so that the generalization exists for a larger class of signals. These generalizations provide additional insights into system analysis and design. If time is discrete, the generalization is called the *z*-transform. The definition of the DTFT is modified by replacing $e^{j\omega}$ by a complex variable $z = re^{j\omega}$. In the case of continuous time, the definition of the CTFT is modified by replacing $j\Omega$ by a complex variable $s = \sigma + j\Omega$.

1.5.1 *z*-Transform and Its Properties

The discrete-time Fourier transform of a signal $x[n]$, expressed as:

$$X(e^{j\omega}) = \sum_{n=-\infty}^{\infty} x[n]e^{-j\omega n}, \tag{1.48}$$

can be viewed as a power series in the complex variable $z = e^{j\omega}$ but with the variable restricted to values on the unit circle in the *z*-plane. Consider allowing z to assume any complex value of $z = re^{j\omega}$, r real, and ≥ 0. The *z*-transform of a discrete-time signal $x[n]$ is defined as:

$$X(z) = \sum_{n=-\infty}^{\infty} x[n]z^{-n}. \tag{1.49}$$

Note the relation of the *z*-transform to a Laurent's series. The DTFT of $x[n]$ is identical to values that the *z*-transform assumes on the unit circle (i.e., the circle with unit radius centered at the origin in the *z*-plane). With $z = re^{j\omega}$ viewed as a position vector, r is the distance from the origin, and ω is the angle between the vector z and the real axis.

The *z*-transform may converge only over some region in the complex *z*-plane. In general, the region of convergence of z-transform, if not empty, is either the interior, $|z| < R$, of a circle or an annular region in the *z*-plane:

$$R_1 < |z| < R_2, \tag{1.50}$$

where $0 < R_1 < R_2 \leq \infty$.

If the region of convergence includes the unit circle, then the DTFT of the signal exists.

Example 1

Consider the discrete-time signal:

$$x[n] = a^n u[n] = \begin{cases} a^n, & n \geq 0. \\ 0, & n < 0. \end{cases} \tag{1.51}$$

The *z*-transform of $x[n]$ is the following:

$$X(z) = \sum_{n=-\infty}^{\infty} x[n]z^{-n} = \sum_{n=0}^{\infty} a^n z^{-n} = \sum_{n=0}^{\infty} (az^{-1})^n = \frac{1}{1 - az^{-1}}, \tag{1.52}$$

provided $|az^{-1}| < 1$ (i.e., $|z| > |a|$). For the DTFT of the signal to exist, we require that $|a| < 1$.

Example 2

Consider a signal $x[n]$ given by:

$$x[n] = b^n u[-n] = \begin{cases} b^n, & n < 0. \\ 0, & n \geq 0. \end{cases}$$

The *z*-transform of $x[n]$ is expressed as:

$$X(z) = \sum_{n=-\infty}^{-1} b^n z^{-n} = \sum_{m=1}^{\infty} (bz^{-1})^{-m} = \sum_{m=1}^{\infty} (b^{-1}z)^m = \frac{b^{-1}z}{1 - b^{-1}z},$$

provided $|b^{-1}z| < 1 \Rightarrow |z| < |b|$. In this case, the existence of the DTFT requires $|b| > |1|$.

Example 3

The *z*-transform of the signal:

$$x[n] = a^{|n|} = \begin{cases} a^n, & n \geq 0, \\ a^{-n}, & n < 0, \end{cases}$$

is expressed as:

$$X(z) = \sum_{n=0}^{\infty} a^n z^{-n} + \sum_{n=-\infty}^{-1} a^{-n} z^{-n} = \frac{z}{z - a} - \frac{z}{z - \frac{1}{a}}.$$

The region of convergence $ROC = \{[|z| > |a|] \cap [|z| < |1/a|]\}$ is $\{|1/a| < |z| < |a|\}$ provided $|a| < 1$. One notices that in these examples, the *z*-transforms are rational functions in z, with pole locations defining the boundaries of the region of convergence. In example 3, the two poles are located at $z = a$ and $z = 1/a$.

When signals are sums of left-sided or right-sided complex exponential sequences, of the form $a^n u[n - n_a]$ or $b^n u[-(n - n_b)]$, then the *z*-transforms are rational functions in z.

Given a *z*-transform of a signal $x[n]$, the signal can be recovered with the *inverse z-transform*:

$$x[n] = \frac{1}{2\pi j}\oint_C X(z)z^{n-1}dz, \tag{1.53}$$

where the integral is evaluated in the counterclockwise direction over a contour within the region of convergence that encloses the origin. To compute the inverse z-transform, we need information not only about the functional form of the z-transform but also about the region of convergence. In fact, two identical functions with different regions of convergence have different inverse transforms.

Let us consider the case of a z-transform $X(z)$ with two poles located at $z = a$ and $z = b$, $|a| < |b|$. There are three possible regions of convergence:

- ROC$_1$—the region $|z| < |a|$
- ROC$_2$—the annulus $|a| < |z| < |b|$
- ROC$_3$—the region $|z| > |b|$

Figure 1.13 shows the three possible regions of convergence for $a = 1/2$ and $b = 2$. To select the correct region of convergence, we need further information about the signal.

If for example we know that the DTFT of the signal exists (i.e., signal is absolutely summable), then we know that the unit circle is included in the region of convergence. Among the three previous regions, we choose the one that includes the unit circle. In our example, $b = 1/2$ and $a = 2$, and therefore, the ROC is the annulus $|1/2| < |z| < |2|$ (i.e., region ROC$_2$).

If the system is causal, then the z-transform converges in the region outside the largest pole, which is region ROC$_3$ in the example.

Depending on the selected region of convergence, the signal obtained through the inverse transform is different. For example, the inverse z-transform of $X(z) = z/z - a$ is equal to $x[n] = (a)^n u[n]$ if the ROC is $|z| > |a|$, whereas it is equal to $x[n] = -(a)^n u[-n-1]$ if the ROC is $|z| < |a|$.

Table 1.2 summarizes the properties of the z-transform. The derivation of these properties is similar to that carried out for the discrete-time Fourier transform and is not presented here.

Example

Consider the z-transform of a finite-duration sequence:

$$x[n] = a^n,\ 0 \le n \le N-1.$$

The z-transform of this sequence is as written here:

$$X(z) = \sum_{n=0}^{N-1} x[n]z^{-n} = \begin{cases} \frac{1-(az^{-1})^N}{1-az^{-1}} = \frac{1}{z^{N-1}}\frac{z^N-a^N}{z-a}, & z \neq a \\ N, & z = a. \end{cases}$$

Zeros of the z-transform are located at:

$$z_k = ae^{j2\pi k/N},\ 1 \le k \le N-1.$$

There are $N-1$ poles at $z = 0$ and $N-1$ zeros as shown in Figure 1.14. In general, the z-transform of a finite-duration sequence can possibly have poles only at $z = 0$ or $z = \infty$, while the zeros may be located anywhere in the z-plane. This means that for finite sequences, the ROC is the whole z-plane except perhaps the origin and/or $z = \infty$.

TABLE 1.2 Properties of the z-Transform

Property	Discrete-time signal	z-Transform
Linearity	$y[n] = ax_1[n] + bx_2[n].$	$Y(z) = aX_1(z) + bX_2(z).$
Time shift	$y[n] = x[n-n_0].$	$Y(z) = X(z)z^{-zn_0}.$
Exponential weighting	$y[n] = x[n]a^n.$	$Y(z) = X(a^{-1}z).$
Linear weighting	$y[n] = nx[n].$	$Y(z) = z\frac{dX(z)}{dz}$
Convolution	$y[n] = x_1[n] * x_2[n].$	$Y(z) = X_1(z)X_2(z).$
Product	$y[n] = x_1[n]x_2[n].$	$Y(z) = \frac{1}{2\pi j}\int_C X_1(v)X_2(\frac{z}{v})\frac{dv}{v}.$

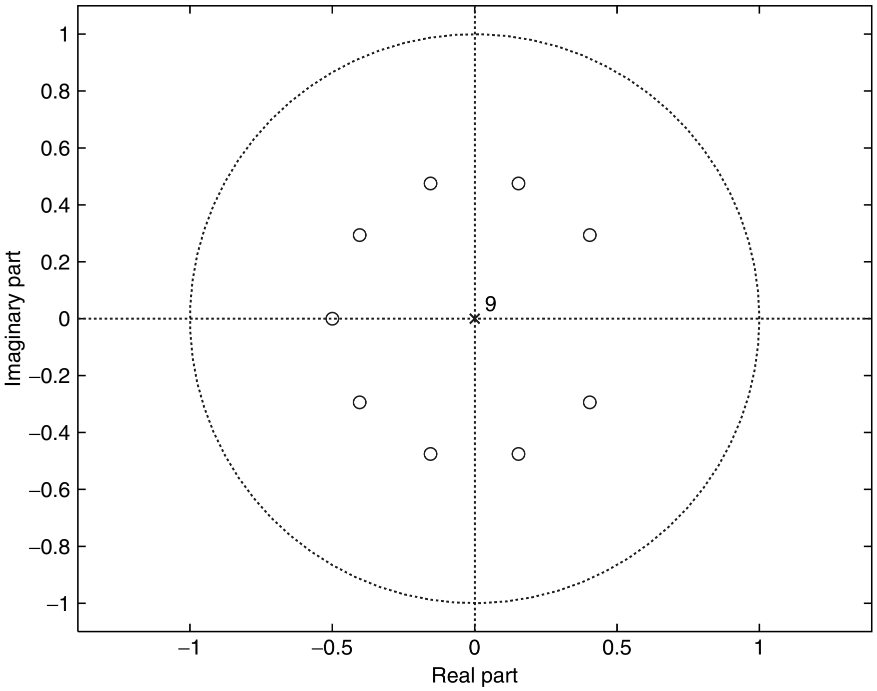

FIGURE 1.14 Location of Zeros and Poles for a Finite Sequence with $N = 10$ and $a = 0.5$

The magnitude and the phase of the z-transform and the DTFT of the finite-duration sequence are shown in Figure 1.15.

1.5.2 The Laplace Transform and Its Properties

For continuous-time signals, the Fourier transform integral of equation 1.39 can be generalized as:

$$X(s) = \int_{-\infty}^{\infty} x(t)e^{-st}dt, \tag{1.54}$$

where $s = \sigma + j\Omega$. Equation 1.54 is the **Laplace transform** of the signal $x(t)$.

The Laplace transform can be represented in the two-dimensional s-plane, with σ along the real axis, and the frequency Ω on the imaginary axis. The Laplace transform evaluated for $\sigma = 0$ (i.e., for $s = j\Omega$) is identical to the Fourier transform $X(\Omega)$.

If a continuous-time signal $x(t)$ is bounded by:

$$|x(t)| \leq K_1 e^{\sigma_1 t} u_c(t) + K_2 e^{\sigma_2 t} u_c(-t),$$

then one can determine that the Laplace transform converges for:

$$\sigma_1 < Re\{s\} < \sigma_2.$$

The signal $x(t)$ can be recovered using the inverse Laplace transform:

$$x(t) = \frac{1}{2\pi j} \int_{\Gamma} X(s)e^{st} ds, \tag{1.55}$$

where Γ is a contour within the region of convergence that goes from $s = \sigma - j\infty$ to $s = \sigma + j\infty$. The following rules are useful in determining the region of convergence:

- If $x(t)$ is causal and of infinite duration, then the ROC lies to the right of all poles.
- If $x(t)$ is anticausal and of infinite duration, then the ROC lies to the left of all the poles.
- If $x(t)$ is a two-sided infinite-duration signal, then the ROC is the section of plane included between the poles of the causal part and the poles of the anticausal part.
- If $x(t)$ is of finite duration and there exists at least one value of σ for which the Laplace transform exists, then the ROC is the whole plane.

The properties of the Laplace transform are similar to the properties of the z-transform and are summarized in Table 1.3.

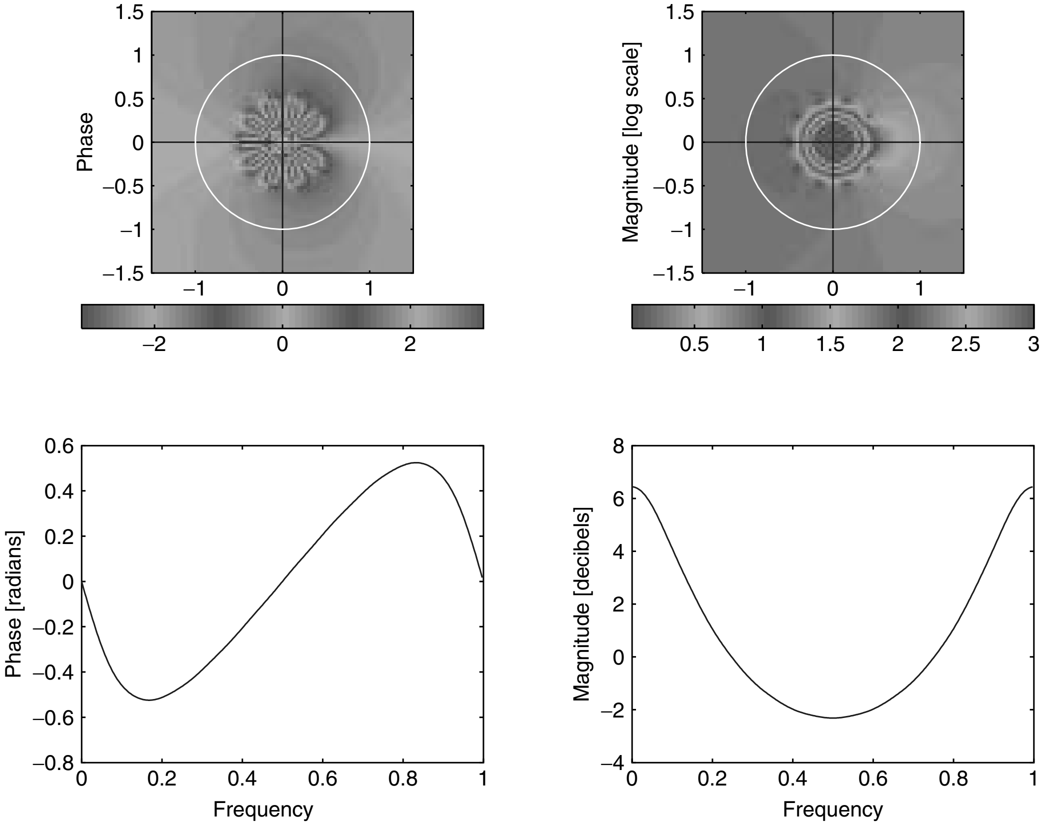

FIGURE 1.15 Phase and Log-Magnitude of z-Transform and of DTFT of Finite Sequence With $N = 10$ and $a = 0.5$

1.6 Sampling and Quantization

Until this point in our discussion, continuous-time and discrete-time signals have been considered separately. We did not consider how the signals arise in practice and where they are linked in some cases. Now we examine a mechanism—the sampling process—by which a discrete-time signal is obtained from a continuous-time signal.

1.6.1 Sampling

Sampling refers to the process of obtaining a discrete-time signal by extracting values of a continuous-time signal at predetermined instants that are usually equally spaced. This process maps a function with an uncountably infinite domain to a function with a countable domain. One would like the mapping to be such as to allow an exact recovery of the continuous-time signal from the sampled signal. The conditions that allow a continuous-time signal to be reconstructed from its samples can be obtained from examining the signal Fourier transform. The main requirements are that the signal be bandlimited and that an adequate sampling rate be used.

Consider a signal sampled at equally spaced instants. The time separation between two adjacent samples is called **sampling period (T)**, and its inverse is the **sampling rate** *or* **sampling frequency** (f_s). Because signal values are retained only at sampling instants, the signal information can be captured in the product of the continuous-time signal with a train, $s(t)$, of impulses spaced apart by T:

$$s(t) = \sum_{n=-\infty}^{\infty} \delta(t - nT). \qquad (1.56)$$

A sampled **continuous-time** signal is just the product of the original signal $x_c(t)$ and the sampling signal $s(t)$:

$$x_s(t) = s(t)x_c(t) = \sum_{n=-\infty}^{\infty} x_c(nT)\delta(t - nT). \qquad (1.57)$$

The Fourier transform of the signal $x_s(t)$ is as follows:

TABLE 1.3 Properties of the Laplace Transform

Property	Continuous-time signal	Laplace transform
Linearity	$y(t) = ax_1(t) + bx_2(t).$	$Y(s) = aX_1(s) + bX_2(s).$
Time shift	$y(t) = x(t - t_0).$	$Y(s) = X(s)e^{-st_0}.$
Exponential weighting	$y(t) = x(t)e^{at}.$	$Y(s) = X(s - a).$
Differentiation	$tx(t)$	$-\frac{dX(s)}{ds}$
Convolution	$y(t) = x_1(t) * x_2(t).$	$Y(s) = X_1(s)X_2(s).$
Product	$y(t) = x_1(t)x_2(t).$	$Y(s) = X_1(s) * X_2(s).$

$$\begin{aligned} X_s(j\Omega) &= \int_{-\infty}^{\infty} \left(\sum_{n=-\infty}^{\infty} x_c(nT)\delta(t - nT) \right) e^{-j\Omega t dt} \\ &= \sum_{n=-\infty}^{\infty} x_c(nT)e^{-j\Omega nT}. \end{aligned} \tag{1.58}$$

The samples define a discrete-time signal $x[n] = x_c(nT)$, so that equation 1.58 becomes:

$$X_s(j\Omega) = \sum_{n=-\infty}^{\infty} x[n]e^{-j\Omega nT} = X(e^{j\Omega T}) = X(e^{j\omega}), \tag{1.59}$$

where $\omega = \Omega T$ is the **normalized frequency.**

In Figure 1.16, a continuous-time signal $x_c(t)$ is shown, and we assume that its Fourier transform is bandlimited. If $x_c(t)$ is multiplied with an impulse train, $s(t)$, we obtain the sampled signal $x_s(t)$. Multiplication in the time domain yields convolution in the frequency domain. This is another way of expressing the Fourier transform of the sampled signal $x_s(t)$ as a convolution integral of the Fourier transforms $X_c(e^{j\Omega})$ and $S(e^{j\Omega})$.

If $s(t)$ is a train of impulses with spacing T, its Fourier transform is a train of impulses with spacing $f = 1/T$

$$S(j\Omega) = \frac{2\pi}{T} \sum_{k=-\infty}^{\infty} \delta\left(\Omega - k\frac{2\pi}{T}\right). \tag{1.60}$$

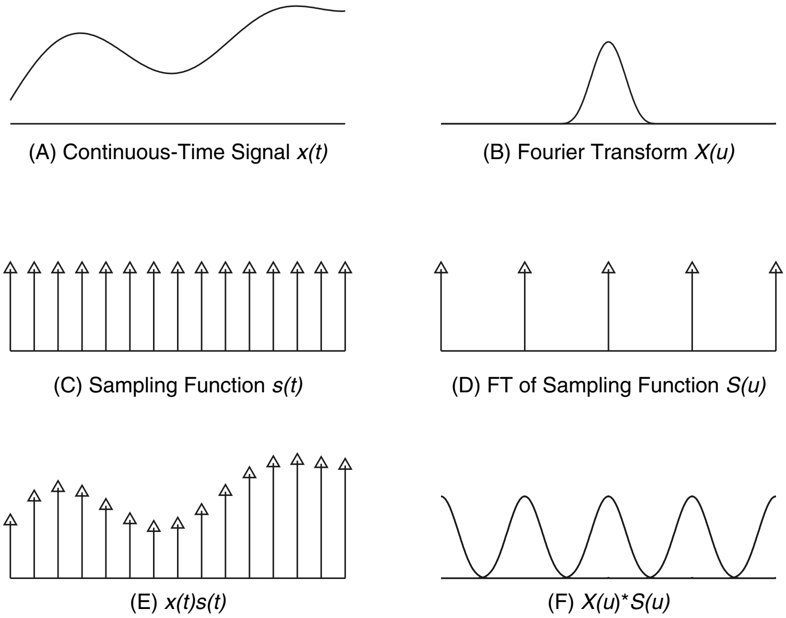
The convolution of this train of impulses with the $X(e^{j\Omega})$ results in periodic repetition of the Fourier transform image at the locations of the impulses.

$$\begin{aligned} X_s(j\Omega) &= \frac{1}{2\pi} X_c(j\Omega) * S(j\Omega) = \frac{1}{T} X_c(j\Omega) \\ &* \sum_{k=-\infty}^{\infty} \delta\left(\Omega - k\frac{2\pi}{T}\right) = \frac{1}{T} \sum_{k=-\infty}^{\infty} X_c\left(j\left(\Omega - k\frac{2\pi}{T}\right)\right). \end{aligned} \tag{1.61}$$

Equating the Fourier transform of $x_s(t)$ in equation 1.59 to 1.61, we get:

$$X(e^{j\Omega T}) = \frac{1}{T} \sum_{k=-\infty}^{\infty} X_c\left(j\left(\Omega - k\frac{2\pi}{T}\right)\right). \tag{1.62}$$

If we substitute the discrete frequency $\omega = \Omega T$, equation 1.62 becomes:



(A) Continuous-Time Signal *x(t)*

(B) Fourier Transform *X(u)*

(C) Sampling Function *s(t)*

(D) FT of Sampling Function *S(u)*

(E) *x(t)s(t)*

(F) *X(u)*S(u)*

FIGURE 1.16 Graphic Development of Sampling Concepts

$$X(e^{j\omega}) = \frac{1}{T}\sum_{k=-\infty}^{\infty} X_c\left(j\frac{\omega - k2\pi}{T}\right). \tag{1.63}$$

Therefore, sampling in the time domain corresponds to adding shifted replicas of the Fourier transform in the frequency domain. To avoid losing information, we need to avoid any overlap in the replicas in the frequency domain.

1.6.2 Signal Reconstruction

To reconstruct the original signal (i.e., to extract the central replica from $X_s(j\Omega)$), we need to apply an ideal low-pass filter. In the time domain, this means that we need to convolve the signal with a sinc function, shown in Figure 1.17, and given by:

$$h(t) = \frac{\sin(\pi \pm /T)}{\pi t/T} = \mathrm{sinc}\left(\frac{\pi t}{T}\right). \tag{1.64}$$

The reconstructed signal, $x_r(t)$, is the sum of shifted sinc functions weighted by the signal samples:

$$\begin{aligned} x_r(t) &= \sum_{n=-\infty}^{\infty} x[n]\frac{\sin(\pi/T(t-nT))}{\pi/T(t-nT)} \\ &= \sum_{n=-\infty}^{\infty} x[n]\,\mathrm{sinc}\left(\frac{\pi}{T}(t-nT)\right). \end{aligned} \tag{1.65}$$

The reconstructed signal $x_r(t)$ equals the original signal $x(t)$ only if there is no overlapping of the replicas in the frequency domain.

In Figure 1.16 replicas of the Fourier transform do not overlap, so the original signal can be recovered by simply using a low-pass filter. The sampling rate has been chosen adequately to avoid loss of information.

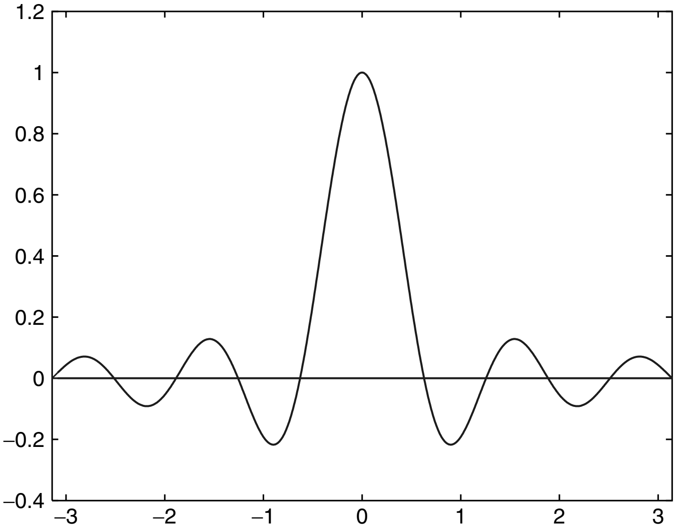


FIGURE 1.17 Impulse Response of an Ideal Low-Pass Filter

Suppose that the Fourier transform of the signal $x_c(t)$ is bandlimited to $|\Omega| \leq \Omega_0 = 2\pi W$ so that:

$$X_c(j\Omega) = 0. \quad |\Omega| \geq \Omega_0 = 2\pi W. \tag{1.66}$$

We need to choose a sampling rate such that:

$$f_s = \frac{1}{T} \geq 2W. \tag{1.67}$$

In the example of Figure 1.17, the sampling period is $T = 1/2W$.

Figure 1.18 shows the case of **undersampling** for the signal with Fourier transforms shown in Figure 1.16. Undersampling means that the sampling rate is below the so-called Nyquist rate of $2W$, resulting in a frequency content above $\Omega > 2\pi W$ that cannot be recovered by applying the low-pass reconstruction filter. The content is folded back to lower frequencies, a phenomenon called **aliasing**.

Finally, Figure 1.19 illustrates the case of **oversampling** where $f_s > 2W$. The requirements on the low-pass reconstruction filter can be more relaxed.

In many applications, there is a need to increase or decrease the sampling rate of a discrete-time signal directly in the discrete-time domain without reconstructing the continuous-time signal. These tasks are referred to as **interpolation** and **decimation**. These are basic operations needed in multirate signal processing, filter banks, and sub-band/wavelet analysis (Akansu *et al.*, 1996; Strang and Nguyen, 1996; Vaidyanathan, 1993; Vetterli and Kovacevic, 1995).

1.6.3 Quantization

At the beginning of this chapter, signals were classified into four categories according to the values assumed by the independent and the dependent variables. So far, we have focused our attention only on the independent variable, namely time, to distinguish signals between continuous-time and discrete-time signals, and we assumed that the dependent variable can assume a continuum of values.

However, when processing data with a computer or with a digital signal processor, both variables can assume only discrete values. This means that not only is the signal discrete in time but also in amplitude. These signals are referred to as **digital signals**. Therefore, if a signal has to be processed in digital form, first its independent variable and then its dependent variable are converted from continuous to discrete form through **sampling** and **quantization** respectively. Quantization is the process that converts data from infinite or high precision to finite or lower precision.

(F) *X*(*u*)***S*(*u*)

FIGURE 1.18 Graphic Development of Undersampling Concepts

Each digital variable is stored in a finite length register and is represented by a finite number of bits, B. There are two possible ways of representing data in binary form: **fixed point** and **floating point**. In fixed point representation, the binary point is fixed at a specific location, and the implementation of arithmetic operations takes into account this property. On the other hand, in the floating point representation, each number is represented by two parameters: a **mantissa**, represented with B_M bits, and an **exponent** E, represented as B_E bits, with $B = B_M + B_E$.

The error introduced in the processing of digital signals due to quantization depends on the format of the numbers, the quantization method (**truncation** or **rounding**), the number of bits used to represent signal values and filter coefficients, and so on. Details can be found in Mitra (1998) and Oppenheim *et al.* (1999).

FIGURE 1.19 Graphic Development of Oversampling Concepts

1.7 Discrete Fourier Transform

For general discrete-time signals, we examined the discrete-time Fourier transform (DTFT) as a useful analysis and design tool for frequency domain representation. We now consider Fourier analysis that is expressly formulated for finite-duration discrete-time and that serves as a computational aid in many signal processing tasks.

Consider a sequence $x[n]$ that is zero for n other than $0 \le n \le N-1$. The **discrete Fourier transform** (DFT) of the signal $x[n]$ is defined as:

$$X[k] = \begin{cases} \sum_{n=0}^{N-1} x[n] e^{-j2\pi nk/N}, & 0 \le k \le N. \\ 0, & \text{otherwise.} \end{cases} \tag{1.68}$$

With the following two equations:

$$W_N = e^{-j2\pi/N}, \tag{1.69}$$

$$R_N[n] = \sum_{m=0}^{N-1} \delta[n-m], \tag{1.70}$$

the DFT can be rewritten as:

$$X[k] = \sum_{n=0}^{N-1} x[n] W_N^{nk} R_N[k]. \tag{1.71}$$

Note that the DFT maps sequences to sequences. In other words, the frequency variable (k) is discrete, unlike that for the DTFT, where ω assumes all real values. The signal $x[n]$ can be recovered from X[k] through the **inverse discrete Fourier transform** (IDFT) relation:

$$x[n] = \left(\frac{1}{N} \sum_{k=0}^{N-1} X[k] e^{j\frac{2\pi}{N}nk} \right) R_N[n] = \frac{1}{N} \sum_{k=0}^{N-1} X[k] W_N^{-nk} R_N[n], \tag{1.72}$$

which differs from the forward transform in the normalization factor $\frac{1}{N}$ and in the sign of the exponent.

1.7.1 Relation Between the DFT and the Samples of DTFT

In equation 1.37, we defined the DTFT of a signal $x[n]$ as:

$$X(e^{j\omega}) = \sum_{n=-\infty}^{\infty} e^{-j\omega n} x[n]. \tag{1.73}$$

If the signal $x[n]$ has finite duration and it is limited to the interval $0 \le n \le N-1$, then the previous expression becomes:

$$X(e^{j\omega}) = \sum_{n=0}^{N-1} e^{-j\omega n} x[n]. \tag{1.74}$$

Clearly $X[k]$, the DFT of $x[n]$, consists of samples of $X(e^{j\omega})$ at $\omega = 2\pi k/N$ for $0 \le k \le N-1$.

Therefore:

$$X[k] = X(e^{j\omega})|_{\omega=\frac{2\pi k}{N}} R_N[k] = X(e^{j2\pi k/2}) R_N[k]. \tag{1.75}$$

Because a sequence of duration N can be recovered from its DFT $X[k]$, then $x[n]$ of duration N samples can be recovered from N samples of $X(e^{j\omega})$ at $\omega = 2\pi k/N$, $0 \le k \le N-1$, by computing the inverse DFT of these samples.

We conclude that a sequence $x[n]$ of duration N can be completely recovered from N equally spaced samples of its DTFT by computing the inverse DFT.

But what happens in the case of a general sequence that is not necessarily of duration N? That is, what is the inverse DFT of the samples of $X(e^{j\omega})$ at $\omega = 2\pi k/N$, $0 \le k \le N-1$, when the sequence $x[n]$ is not necessarily of duration N?

Let $X(e^{j\omega})$ be the DTFT of $x[n]$ that may be of duration $> N$. Then the following applies.

- Denote samples of $X(e^{j\omega})$ as $X_N[k] = X(e^{j2\pi k/N})$ for $k = 0, 1, \ldots.\ N-1$.
- Compute the inverse DFT of $X_N[k]$ and call the result $x_N[n]$.
- Determine $x_N[n]$ such that:

$$X_N[k] = \sum_{n=0}^{N-1} x_N[n] e^{-j2\pi kn/N}. \tag{1.76}$$

It can be shown that:

$$x_N[n] = \sum_{r=-\infty}^{\infty} x[n+rN],\ n = 0, 1, \ldots, N-1. \tag{1.77}$$

Proof: $X_N[k] = X(e^{j2\pi k/N}) = \sum_{n=-\infty}^{\infty} x[n] e^{-j2\pi kn/N}$

$$= \sum_{n=0}^{N-1} \sum_{r=-\infty}^{\infty} x[n+rN] e^{-j2\pi k(n+rN)/N}$$

$$= \sum_{n=0}^{N-1} \left(\sum_{r=-\infty}^{\infty} x[n+rN] \right) e^{-j2\pi kn/N}.$$

1.7.2 Linear and Circular Convolution

In implementing discrete-time LSI systems, we need to compute the convolution sum, otherwise called linear convolution, of the input signal $x[n]$ and the impulse response $h[n]$ of the system. For finite duration sequences, this convolution can be carried out using DFT computation.

Let $x[n]$ and $h[n]$ be of finite duration. Assume $x[n]$ is zero outside the interval $0 \leq n \leq N-1$ and $h[n]$ is zero outside the interval $0 \leq n \leq M-1$.

The sequence $y[n]$ is the **linear convolution** between $x[n]$ and $h[n]$:

$$y[n] = x[n] * h[n] = \sum_{k=-\infty}^{\infty} x[k]h[n-k], \qquad (1.78)$$

and it is of duration $M + N - 1$.

If we wish to recover $y[n]$ from its DTFT $Y(e^{j\omega})$, we need samples of it at $(M + N - 1)$ points $\omega = 2\pi/Nk$ and $k = 0, 1, \ldots, M + N - 2$.

To get these samples, we observe that $Y(e^{j\omega}) = X(e^{j\omega})H(e^{j\omega})$. Therefore, if we know the values of the samples of $X(e^{j\omega})$ and $H(e^{j\omega})$ at $\omega = 2\pi/Nk$ for $k = 0, 1, \ldots, M + N - 2$, then $Y(e^{j2\pi/Nk})$ can be obtained as a product of these samples.

But the samples of $X(e^{j\omega})$ at these points are the same as the $(M + N - 1)$-point DFT of $x[n]$. Similarly the samples of $H(e^{j\omega})$ at these points are obtained by computing the $(M + N - 1)$-point DFT of $h[n]$.

The product $X[k]$ $H[k]$ is therefore equal to $Y[k]$, the DFT of $y[n]$.

However the relationship $Y[k] = X[k]H[k]$ is valid only if $Y[k]$ is of length $\geq (M + N - 1)$, which is the length of the linear convolution $y[n]$. To obtain this result, we need to zero-pad the sequences to the desired length before computing the DFTs and multiplying them together.

Let $L \geq \max\{N, M\}$. If we compute the product $X[k]H[k]$ using an L-point DFT $\max\{N, M\}$, possibly without the necessary zero-padding, then the resulting sequence can be denoted as $Y_L[k]$, with inverse DFT given by:

$$y_L[n] = \sum_{r=-\infty}^{\infty} y[n + rL] = x[n] \; o \; h[n]. \qquad (1.79)$$

Here o denotes **circular convolution** of the sequences $x[n]$ and $h[n]$.

The samples of circular convolution, $y_L[n]$, are obtained from the samples of linear convolution, $y[n]$, by wrapping around all samples that exceed the index $n = L - 1$ as shown in equation 1.79.

From the definitions of linear and circular convolution, we observe that if $L \geq (N + M - 1)$, then the two expressions coincide and $y_L[n] = y[n]$ as determined previously.

1.7.3 Use of DFT

Many fast algorithms have been developed to implement the DFT, and these are referred to as **fast Fourier transform** (FFT) algorithms (Oppenheim *et al.*, 1997). FFT allows an efficient computation of the DFT with a number of operations proportional to $NlogN$ instead of N^2.

Algorithms are commonly used in implementing signal processing tasks:

- Convolution of two finite duration sequences can be performed using DFTs of adequate length. The use of FFT enables an efficient implementation of convolution and FIR filters.
- The DFT of a sequence consists of samples of the DTFT of the sequence. It thus provides information about the frequency content of signals, and it is used in estimating the spectra of signals.

1.8 Summary

In this chapter, we provided an overview of discrete-time and continuous-time signals and systems. The emphasis was on discrete time, but notions for the two cases were presented in parallel. Fundamentals of discrete-time systems and properties such as linearity, time-invariance, causality, and stability were presented. Fourier analysis of signals was presented followed by a discussion of frequency-selective filtering. Basics of *z*-transforms were covered next along with a discussion of the *z*-domain interpretation of system properties, such as causality and stability. The operations of sampling and quantization that relate continuous and discrete time signals were briefly discussed. Finally, the discrete Fourier transform was presented and its importance in implementing signal processing algorithms described. Our discussion was largely confined to the description and processing of deterministic signals. A discussion of issues in implementation and the use and design of digital signal processors (Lapsley *et al.*, 1997) is not within the scope of this chapter.

Many excellent books cover the topic of signal processing, such as those by Haykin and Van Veen (1999), Lathi (1998), Mitra (1998), Oppenheim (1999, 1997), Proakis and Manolakis (1995) Strang and Nguyen (1996), Vaidyanathan (1993), and Vetterli and Kovacevic (1995). Introductory articles on new developments and research in signal processing appear in *IEEE Signal Processing Magazine*. Most of the research articles describing the advances in signal processing appear in *IEEE Transactions on Signal Processing, IEEE Transactions on Image Processing, IEEE Transactions on Circuits and Systems, Electronics Letters; International Conference on Acoustics, Speech, and Signal Processing (ICASSP)*, and *International Symposium on Circuits and Systems*. Several information resources are available on the World Wide Web. The impact of signal processing on information technology is described in a workshop report by the National Science Foundation (1994).

Digital Filters

Marcio G. Siqueira
Cisco Systems, Sunnyvale, California, USA

Paulo S.R. Diniz
Program of Electrical Engineering, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil,

2.1 Introduction

The rapid development of integrated circuit technology led to the development of very powerful digital machines able to perform a very high number of computations in a very short period of time. In addition, digital machines are flexible, reliable, reproducible, and relatively cheap. As a consequence, several signal processing tasks originally performed in the analog domain have been implemented in the digital domain. In fact, several signal processing tools are only feasible to be implemented in the digital domain.

As most real life signals are continuous functions of one or more independent variables, such as time, temperature, and position, it would be natural to represent and manipulate these signals in their original analog domain. In this chapter we will consider time as the single independent variable. If sources of information are originally continuous in time, which is usually the case, and they occupy a limited range of frequencies, it is possible to transform continuous-time signals into discrete-time signals without losing any significant information. By interpolation, the discrete-time signal can be mapped back into the original continuous-time signal.

It is worth mentioning that signals exist that are originally discrete in time, such as the monthly earnings of a worker or the average yearly temperature of a city.

As a result, the current technological trend is to sample and quantize the signals as early as possible so that most of the operations are performed in the digital domain. The sampling process consists of transforming a continuous signal into a discrete signal (a sequence). This transformation is necessary because digital machines are suitable to manipulate sequences of quantized numbers at high speed. Therefore, quantization of the continuous amplitude samples generate digital signals tailored to be processed by digital machines.

A **digital filter** is one of the basic building blocks in digital signal processing systems. Digital filtering consists of mapping a discrete-time sequence into another discrete-time sequence that highlights the desired information while reducing the importance of the undesired information.

Digital filters are present in various digital signal processing applications related to speech, audio, image, video, and multirate processing systems as well as in communication systems, CD players, digital radio, television, and control systems. Digital filters can have either fixed (Antoniou, 1993; Jackson, 1996; Oppenheim and Schafer, 1989; Mitra, 2001; Diniz, 2002) or adaptive coefficients (Diniz, 2002).

In this chapter, we will describe:

- The most widely used types of digital filter transfer functions;
- How to design these transfer functions (i.e., how to calculate coefficients of digital filter transfer functions);
- How to map a transfer function into a digital filter structure;
- The main concerns in the actual implementation in a finite precision digital machine; and
- The current trends in the hardware and software implementations of digital filters

In particular, we focus on digital filters that implement linear systems represented by difference equations. We will show how to design digital filters based on magnitude specifications. In addition, we present efficient digital filter structures that are often required for implementation with minimal cost, taking into consideration that real-time implementation leads to nonlinear distortions caused by the finite word length representations of internal signals and coefficients. Finally, the mostly widely used approaches to implement a digital filter are briefly discussed.

2.2 Digital Signal Processing Systems

A typical digital signal processing (DSP) system comprises the following modules, shown in Figure 2.1.

- **Analog-to-digital (A/D) converter**: Assuming that the input signal is band-limited to frequency components below half of the sampling frequency, the A/D converter obtains signal samples at equally spaced time intervals and converts the level of these samples into a numeric representation that can be used by a digital filter.
- **Digital filter**: The digital filter uses the discrete-time numeric representation obtained by the A/D converter to perform arithmetic operations that will lead to the filtered output signal.
- **Digital-to-analog (D/A) converter**: The D/A converter converts the digital filter output into analog samples that are equally spaced in time.
- **Low-pass filter**: The low-pass filter converts the analog samples of the digital filter output into a continuous-time signal.

2.3 Sampling of Analog Signals

Figure 2.2 shows the mechanism behind sampling of continuous time signals and its effect on the frequency representation. Figure 2.2(A) shows that a continuous signal $x(t)$ is multiplied in the time domain by a train of unitary impulses $x_i(t)$. The resulting signal from the multiplication operation is $x^*(t)$, which contains samples of $x(t)$. Figure 2.2(B) shows the frequency representation of the original signal $x(t)$ before sampling. Figure 2.2(C) shows the spectrum of the impulse train $x_i(t)$. Finally, Figure 2.3 shows the spectrum of the sampled signal $x^*(t)$. According to the convolution theorem, the Fourier transform of the sampled signal $x^*(t)$ should be the convolution, in the frequency domain, of the Fourier transform of the impulse train and the Fourier transform of the original signal before sampling. Therefore, it can be shown that:

$$\begin{aligned} X_D(e^{j\omega}) &= \frac{1}{T}\sum_{l=-\infty}^{\infty} X\left(j\frac{\omega}{T}+j\frac{2\pi l}{T}\right) \\ &= \frac{1}{T}\sum_{l=-\infty}^{\infty} X(j\omega_a + j\omega_s l). \end{aligned} \tag{2.1}$$

From the above equation and from Figure 2.2, it can be seen that the spectrum of the sampled signal will be repeated at every $\omega_s = 2\pi/T$ interval. An important consequence of the spectrum repetition is the sampling theorem shown next.

2.3.1 Sampling Theorem

If a continuous signal is band-limited (i.e., $X(j\omega_a) = 0$ for $\omega_a > \omega_c$), $x(t)$ can be reconstructed from $x_D(n)$ for

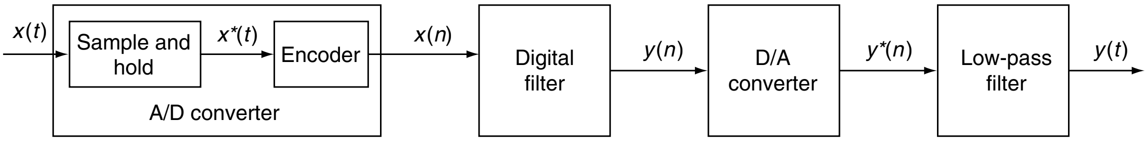

FIGURE 2.1 Architecture of a Complete DSP System Used to Filter an Analog Signal

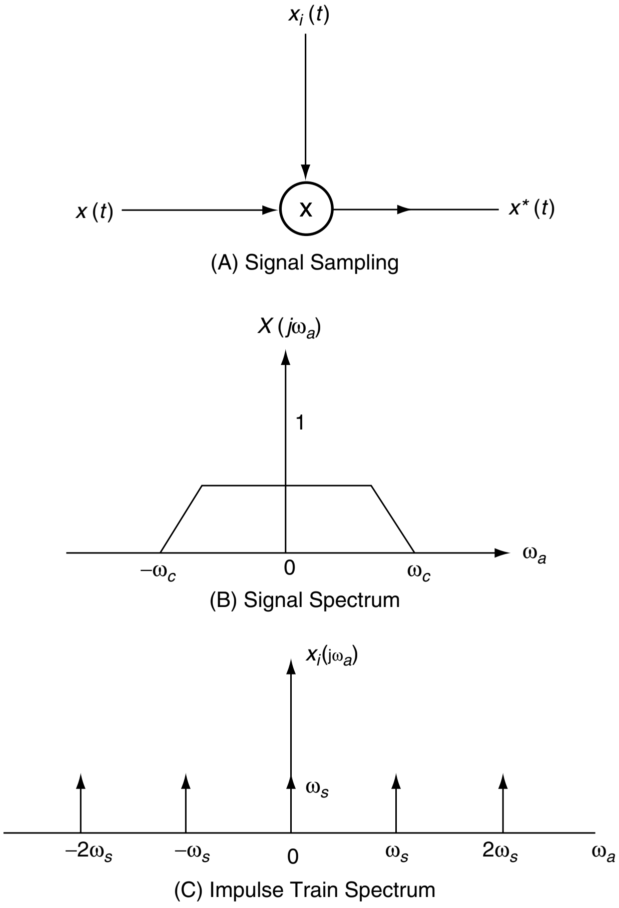

(A) Signal Sampling

(B) Signal Spectrum

(C) Impulse Train Spectrum

FIGURE 2.2 Sampling of Continuous-Time Signals

$-\infty < n < \infty$ if $\omega_s > 2\omega_c$, where ω_s is the sampling frequency in radians per second.

Figure 2.4 shows sampling effects on a continuous-time signal. Figure 2.4(A) shows the continuous-time signal spectrum, and Figures 2.4(B), 2.4(C), and 2.4(D) show the sampled signal spectra for the cases $\omega_c = \omega_s/2$, $\omega_c > \omega_s/2$, and $\omega_c < \omega_s/2$. It can be seen from these pictures that only Figure 2.4(D) does not produce distortion in the frequencies between $-\omega_c$ and ω_c. Figure 2.4(C) shows that when the sampled signal has frequency components above $\omega_s/2$ (half of the sampling frequency), the sampled signal spectrum will be distorted in the frequencies around $\omega_s/2$. In the case of Figure 2.4(B), no distortion occurred only because the signal had no power at $\omega_s/2$. This distortion is known as aliasing and is undesirable in most cases. As a consequence, only case 2.4(D)[1] can be used to recover the spectrum of the original continuous signal shown in Figure 2.4(A).

The recovery of the continuous signal spectrum from the sampled signal can be theoretically accomplished by using an analog filter with flat frequency response to retain only the components between $-\omega_s/2$ and $\omega_s/2$ of the spectra shown in Figure 2.4(A). The frequency response of the analog filter with these characteristics is shown in Figure 2.5. The impulse response of this filter is as follows:

$$h(t) = \frac{T \sin(\omega_{LP} t)}{\pi t}. \tag{2.2}$$

In equation 2.2, ω_{LP} is the cutoff frequency of the designed low-pass filter. The ω_{LP} shall be chosen to guarantee no aliasing (i.e., $\omega_c < \omega_{LP} < \omega_s/2$). The impulse response in the above equation is depicted in Figure 2.5. It is easy to verify that a causal filter with this exact impulse response cannot be implemented. In practice, it is possible to design analog filters that are good approximations for the frequency response in Figure 2.5.

2.4 Digital Filters and Linear Systems

An example of a discrete-time signal is shown in Figure 2.6. In a digital filter, the input signal $x(n)$ is a sequence of numbers indexed by the integer n that can assume only a finite number of amplitude values. Such a sequence might originate from a continuous-time signal $x(t)$ by periodically sampling it at the time instants $t = nT$, where T is the sampling interval. The output sequence $y(n)$ arises by applying $x(n)$ to the input of the digital filter, with the relationship between $x(n)$ and $y(n)$ represented by the operator $\mathcal{F}$ as:

$$y(n) \equiv \mathcal{F}[x(n)]. \tag{2.3}$$

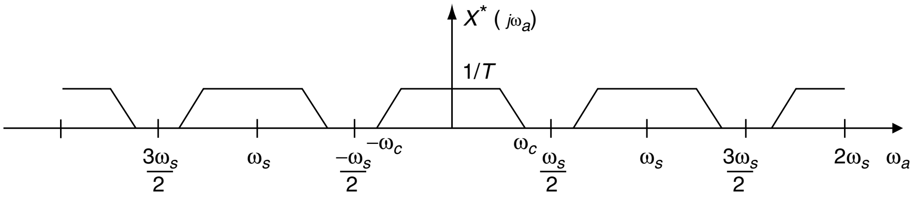

FIGURE 2.3 Spectrum of Sampled Signal

[1] In the case of Figure 2.4(B), distortion could occur only at $\omega_s/2$.

FIGURE 2.4 Sampling Effects

2.4.1 Linear Time-Invariant Systems

The main classes of digital filters are the **linear, time-invariant** (LTI) and **causal** filters. A linear digital filter responds to a weighted sum of input signals with the same weighted sum of the corresponding individual responses; that is:

$$\mathcal{F}[\alpha_1 x_1(n) + \alpha_2 x_2(n)] = \alpha_1 \mathcal{F}[x_1(n)] + \alpha_2 \mathcal{F}[x_2(n)], \quad (2.4)$$

for any sequences $x_1(n)$ and $x_2(n)$ and for any arbitrary constants α_1 and α_2. A digital filter is said to be time-invariant when its response to an input sequence remains the same, irrespective of the time instant that the input is applied to the filter. That is, $\mathcal{F}[x(n)] = y(n)$, and then:

$$\mathcal{F}[x(n - n_0)] = y(n - n_0), \quad (2.5)$$

for all integers n and n_0. A causal digital filter is one whose response does not anticipate the behavior of the excitation signal. Therefore, for any two input sequences $x_1(n)$ and $x_2(n)$ such that $x_1(n) = x_2(n)$ for $n \leq n_0$, the corresponding responses of the digital filter are identical for $n \leq n_0$; that is:

$$\mathcal{F}[x_1(n)] = \mathcal{F}[x_2(n)], \text{ for } n \leq n_0. \quad (2.6)$$

An initially relaxed linear-time invariant digital filter is characterized by its response to the unit sample or impulse sequence $\delta(n)$. The filter response when excited by such a sequence is denoted by $h(n)$, and it is referred to as **impulse response** of the digital filter. Observe that if the digital filter is causal, then $h(n) = 0$ for $n < 0$. An arbitrary input sequence

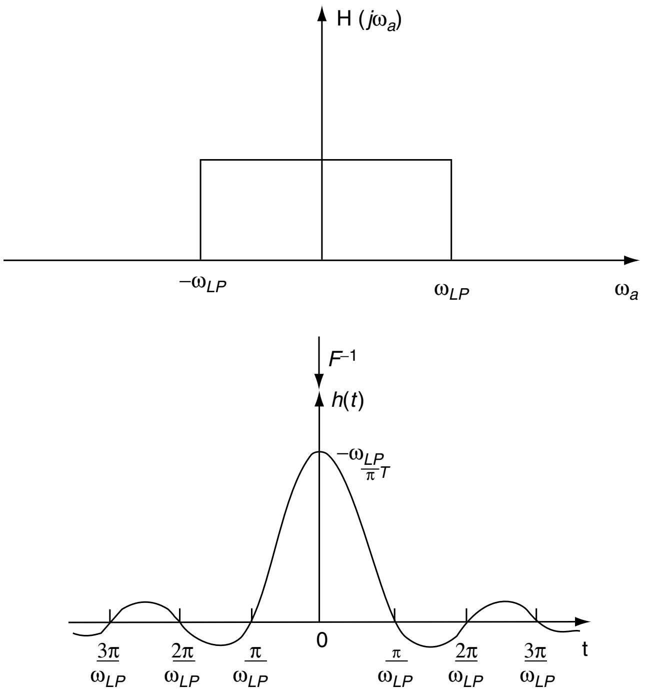

FIGURE 2.5 Ideal Low-Pass Filter

can be expressed as a sum of delayed and weighted impulse sequences:

$$x(n) = \sum_{k=-\infty}^{\infty} x(k)\delta(n-k), \tag{2.7}$$

and the response of an LTI digital filter to $x(n)$ can then be expressed by:

$$\begin{aligned} y(n) &= \mathcal{F}\left[\sum_{k=-\infty}^{\infty} x(k)\delta(n-k)\right] \\ &= \sum_{k=-\infty}^{\infty} x(k)\mathcal{F}[\delta(n-k)] \\ &= \sum_{k=-\infty}^{\infty} x(k)h(n-k) \\ &= x(n) * h(n). \end{aligned} \tag{2.8}$$

The summation in the last two lines of the above expression, called the **convolution sum**, relates the output sequence of a digital filter to its impulse response $h(n)$ and to the input sequence $x(n)$. Equation 2.8 can be rewritten as:

$$y(n) = \sum_{k=-\infty}^{\infty} h(k)x(n-k). \tag{2.9}$$

Defining the z-transform of a sequence $x(n)$ is written as:

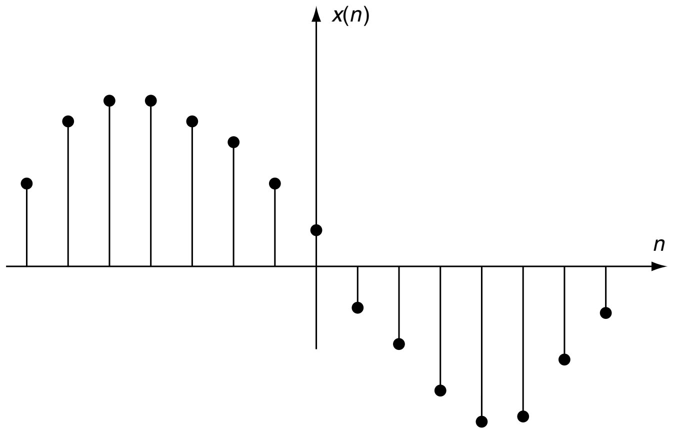

FIGURE 2.6 Discrete-Time Signal Representation

$$X(z) = \sum_{n=-\infty}^{\infty} x(n)z^{-n}. \tag{2.10}$$

The **transfer function** of a digital filter is the ratio of the z transform of the output sequence to the z-transform of the input signal:

$$H(z) = \frac{Y(z)}{X(z)}. \tag{2.11}$$

Taking the z-transform of both sides of the convolution expression of equation 2.9 yields:

$$\sum_{n=-\infty}^{\infty} y(n)z^{-n} = \sum_{n=-\infty}^{\infty}\sum_{k=-\infty}^{\infty} h(k)x(n-k)z^{-n}, \tag{2.12}$$

and substituting variables ($l = n - k$):

$$\sum_{n=-\infty}^{\infty} y(n)z^{-n} = \sum_{k=-\infty}^{\infty} h(k)z^{-k} \sum_{l=-\infty}^{\infty} x(l)z^{-l}. \tag{2.13}$$

The following relation among the z-transforms of the output $Y(z)$, of the input $X(z)$, and of the impulse response $H(z)$ of a digital filter is obtained as:

$$Y(z) = H(z)X(z). \tag{2.14}$$

Hence, the transfer function of an LTI digital filter is the z-transform of its impulse response.

2.4.2 Difference Equation

A general digital filter can be described according to the following **difference equation**:

$$\sum_{i=0}^{N} a_i y(n-i) - \sum_{l=0}^{M} b_l x(n-l) = 0. \tag{2.15}$$

Most digital filters can be described by difference equations that are suitable for implementation in digital machines. It is important to guarantee that the difference equation represents a system that is linear, time-invariant, and causal. This is guaranteed if the auxiliary conditions for the underlying difference equation correspond to its initial conditions, and the system is initially relaxed.

Nonrecursive digital filters are a function of past input samples. In general, they can be described by equation 2.15 if $a_0 = 1$ and $a_i = 0$ for $i = 1, \dots, N$:

$$y(n) = \sum_{l=0}^{M} b_l x(n-l). \tag{2.16}$$

It can be easily shown that these filters have finite impulse response and are known as FIR filters. For $a_0 = 1$, equation 2.15 can be rewritten as:

$$y(n) = -\sum_{i=1}^{N} a_i y(n-i) + \sum_{l=0}^{M} b_l x(n-l). \tag{2.17}$$

It can be shown that these filters have, in most cases, infinite impulse response [i.e., $y(n) \neq 0$ when $n \to \infty$] and are therefore known as IIR filters.

2.5 Finite Impulse Response (FIR) Filters

The general transfer function of an **finite impulse response** (FIR) filter is given by:

$$H(z) = \sum_{l=0}^{M} b_l z^{-l} = H_0 z^{-M} \prod_{l=0}^{M} (z - z_l). \tag{2.18}$$

A filter with the transfer functions in equation 2.18 will always be stable because it does not have poles outside the unit circle. FIR filters can be designed to have a linear phase. A linear phase is a desirable feature in a number of signal processing applications (e.g., image processing). FIR filters can be designed by using optimization packages or by using approximations based on different types of windows. The main drawback is that to satisfy demanding magnitude specifications, the FIR filter requires a relatively high number of multiplications, additions, and storage elements. These facts make FIR filters potentially more expensive than IIR filters in applications where the number of arithmetic operations or number of storage elements are expensive or limited. However, FIR filters are widely used because they are suitable for designing linear-phase filters.

An FIR filter has a linear phase if and only if its impulse response is symmetric or antisymmetric; that is $h(n) = \pm h(M-n)$.

Let us consider in detail a particular case of linear-phase FIR filters:

For M even:

$$\begin{aligned} H(z) &= \sum_{n=0}^{M/2-1} h(n) z^{-n} + h\left(\frac{M}{2}\right) z^{-M/2} + \sum_{n=M/2+1}^{M} h(n) z^{-n} \\ &= \sum_{n=0}^{M/2-1} h(n)(z^{-n} + z^{-(M-n)}) + h\left(\frac{M}{2}\right) z^{-M/2}. \end{aligned} \tag{2.19}$$

At unity circle:

Evaluating equation 2.19 (M even) at $z = e^{j\omega}$, we have:

$$H(e^{j\omega}) = \sum_{n=0}^{M/2-1} h(n) e^{-j\omega n} + h\left(\frac{M}{2}\right) e^{-j\omega M/2} + \sum_{n=M/2+1}^{M} h(n) e^{-j\omega n}.$$

Considering the case of symmetric impulse response (i.e., $h(n) = h(M-n)$ for $n = 0, 1, \dots, M/2$), we have:

$$H(e^{j\omega}) = e^{-j\omega M/2} \left[h\left(\frac{M}{2}\right) + \sum_{n=0}^{M/2-1} 2h(n) \cos\left[\omega\left(n - \frac{M}{2}\right)\right]\right].$$

By replacing n by $(M/2 - m)$, the equation above becomes:

$$H(e^{j\omega}) = e^{-j\omega M/2} \left[h\left(\frac{M}{2}\right) + \sum_{m=1}^{M/2} 2h\left(\frac{M}{2} - m\right) \cos\left[\omega(m)\right]\right].$$

Defining $a_0 = h(M/2)$ and $a_m = 2h(M/2 - m)$, for $m = 1, 2, \dots, M/2$, we have:

$$H(e^{j\omega}) = e^{-j\omega M/2} \sum_{m=0}^{M/2} a_m \cos(\omega m). \tag{2.20}$$

In summary, we have four possible cases of FIR filters with a linear phase:

- *Case A*: M Even and Symmetric Impulse Responses
  (1) Characteristics:
  $h(n) = h(M-n)$ for $n = 0, 1, \dots, M/2$
  $H(e^{j\omega}) = e^{-j\omega M/2} \sum_{m=0}^{M/2} a_m \cos(\omega m)$, where $a_0 = h(M/2)$ and $a_m = 2h(M/2 - m)$ for $m = 1, 2, \dots, M/2$
  (2) Phase: $\Theta(\omega) = \tan^{-1}\left\{\frac{\mathrm{Im}[H(e^{j\omega})]}{\mathrm{Re}[H(e^{j\omega})]}\right\} = -\omega \frac{M}{2}$.
  (3) Group delay: $\tau = -\frac{\partial \Theta(\omega)}{\partial \omega} = \frac{M}{2}$.
- *Case B*: M Odd and Symmetric Impulse Responses
  (1) Characteristics:
  $h(n) = h(M-n)$ for $n = 0, 1, \dots, (M/2 - 0.5)$.
  $H(e^{j\omega}) = e^{-j\omega M/2} \sum_{m=1}^{M/2+0.5} b_m \cos[\omega(m - \frac{1}{2})]$, where $b_m = 2h(M/2 + 0.5 - m)$ for $m = 1, 2, \dots, (M/2 + 0.5)$.

(2) Phase: $\Theta(\omega) = -\omega\frac{M}{2}$.

(3) Group delay: $\tau = -\frac{\partial\Theta(\omega)}{\partial\omega} = \frac{M}{2}$.

- *Case C*: M Even and Antisymmetric Impulse Response

  (1) Characteristics:
  $h(n) = -h(M-n)$ for
  $n = 0, 1, \ldots, (M/2-1)$ and $h(M/2) = 0$.
  $H(e^{j\omega}) = e^{-j(\omega M/2-\pi/2}\sum_{m=1}^{M/2} c_m \sin(\omega m)$, where $c_m = 2h(M/2-m)$ for $m = 1, 2, \ldots, M/2$.

  (2) Phase: $\Theta(\omega) = -\omega\frac{M}{2} + \frac{\pi}{2}$.

  (3) Group delay: $\tau = -\frac{\partial\Theta(\omega)}{\partial\omega} = \frac{M}{2}$.
- *Case D*: M Odd and Antisymmetric Impulse Response

  (1) Characteristics:
  $h(n) = -h(M-n)$, for $n = 0, 1, \ldots, (M/2-0.5)$.
  $H(e^{j\omega}) = e^{-j(\omega M/2-\pi/2)}\sum_{m=1}^{M/2+0.5} d_m \sin[\omega(m-\frac{1}{2})]$, where $d_m = 2h(\frac{M}{2}+0.5-m)$, for $m = 1, 2, \ldots, (M/2+0.5)$.

  (2) Phase: $\Theta(\omega) = -\omega\frac{M}{2} + \frac{\pi}{2}$.

  (3) Group delay: $\tau = -\frac{\partial\Theta(\omega)}{\partial\omega} = \frac{M}{2}$.

As an illustration, Figure 2.7 depicts the typical impulse responses for the linear-phase FIR filter.

Equation 2.19 for linear-phase FIR filters can be rewritten as:

$$H(z) = z^{-M/2}\sum_{l=0}^{L} g_l(z^l \pm z^{-l}), \qquad (2.21)$$

where the g_l's are related to $h(l)$, where $L = M/2 - 0.5$ for M odd and $L = M/2$ for M even. If there is a zero of $H(z)$ at z_0, z_0^{-1} is also a zero of $H(z)$. This means that all complex zeros not located on the unit circle occur in conjugate and reciprocal quadruples. Zeros on the real axis outside the unit circle occur in reciprocal pairs. Zeros on the unit circle occur in conjugate pairs.

It is possible to verify that the case B linear-phase transfer function has a zero at $\omega = \pi$, such that high-pass and band-stop filters cannot be approximated using this case. For case C, there are zeros at $\omega = \pi$ and $\omega = 0$; therefore they are not suitable for low-pass, high-pass, and band-stop filter designs. Case D has zero at $\omega = 0$ and is not suitable for low-pass and band-stop design.

(C) Case C

(D) Case D

FIGURE 2.7 Linear-Phase FIR Filter: Typical Impulse Response

2.6 Infinite Impulse Response Filters

The general transfer function for **infinite impulse response** (IIR) **filters** is shown below:

$$H(z) = \frac{Y(z)}{X(z)} = \frac{\sum_{l=0}^{M} b_l z^{-l}}{1 + \sum_{i=1}^{N} a_i z^{-i}}. \qquad (2.22)$$

The above equation can be rewritten in the following alternative forms:

$$H(z) = H_0\frac{\prod_{l=0}^{M}(1-z^{-1}z_l)}{\prod_{i=0}^{N}(1-z^{-1}p_i)} = H_0 z^{N-M}\frac{\prod_{l=0}^{M}(z-z_l)}{\prod_{i=0}^{N}(z-p_i)}. \qquad (2.23)$$

The above equation shows that, unlike FIR filters, IIR filters have poles located at p_i. Therefore, it is required that $|p_i| < 1$ to guarantee stability for the IIR transfer functions.

2.7 Digital Filter Realizations

From equation 2.15, it can be seen that digital filters use three basic types of operations:

- **Delay**: Used to store previous samples of the input and output signals, besides internal states of the filter
- **Multiplier**: Used to implement multiplication operations of a particular digital filter structure; also used to implement divisions
- **Adder**: Used to implement additions and subtractions of the digital filter

2.7.1 FIR Filter Structures

General FIR and IIR filter structures are shown in Figures 2.8 and 2.9. Figure 2.8 shows the direct-form nonrecursive structure for FIR filters, while Figure 2.9 depicts an alternative transposed[2] structure. These structures are equivalent when implemented in software.

Since the impulse responses of linear-phase FIR filters are either symmetric or antisymmetric [e.g., $h(n) = \pm h(M - n)$], this property can be exploited to reduce the overall number of multiplications of the FIR filter realization. In Figure 2.10 the resulting realizations for the case of symmetric $h(n)$ are shown. For the antisymmetric case, the structures are straightforward to obtain.

2.7.2 IIR Filter Realizations

A general IIR transfer function can be written as in equation 2.22. The numerator in this transfer function can be implemented by using an FIR filter. The denominator entails the use of a recursive structure. The cascade of these realizations for the numerator and denominator is shown in Figure 2.11. If the recursive part is implemented first, the realization in Figure 2.11 can be transformed into the structure in Figure 2.12 for the case $N = M$. The transpose of the structure in Figure 2.12 is shown in Figure 2.13.

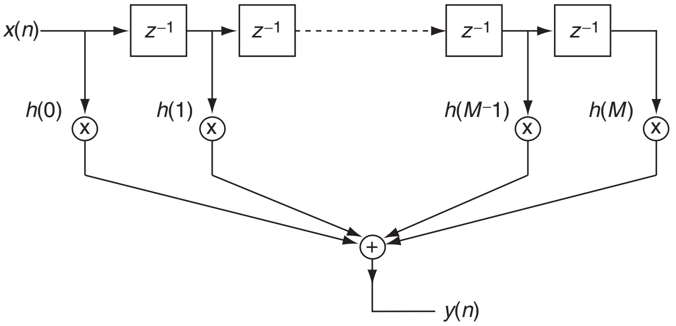

FIGURE 2.8 Direct-Form Nonrecursive Structure

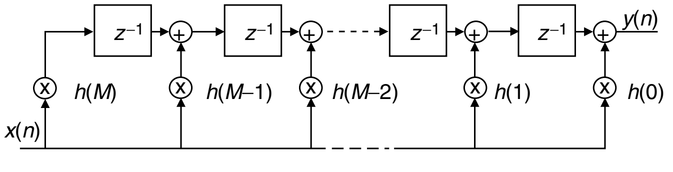

FIGURE 2.9 Alternative Form Nonrecursive Structure

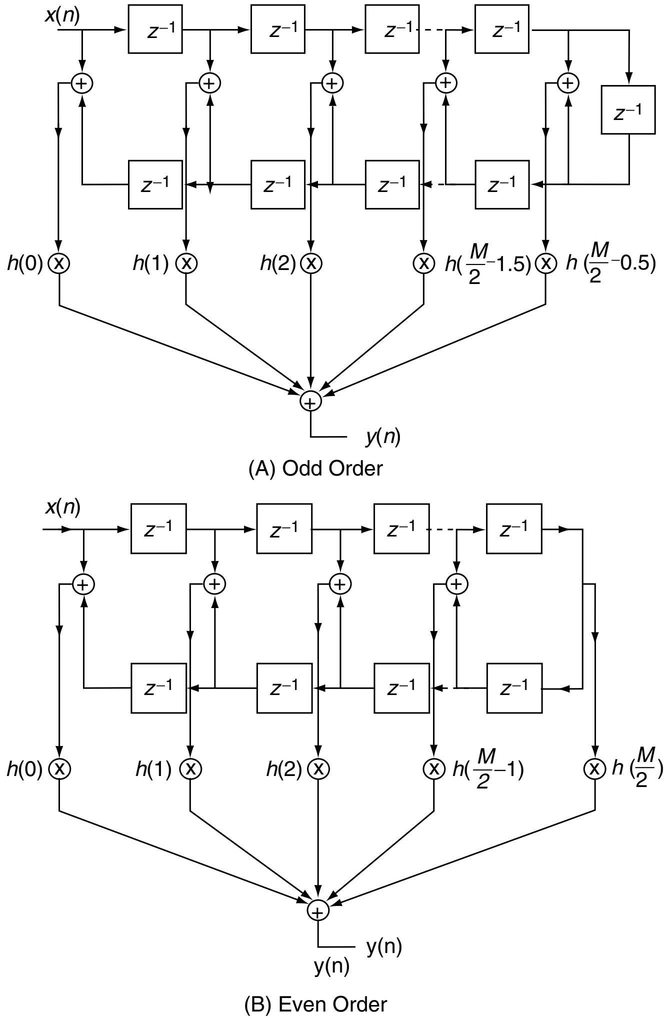

(A) Odd Order

(B) Even Order

FIGURE 2.10 Linear-Phase FIR Filter Realization With Symmetric Impulse Response

In general, IIR transfer functions can be implemented as a cascade or as a summation of lower order IIR structures. In case an IIR transfer function is implemented as a cascade of second-order sections of order m, it is possible to write:

$$
\begin{aligned}
H(z) &= \prod_{k=1}^{m} \frac{\gamma_{0k} + \gamma_{1k} z^{-1} + \gamma_{2k} z^{-2}}{1 + m_{1k} z^{-1} + m_{2k} z^{-2}} = \prod_{k=1}^{m} \frac{\gamma_{0k} z^{2} + \gamma_{1k} z + \gamma_{2k}}{z^{2} + m_{1k} z + m_{2k}} \\
&= H_0 \prod_{k=1}^{m} \frac{z^{2} + \gamma'_{1k} z + \gamma'_{2k}}{z^{2} + m_{1k} z + m_{2k}} = \prod_{k=1}^{m} H_k(z).
\end{aligned}
\tag{2.24}
$$

[2] This structure is characterized by the branches being reversed, such that the sinks turn to summations, and the summations become distribution nodes.

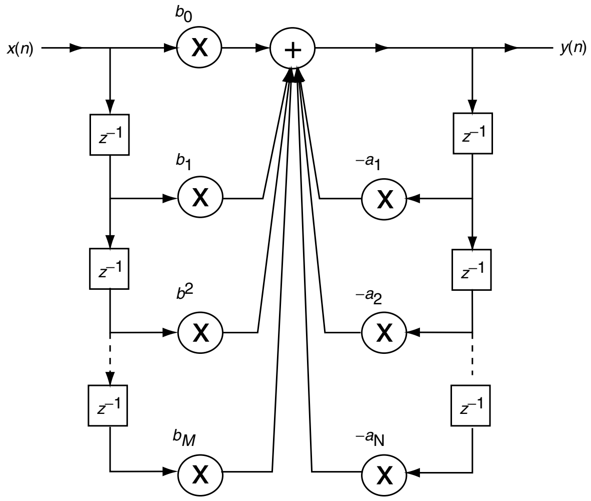

FIGURE 2.11 Recursive Structure in Direct Form

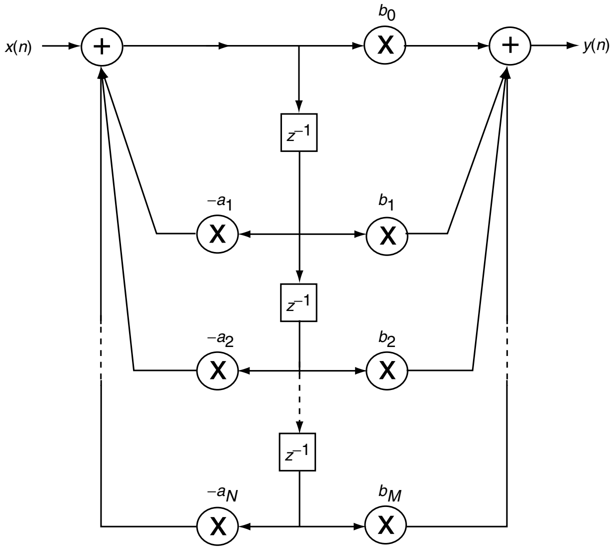

FIGURE 2.12 Direct Form Structure for $N = M$

Equation 2.24 is depicted in Figure 2.14(A).

In the case an IIR transfer function is implemented as the addition of lower order sections of order m, it is possible to write:

$$H(z) = \sum_{k=1}^{m} \frac{\gamma_{0k}^{p} z^2 + \gamma_{1k}^{p} z + \gamma_{2k}^{p}}{z^2 + m_{1k} z + m_{2k}} = h_0 + \sum_{k=1}^{m} \frac{\gamma_{0k}^{p'} z^2 + \gamma_{1k}^{p'} z}{z^2 + m_{1k} z + m_{2k}}$$

$$= h_0' + \sum_{k=1}^{m} \frac{\gamma_{1k}^{p''} z + \gamma_{2k}^{p''}}{z^2 + m_{1k} z + m_{2k}} = \sum_{k=1}^{m} H_k(z). \tag{2.25}$$

(A) Cascade

(B) Parallel

FIGURE 2.14 Realization with Second-Order Sections

Equation 2.25 depicted in Figure 2.14(B).

In general, for implementations with high signal-to-quantization noise ratios, sections of order two are preferred. Different types of structures can be used for second-order sections, such as the direct-form structures shown in Figures 2.15(A) and 2.15(B) or alternative biquadratic structures like state-space (Diniz and Antoniou, 1986).

(B) Type 2

FIGURE 2.15 Basic Second-Order Sections

2.8 FIR Filter Approximation Methods

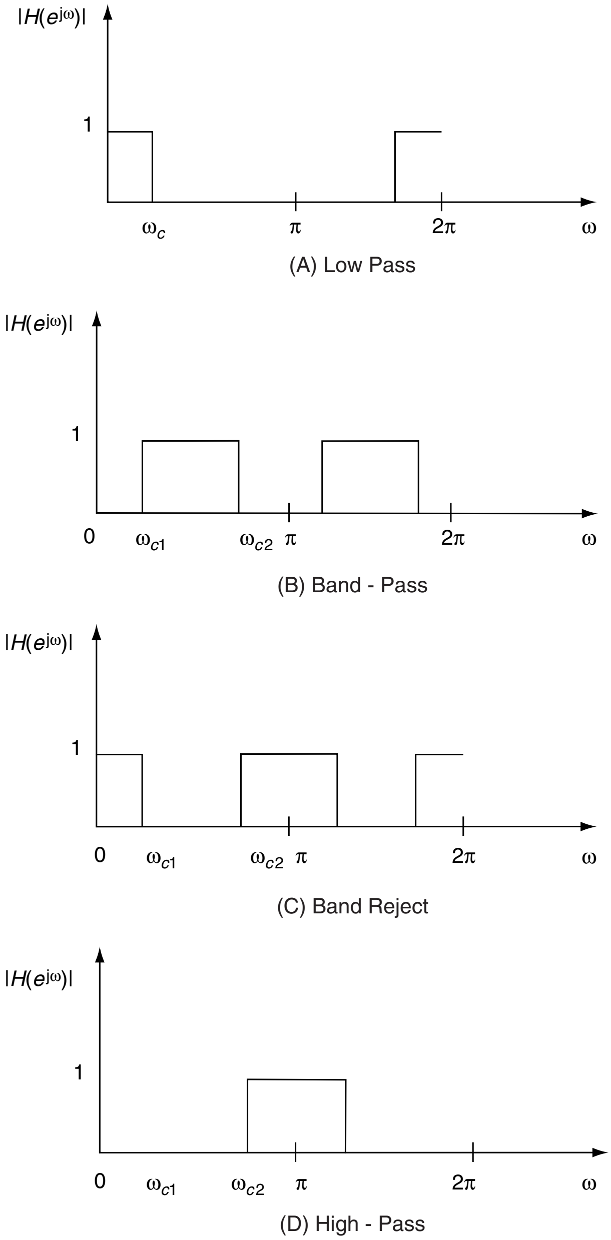
There are three basic approximation methods for FIR filters satisfying given specifications. The first one, the **window method**, is very simple and well established but generally leads to transfer functions that normally have a higher order than those obtained by optimization methods. The second method, known as **minimax method**, calculates a transfer function that has minimum order to satisfy prescribed specifications. The minimax method is an iterative method and is available in most filter design packages. The third method, known as **weighted least squares-Chebyshev**[3] (WLS-Chebyshev) is a reliable but not widely known method. The WLS-Chebyshev method is particularly suitable for multirate systems because the resulting transfer functions might have decreasing energy at a prescribed range of frequencies.

2.8.1 Window Method

The **window method** starts by obtaining the impulse response of ideal prototype filters. These responses for standard filters are shown in Figure 2.16. In general, the impulse response is calculated according to:

$$h(n) = \frac{1}{2\pi}\int_{-\pi}^{\pi} H(e^{j\omega})e^{j\omega n}d\omega, \tag{2.26}$$

for a desired filter.



(A) Low Pass

(B) Band - Pass

(C) Band Reject

(D) High - Pass

FIGURE 2.16 Ideal Frequency Responses

[3] The WLS-Chebyshev method is also known as the peak constrained method.

In the case of a band-pass filter, the prototype filter can be described by following transfer function:

$$|H(e^{j\omega})| = \begin{cases} 0 & \text{for } 0 < |\omega| < \omega_{c1}. \\ 1 & \text{for } \omega_{c1} \leq |\omega| \leq \omega_{c2}. \\ 0 & \text{for } \omega_{c2} < |\omega| \leq \pi. \end{cases} \tag{2.27}$$

Using the inverse Fourier transform, the impulse response of the filter with the response in equation 2.27 can be obtained as follows:

$$\begin{aligned} h(n) &= \frac{1}{2\pi}\int_{-\pi}^{\pi} H(e^{j\omega})e^{j\omega n}d\omega \\ &= \frac{1}{2\pi}\left[\int_{\omega_{c1}}^{\omega_{c1}} 2\cos(\omega n)d\omega\right] \\ &= \frac{1}{\pi n}[\sin(\omega_{c2}n) - \sin(\omega_{c1}n)], \end{aligned} \tag{2.28}$$

for $n \neq 0$, for $n = 0$, $h(0) = \frac{1}{\pi}(\omega_{c2} - \omega_{c1})$.

Different window sequences can be multiplied to $h(n)$ to limit its length, generating the impulse response for the designed FIR filter as follows:

$$h'(n) = h(n)w(n). \tag{2.29}$$

In equation 2.29, $w(n)$ is the window sequence, and $h'(n)$ is the impulse response of the obtained filter. The rectangular window consists of truncating the sequence $h(n)$; that is, $w(n) = 1$ for $n = -M/2, \ -M/2 + 1, \ldots, 0, \ldots, M/2 - 1, M/2$.

2.8.2 Sarämaki Window

The abrupt truncation of the impulse response performed by the rectangular window leads to oscillations at frequencies close to the resulting filter band edges. The satisfaction of prescribed specification is difficult because these ripples have uncontrollable maximum magnitude.

As alternatives, there are more flexible windows incorporating design parameters that allow a trade-off between the transition bandwidth and the ripples magnitude (Sarämaki, 1992).

The frequency response of the unscaled **Sarämaki window** is known to be the following:

$$\begin{aligned} \Psi(\omega) &= \sum_{n=-\frac{M}{2}}^{\frac{M}{2}} \bar{\mathbf{w}}(n)e^{-j\omega n} = 1 + \sum_{k=1}^{\frac{M}{2}} 2T_k[\gamma\cos\omega + (\gamma - 1)] \\ &= \frac{\sin\left[\frac{M+1}{2}\cos^{-1}\{\gamma\cos\omega + (\gamma - 1)\}\right]}{\sin\left[\frac{1}{2}\cos^{-1}\{\gamma\cos\omega + (\gamma - 1)\}\right]}, \end{aligned} \tag{2.30}$$

where T_k is the kth degree Chebyshev polynomial and:

$$\gamma = \frac{1 + \cos(2\pi/M + 1)}{1 + \cos(2\beta\pi/M + 1)}. \tag{2.31}$$

In the above equation, β is a variable parameter that adjusts the Sarämaki window main lobe width given by $4\beta\pi/M + 1$. In the special case of $\beta = 1$, the Sarämaki window becomes identical to the rectangular window.

The desired normalized window function is as written here:

$$\mathbf{w}(n) = \bar{\mathbf{w}}(n)/\bar{w}(0), \tag{2.32}$$

for $-M/2 \leq n \leq M/2$ and $w(0) = 1$.

The unscaled coefficients $\mathbf{w}(n)$ can be expressed as:

$$w(n) = v_0(n) + 2\sum_{k=1}^{M/2} v_k(n), \tag{2.33}$$

where $v_k(n)$ can be calculated according to the recursive equations below:

$$v_0(n) = \begin{cases} 1 & n = 0. \\ 0, & \text{otherwise.} \end{cases} \tag{2.34}$$

$$v_1(n) = \begin{cases} \gamma - 1, & n = 0. \\ \gamma/2, & |n| = 1. \\ 0, & \text{otherwise.} \end{cases} \tag{2.35}$$

$$v_k(n) = \begin{cases} 2(\gamma - 1)v_{k-1}(n) - v_{k-2}(n) + \gamma[v_{k-1}(n-1) + v_{k-1}(n+1)], & -k \leq n \leq k. \\ 0, & \text{otherwise.} \end{cases} \tag{2.36}$$

The causal transfer function is given by:

$$H(z) = z^{-M/2}\sum_{n=-M/2}^{M/2} h'(n)z^{-n} \tag{2.37}$$

Example

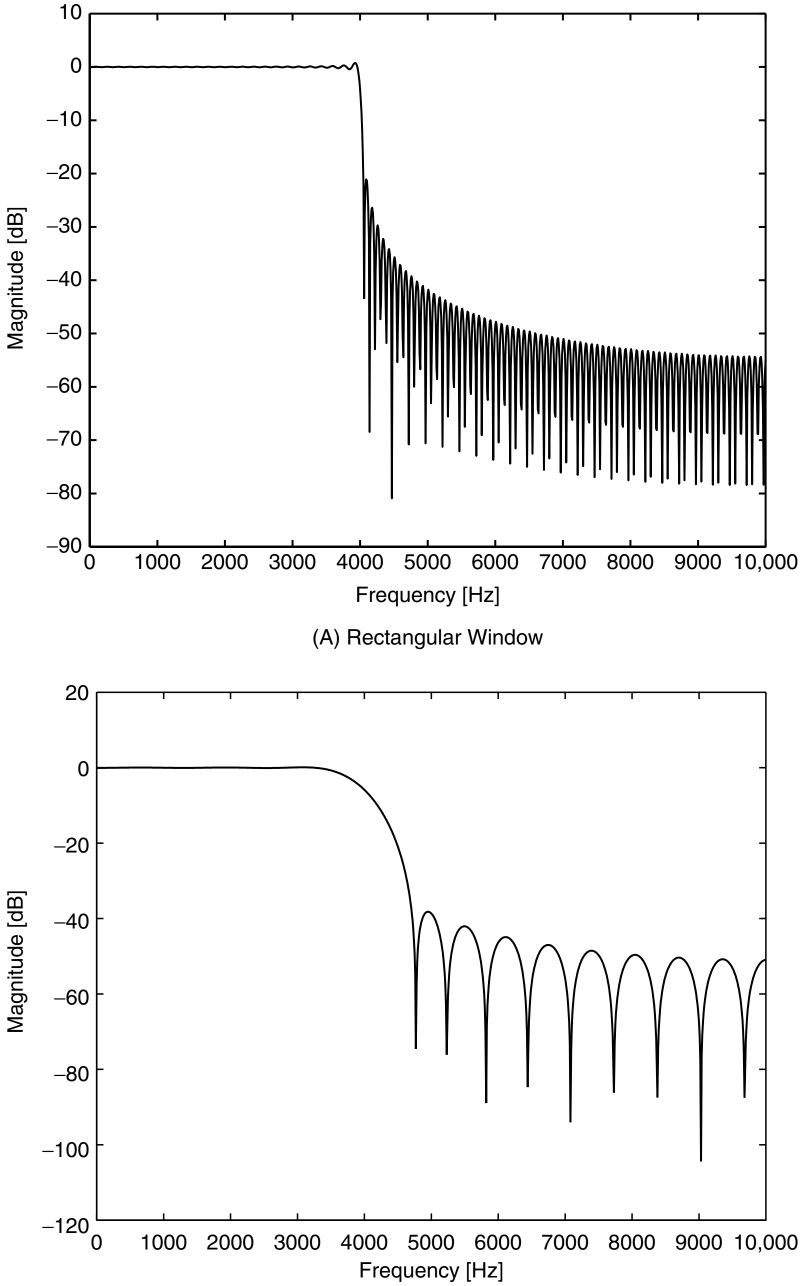
Design an FIR filter satisfying the following specifications: $A_p = 0.2$ dB, $A_r = 32$ dB, $\omega_p = 2\pi \times 3400$ rad/sec, $\omega_r = 2\pi \times 4600$ rad/sec, and $\omega_s = 2\pi \times 20,000$ rad/sec

Solution

Figure 2.17 shows different responses obtained by using the rectangular and Sarämaki windows on a low-pass filter. It can be seen that the Sarämaki window showed improvements with respect to the rectangular window response. In fact, the rectangular window has a high order of 248; to satisfy the specifications, the transition band had to be reduced due to the high ripples close to the band edges. The Sarämaki window required order 48 to meet the specifications.

2.9 FIR Filter Design by Optimization

In the minimax approach, our aim is to design filters that minimize the peak (maximum) of the error with respect to



(A) Rectangular Window

(B) Sarämaki Window

FIGURE 2.17 Low-Pass Filter Using Window Method

desired characteristics without directly considering the error energy. On the other hand, the least squares approach aims to minimize the error energy. As can be observed in Figure 2.18, there are solutions between these two extremal types of objective functions that provide good trade-off between peak error and error energy. In this section, we present a very flexible approach to designing FIR digital filters satisfying prescribed specifications in terms of the maximum deviation the passband and in part of the stopband, while minimizing the energy in the stopband frequency range. This type of approximation is very useful in modern DSP systems involving subsystems with different sampling periods. The approximation method discussed here includes the least squares and minimax approaches as special cases.

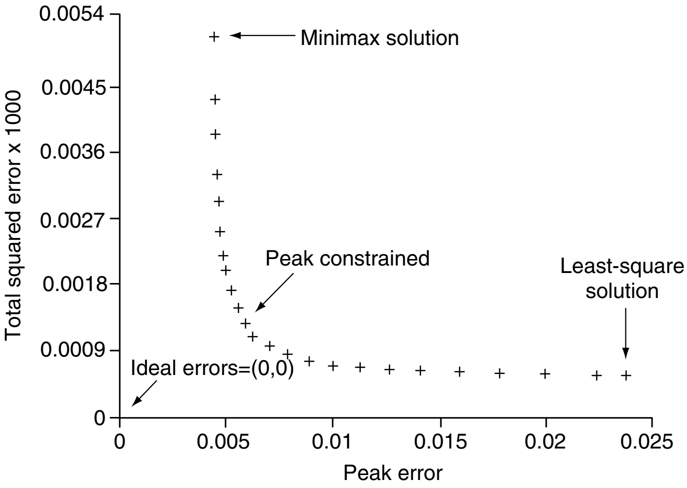


FIGURE 2.18 Minimax Versus Least Squares

2.9.1 Problem Formulation

Consider a nonrecursive filter of length $M+1$ described by the transfer function:

$$H(z) = \sum_{n=0}^{M} h(n) z^{-n}, \tag{2.38}$$

assuming that $\omega_s = 2\pi$. The frequency response of such filter is then given by:

$$H(e^{j\omega}) = \sum_{n=0}^{M} h(n) e^{-j\omega n} = e^{j\Theta(\omega)} \hat{H}(\omega), \tag{2.39}$$

where $\Theta(\omega)$ and $\hat{H}(\omega)$ are the phase and magnitude responses of $H(e^{j\omega})$, respectively defined as:

$$\Theta(\omega) = \tan^{-1}\left\{\frac{\text{Im}[H(e^{j\omega})]}{\text{Re}[H(e^{j\omega})]}\right\}. \tag{2.40}$$

$$\hat{H}(\omega) = |H(e^{j\omega})|. \tag{2.41}$$

Assume that the phase response $\Theta(\omega)$ is linear on ω, that M is even, and that $h(n)$ is symmetrical. The cases of M odd and/or $h(n)$ antisymmetrical can be easily derived based on the proposed formulation. The frequency response of such filter thus becomes:

$$H(e^{j\omega}) = e^{-jM/2\omega} \sum_{n=0}^{M/2} a_n \cos(\omega n), \tag{2.42}$$

with $a_0 = h(M/2)$ and $a_n = 2h(\frac{M}{2} - n)$ for $n = 1, \ldots, M/2$.

The desired frequency response is given by $e^{-jM/2\omega} D(\omega)$, and $W(\omega)$ is a strictly positive weighting function. The weighted error function $E(\omega)$ is defined in the frequency domain as:

$$E(\omega) = W(\omega)[D(\omega) - \hat{H}(\omega)]. \tag{2.43}$$

The approximation problem for FIR linear-phase digital filters is equivalent to the minimization of some objective function of $E(\omega)$ in such way that $|E(\omega)| \leq \delta$. Then:

$$|H(\omega) - \hat{H}(\omega)| \leq \frac{\delta}{W(\omega)}. \tag{2.44}$$

A good discrete approximation of $E(\omega)$ can be obtained by evaluating the weighted error function on a dense frequency grid with $0 \leq \omega_i \leq \pi$ for $i = 1, \ldots, L(M+1)$. For practical purposes, for a filter of length $M+1$, we use $8 \leq L \leq 16$. Points placed at the transition band are disregarded, whereas the remaining frequencies should be linearly redistributed in the passband and stopband including their corresponding edges. Thus, the following vector equation results:

$$\boldsymbol{e} = \boldsymbol{W}(\boldsymbol{d} - \boldsymbol{Ub}), \tag{2.45}$$

where:

$$\boldsymbol{e} = [E(\omega_1)E(\omega_2) \ \ldots \ E(\omega_{\bar{L}(M+1)})]^T. \tag{2.46}$$

$$\boldsymbol{W} = \ \text{diag}[W(\omega_1)W(\omega_2) \ \ldots \ W(\omega_{\bar{L}(M+1)})]. \tag{2.47}$$

$$\boldsymbol{d} = [D(\omega_1)D(\omega_2) \ \ldots \ D(\omega_{\bar{L}(M+1)})]^T. \tag{2.48}$$

$$\boldsymbol{U} = \begin{bmatrix} 1 & \cos(\omega_1) & \cos(2\omega_1) & \ldots & \cos(\frac{M}{2}\omega_1) \\ 1 & \cos(\omega_2) & \cos(2\omega_2) & \ldots & \cos(\frac{M}{2}\omega_2) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & \cos(\omega_{\bar{L}(M+1)}) & \cos(2\omega_{\bar{L}(M+1)}) & \ldots & \cos(\frac{M}{2}\omega_{\bar{L}(M+1)}) \end{bmatrix}. \tag{2.49}$$

$$\boldsymbol{b} = \left[a_0 \ a_1 \ \ldots \ a_{\frac{M}{2}}\right]^T. \tag{2.50}$$

In these equations, $\bar{L} < L$ because the transition frequencies were discarded.

A low-pass filter specification includes δ_p as the passband maximum ripple and δ_r as the stopband minimum attenuation, with ω_p and ω_r being the passband and stopband edges, respectively.

Based on these values, the following can be defined:

$$DB_p = 20 \log_{10}\left(\frac{1+\delta_p}{1-\delta_p}\right)[\text{dB}]. \tag{2.51}$$

$$DB_r = 20 \log_{10}(\delta_r)[\text{dB}]. \tag{2.52}$$

The design of a low-pass digital filter using either the minimax method or the WLS approach is performed by choosing the ideal response and weight functions, respectively, as:

$$D(\omega) = \begin{cases} 1, & 0 \leq \omega \leq \omega_p. \\ 0, & \omega_r \leq \omega \leq \pi. \end{cases} \tag{2.53}$$

$$W(\omega) = \begin{cases} 1, & 0 \leq \omega \leq \omega_p. \\ \delta_p/\delta_r, & \omega_r \leq \omega \leq \pi. \end{cases} \tag{2.54}$$

Other types of transfer functions can be similarly defined.

2.9.2 Chebyshev Method

Chebyshev filter design consists of the minimization of the maximum absolute value of $E(\omega)$ with respect to the set of filter coefficients:

$$\|E(\omega)\|_\infty = \min_{\boldsymbol{b}} \max_{0 \leq \omega \leq \pi} [W(\omega)|D(\omega) - \hat{H}(\omega)|]. \tag{2.55}$$

Using equations 2.46 to 2.50, the Chebyshev method attempts to minimize:

$$\|E(\omega)\|_\infty \approx \min_{\mathbf{b}} \max_{0 \leq \omega_i \leq \pi} [\boldsymbol{W}|\boldsymbol{d} - \boldsymbol{Ub}|], \tag{2.56}$$

at the discrete set of frequencies. The Chebyshev method minimizes:

$$\mathrm{DB}_\delta = 20 \log_{10}(\delta)[\mathrm{dB}], \tag{2.57}$$

where $\delta = \max[\delta_p, \delta_r]$.

2.9.3 Weighted Least-Squares Method

The weighted least-squares (WLS) approach minimizes:

$$\|E(\omega)\|_2^2 = \int_0^\pi |E(\omega)|^2 \, d\omega = \int_0^\pi W^2(\omega)|D(\omega) - \hat{H}(\omega)|^2 \, d\omega. \tag{2.58}$$

This objective function at a discrete set of frequencies is estimated by:

$$\|E(\omega)\|_2^2 \approx \boldsymbol{e}^T \boldsymbol{e}, \tag{2.59}$$

the minimization of which is achieved with:

$$\boldsymbol{b}^* = (\boldsymbol{U}^T \boldsymbol{W}^2 \boldsymbol{U})^{-1} \boldsymbol{U}^T \boldsymbol{W}^2 \boldsymbol{d} \tag{2.60}$$

The WLS objective is to maximize the passband-to-stopband ratio (PSR) of energies:

$$\mathrm{PSR} = 10 \log_{10} \left(\frac{\int_0^{\omega_p} |\hat{H}(\omega)|^2 d\omega}{\int_{\omega_r}^{\pi} |\hat{H}(\omega)|^2 \, d\omega} \right) [\mathrm{dB}]. \tag{2.61}$$

2.9.4 Minimax Filter Design Employing WLS

This section describes a scheme that performs Chebyshev approximation as a limit of a special sequence of weighted least-squares approximations. The algorithm is implemented by a series of WLS approximations using a varying weight matrix $\boldsymbol{W}_k$, whose elements are calculated by:

$$W_{k+1}^2(\omega) = W_k^2(\omega) B_k(\omega), \tag{2.62}$$

where:

$$B_k(\omega) = |E_k(\omega)|. \tag{2.63}$$

This approach entails increasing the weight where the error is smaller.

The convergence of this algorithm is slow because usually 10 to 15 WLS designs are required in practice to approximate the Chebyshev solution. An efficiently accelerated algorithm was presented by Lim *et al.* (1992) that is characterized by the weight matrix $\boldsymbol{W}_k$ whose elements are recurrently updated by:

$$W_{k+1}^2(\omega) = W_k^2(\omega) \hat{B}_k(\omega), \tag{2.64}$$

where $\hat{B}_k(\omega)$ is the envelope function of $B_k(\omega)$ formed by a set of piecewise linear segments that start and end at consecutive extremes of $B_k(\omega)$. The band edges are considered extreme frequencies, and the edges from different bands are not connected. By denoting the extreme frequencies at a particular iteration k as ω_l', for $l = 1, 2, \ldots,$ the envelope function is formed as:

$$\hat{B}_k(\omega) = \frac{(\omega - \omega_l') B_k(\omega_{l+1}') + (\omega_{l+1}' - \omega) B_k(\omega_l')}{(\omega_{l+1}' - \omega_l')}; \; \omega_l' \leq \omega \leq \omega_{l+1}'. \tag{2.65}$$

Figure 2.19 depicts typical cases of the absolute value of the error function (dash-dotted curve) used by the algorithm of equation 2.62 to update the weighting function; the figure also depicts a corresponding envelope (solid curve) used by the algorithm of equation 2.65.

2.9.5 The WLS-Chebyshev Method

Comparing the adjustments used by the algorithms described by equations 2.62 through 2.65 and illustrated by Figure 2.19, with the piecewise-constant weight function used by the WLS method, it is possible to derive a very simple approach for designing digital filters with some compromises on minimax and WLS constraints (Diniz and Netto, 1999). This approach consists of a modification on the weight-function updating procedure in such way that it becomes constant after a particular extreme of the stopband of $B_k(\omega)$:

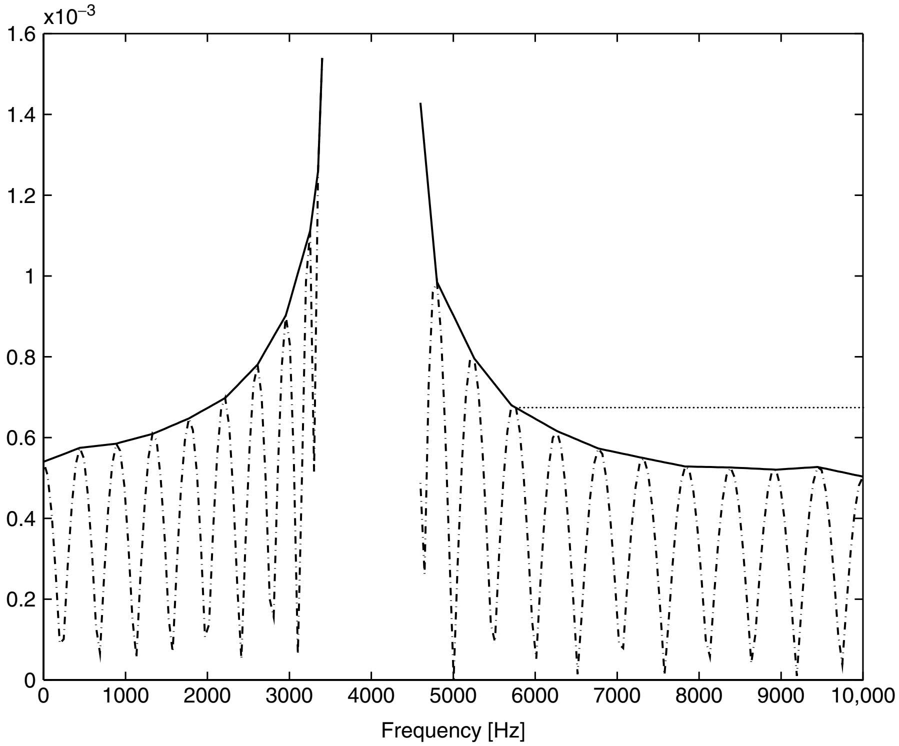

FIGURE 2.19 Typical Absolute Error Function $B(\omega)$ (Dash-Dotted Line) and Corresponding Envelope $\hat{B}(\omega)$ (Solid Curve). The $\beta(\omega)$ corresponds to the WLS-Chebyshev method (darker dotted curve).

$$W_{k+1}^2(\omega) = W_k^2(\omega)\beta_k(\omega). \tag{2.66}$$

For the algorithm of equation 2.65, $\beta_k(\omega)$ is given by:

$$\beta_k(\omega) \equiv \bar{B}_k(\omega) = \begin{cases} \hat{B}_k(\omega), & 0 \leq \omega \leq \omega_L'. \\ \hat{B}_k(\omega_L'), & \omega_L' < \omega \leq \pi. \end{cases} \tag{2.67}$$

The ω_L' is the Lth extreme value of the stopband of $B(\omega) = |E(\omega)|$. The passband values of $B(\omega)$ and $\hat{B}(\omega)$ are left unchanged in equation 2.67 to preserve the equiripple property of the minimax method, although it does not have to be that way. The parameter L is the single design parameter for the proposed scheme. Choosing $L = 1$ makes the new scheme similar to an equiripple-passband WLS design, whereas choosing L to be as large as possible (i.e., making $\omega_L' = \pi$), we return to the original minimax algorithms.

The computational complexity of WLS-based algorithms, like the algorithms here described, is of the order of $(M+1)^3$, where $M+1$ is the length of the filter. This complexity can be greatly reduced by taking advantage of the Toeplitz-plus-Hankel internal structure of the matrix $(\boldsymbol{U}^T\boldsymbol{W}^2\boldsymbol{U})$ in equation 2.60 and by using an efficient grid scheme to minimize the number of frequency values. These simplifications make the computational complexity of WLS-based algorithms comparable to the classic minimax approach (Antoniou, 1993). The WLS-based methods, however, do have the additional advantage of being easily coded into computer routines.

Example

Design FIR using some WLS-Chebyshev filters by satisfying the following specifications: $A_p = 0.02$ dB, $A_r = 32$ dB, $\omega_p = 2\pi \times 3400$ rad/sec, $\omega_r = 2\pi \times 4600$ rad/sec, $\omega_s = 2\pi \times 20{,}000$ rad/sec. These are specifications established by industry standards for prefiltering speech signals before these signals are subsampled to 8kHz.

Solution

This example applied to the functions seen in Figure 2.19 is depicted in Figure 2.20. The results are for the least-squares and minimax approaches and for the WLS-Chebyshev filter where ω_L' was chosen as the fourth extreme in the filter's stopband. The order of all filters is 40. Compared with the filters designed by the window methods, the WLS, WLS-Chebyshev, and the minimax filters are much more economical. The reader should note that the passband ripple specified here is 10 times smaller than the value used in the window example.

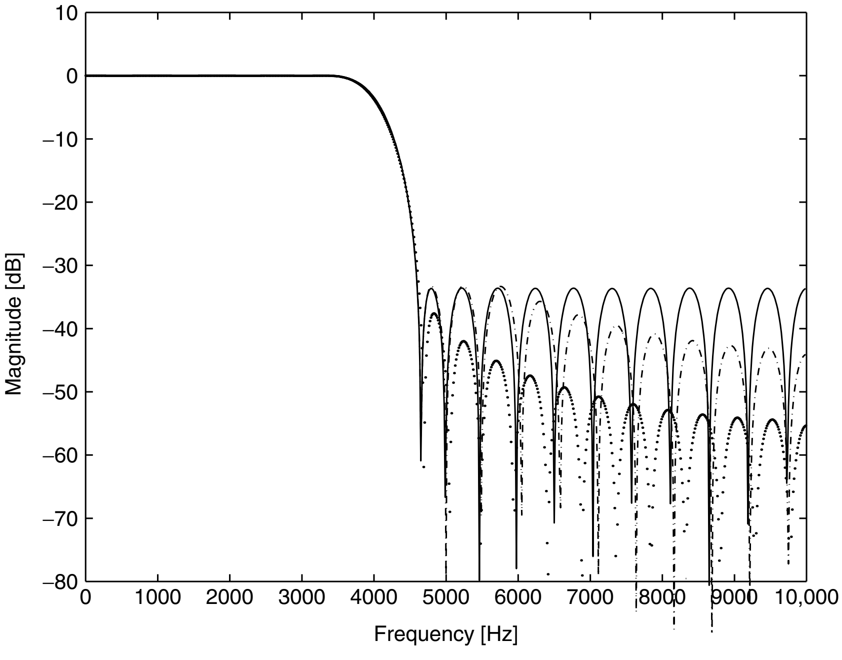

FIGURE 2.20 Frequency Responses of the WLS, WLS (Dotted Line), WLS-Chebyshev (Dashes and Dotted Line), and the Minimax (Solid Line) Filters

2.10 IIR Filter Approximations

IIR filters are usually designed by using analog filter approximations that are easy to apply and are well established. IIR filters can also be designed by using optimization methods. It is known, however, that simultaneous approximation of magnitude and phase is a difficult problem, and no reliable iterative design methods are available. The use of optimization methods in IIR filter design is more common in equalization problems when specifications for both magnitude and phase are given.

2.10.1 Analog Filter Transformation Methods

There are two popular methods for designing digital filters starting from analog approximations: the **impulse invariance method** and the **bilinear transformation method**. These methods are discussed in the following sections.

Impulse Invariance Method

In the impulse invariance method, a digital filter is designed so that its impulse response is close to the sampled analog impulse response. This method is useful for low-pass and some band-pass filter approximations. In general:

$$h_d(n) = Th_a(nT), \tag{2.68}$$

where $h_d(n)$ is the digital filter impulse response and $h_a(t)$ is the analog filter impulse response with desired specifications. The above equation implies:

$$H_d(z) = \sum_{k=1}^{N} T\frac{r_k z}{z - e^{p_k T}}, \tag{2.69}$$

where r_k and p_k are the zeros and poles of the analog transfer function approximation.

Bilinear Transformation Method

The **bilinear transformation method** is based on applying the transformation $s = 2(z-1)/T(z+1)$ to the designed analog transfer function, so that:

$$H_d(z) = H_a(s)|_{s=\frac{2}{T}\frac{z-1}{z+1}}. \tag{2.70}$$

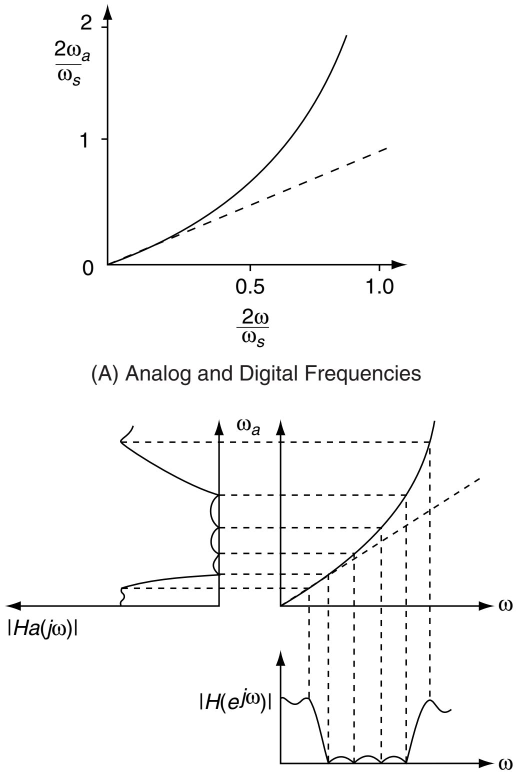
As a consequence, the bilinear transformation maps the analog frequencies into the digital frequencies as follows:

$$\omega_a = \frac{2}{T}\tan\frac{\omega T}{2}. \tag{2.71}$$

Therefore, to design a digital filter with predefined specifications, it is necessary to first design an analog transfer function with adjusted specifications (prewarped) according to the above equation.

Figure 2.21(A) shows how the frequencies in the digital filter are mapped into the designed analog filter frequencies. Figure 2.21(B) shows how the frequency response is affected by the bilinear transformation frequency mapping.

The prewarped specifications of the low-pass analog filter prototype are given by:



(A) Analog and Digital Frequencies

(B) Bilinear Transformation Effects

FIGURE 2.21 Bilinear Transformation Warping Effects

$$\omega_{a_p} = \frac{2}{T}\tan\frac{\omega_p T}{2}. \tag{2.72}$$

$$\omega_{a_r} = \frac{2}{T}\tan\frac{\omega_r T}{2}. \tag{2.73}$$

We can apply prewarping to as many frequencies of interest as desired. These frequencies are given by ω_i for $i = 1, 2, \ldots, n$, such that the analog filter specifications are written as:

$$\omega_{a_i} = \frac{2}{T}\tan\frac{\omega_i T}{2} \text{ for } i = 1, 2, \ldots, n. \tag{2.74}$$

Design Procedure

- Prewarp the prescribed frequency specifications ω_i to obtain ω_{a_i}.
- Generate $H_a(s)$, satisfying the specifications at the frequencies ω_{a_i}.
- Generate $H_d(s)$ by replacing s by $2(z-1)/T(z+1)$ at $H_a(s)$.

2.10.2 Bilinear Transformation by Pascal Matrix

Consider an analog transfer function $H(s)$ shown below:

$$H(s) = \frac{\sum_{l=0}^{N} \hat{b}_{N-l} s^l}{\sum_{i=0}^{N} \hat{a}_{N-i} s^i}. \tag{2.75}$$

When the bilinear transformation in equation 2.70 is applied to the transfer function shown above, the resulting transfer function in the z-domain is shown below:

$$H(z) = \frac{\sum_{l=0}^{N} b_{N-l} z^l}{\sum_{i=0}^{N} a_{N-i} z^i}. \tag{2.76}$$

It can be shown (Psenicka *et al.*, 2002) that it is possible to create a transformation that maps the coefficients $\hat{a}_i$ into a_i and $\hat{b}_l$ into b_l as shown below.

$$\boldsymbol{a} = \boldsymbol{P}_N \times \hat{\boldsymbol{a}}. \tag{2.77}$$

$$\boldsymbol{b} = \boldsymbol{P}_N \times \hat{\boldsymbol{b}}. \tag{2.78}$$

The $\boldsymbol{a}$ and $\boldsymbol{b}$ are vectors for the coefficients a_i and b_l defined by:

$$\begin{aligned} \boldsymbol{a} &= [a_N\ a_{N-1}\ a_{N-2} \ldots a_0]^T. \\ \boldsymbol{b} &= [b_N\ b_{N-1}\ b_{N-2} \ldots b_0]^T. \end{aligned} \tag{2.79}$$

The vectors $\hat{\boldsymbol{a}}$ and $\hat{\boldsymbol{b}}$ contain, respectively, the coefficients $\hat{a}_i$ and $\hat{b}_l$ as follows:

$$\hat{\boldsymbol{a}} = \left[\hat{a}_N\ \hat{a}_{N-1}\left[\frac{2}{T}\right]\ \hat{a}_{N-2}\left[\frac{2}{T}\right]^2\ \ldots\ \hat{a}_0\left[\frac{2}{T}\right]^N\right]^T. \tag{2.80}$$

$$\hat{\boldsymbol{b}} = \left[\hat{b}_N\ \hat{b}_{N-1}\left[\frac{2}{T}\right]\ \hat{b}_{N-2}\left[\frac{2}{T}\right]^2\ \ldots\ \hat{b}_0\left[\frac{2}{T}\right]^N\right]^T. \tag{2.81}$$

It can be shown that $\boldsymbol{P}_N$ is a Pascal matrix with the following properties:

- All elements in the first row must be ones.
- The elements of the last column can be computed by:

$$P_{i,N+1} = (-1)^{i-1}\frac{N!}{(N-i+1)!(i-1)!}, \tag{2.82}$$

  where $i = 1, 2, \ldots, N+1$.
- The remaining elements can be calculated by:

$$P_{i,j} = P_{i-1,j} + P_{i-1,j+1} + P_{i,j+1}, \tag{2.83}$$

  where $i = 2, 3, \ldots, N, N+1$ and $j = N, N-1, \ldots, 2, 1$.

Example

Design an elliptic filter satisfying the following specifications: $A_p = 0.02$ dB, $A_r = 32$ dB, $\omega_p = 2\pi \times 3400$ rad/sec, $\omega_r = 2\pi \times 4600$ rad/sec, and $\omega_s = 2\pi \times 20{,}000$ rad/sec

Solution

According to equations 2.72 and 2.73, it is possible to calculate ω_{a_p} and ω_{a_r} as follows:

$$\omega_{a_p} = 8.8162 \times 10^{-5} \text{rad/sec.}$$
$$\omega_{a_r} = 5.9140 \times 10^{-5} \text{rad/sec.}$$

An analog elliptic filter that meets the above specifications for ω_{a_p} and ω_{a_r} has the following transfer function:

$$H(s) = \frac{\begin{matrix} 6.8799 \times 10^{-6} s^4 + 1.4569 \times 10^{-26} s^3 + 1.1041 \times 10^{-13} s^2 \\ -1.5498 \times 10^{-34} s + 3.9597 \times 10^{-22} \end{matrix}}{\begin{matrix} s^5 + 8.6175 \times 10^{-5} s^4 + 8.6791 \times 10^{-9} s^3 + 4.3333 \times 10^{-13} s^2 \\ +1.6932 \times 10^{-17} s + 3.9597 \times 10^{-22} \end{matrix}}.$$

In this case, the vectors $\hat{\boldsymbol{a}}$ and $\hat{\boldsymbol{b}}$ are as follows:

$$\begin{aligned} \hat{\boldsymbol{a}} = [&3.9597 \times 10^{-26}, 1.5498 \times 10^{-42}, 1.1041 \times 10^{-25}, \\ &1.4569 \times 10^{-42}, 6.8799 \times 10^{-26}, 0]^T. \\ \hat{\boldsymbol{b}} = 10^{-23}&[0.0040\ 0.0169\ 0.0433\ 0.0868\ 0.0862\ 0.1000]^T. \end{aligned}$$

and the matrix $\boldsymbol{P}_5$ is as written here:

$$\boldsymbol{P}_5 = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 \\ 5 & 3 & 1 & -1 & -3 & -5 \\ 10 & 2 & -2 & -2 & 2 & 10 \\ 10 & -2 & -2 & 2 & 2 & -10 \\ 5 & -3 & 1 & 1 & -3 & 5 \\ 1 & -1 & 1 & -1 & 1 & -1 \end{bmatrix}.$$

The resulting transfer function $H(z)$ is as follows:

$$H(z) = 10^{-1} \frac{\begin{matrix} 0.2188 + 0.1020z^{-1} + 0.3127z^{-2} + 0.3127z^{-3} \\ +0.1020z^{-4} + 0.2188z^{-5} \end{matrix}}{\begin{matrix} 0.3372 - 0.7314z^{-1} + 0.9856z^{-2} - 0.7350z^{-3} \\ +0.3406z^{-4} - 0.0703z^{-5} \end{matrix}}.$$

The magnitude response for the transfer function above is shown in Figure 2.22.

2.11 Quantization in Digital Filters

Quantization errors in digital filters can be classified as:

- Round-off errors derived from internal signals that are quantized before or after more down additions;
- Deviations in the filter response due to finite word length representation of multiplier coefficients; and
- Errors due to representation of the input signal with a set of discrete levels.

A general, digital filter structure with quantizers before delay elements can be represented as in Figure 2.23, with the quantizers implementing rounding for the granular quantization and saturation arithmetic for the overflow nonlinearity.

The criterion to choose a digital filter structure for a given application entails evaluating known structures with respect to the effects of finite word length arithmetic and choosing the most suitable one.

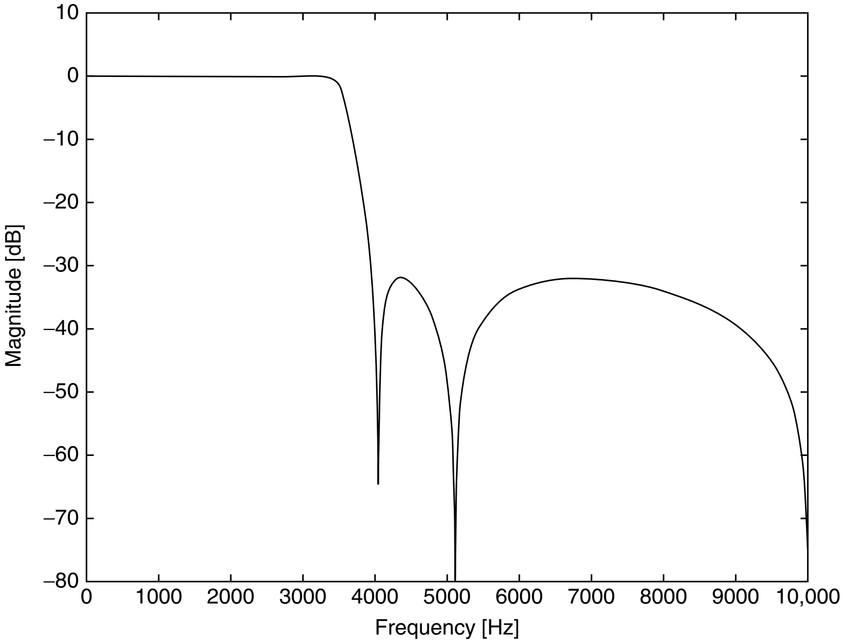


FIGURE 2.22 Magnitude Response of the Designed Low-Pass Elliptic Digital Filter

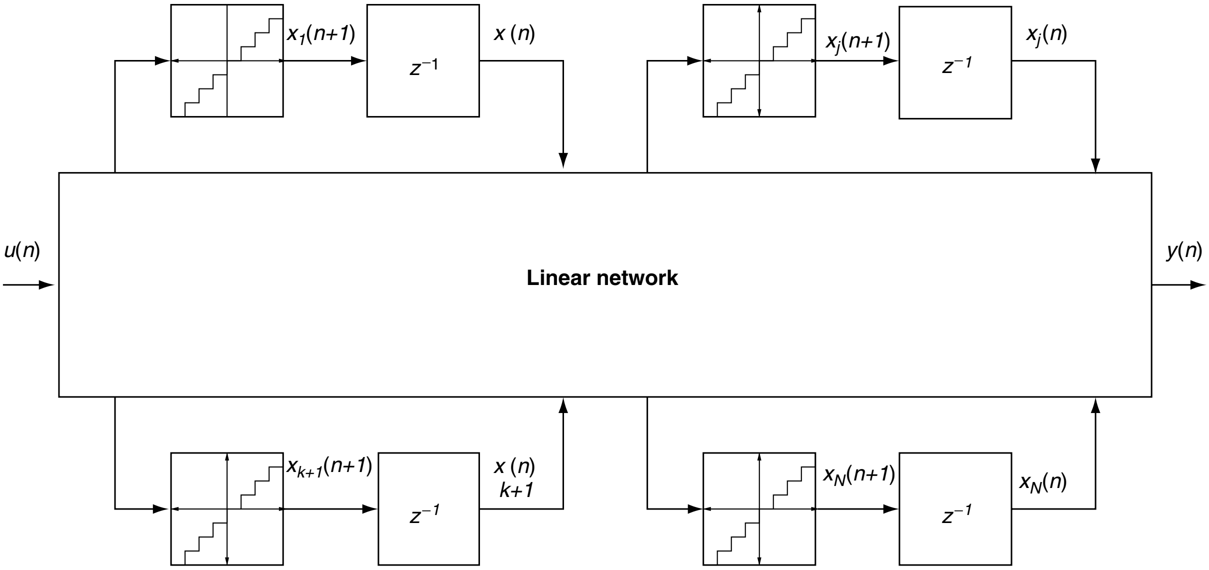

FIGURE 2.23 Digital Filter Including Quantizers at the Delay Inputs

2.11.1 Coefficient Quantization

Approximations are known to generate digital filter coefficients with high accuracy. After coefficient quantization, the frequency response of the realized digital filter will deviate from the ideal response and eventually fail to meet the prescribed specifications. Because the sensitivity of the filter response to coefficient quantization varies with the structure, the development of low-sensitivity digital filter realizations has raised significant interest (Antoniou, 1993; Diniz *et al.*, 2002).

A common procedure is to design the digital filter with infinite coefficient word length satisfying tighter specifications than required, to quantize the coefficients, and to check if the prescribed specifications are still met.

2.11.2 Quantization Noise

In fixed-point arithmetic, a number with a modulus less than one can be represented as follows:

$$x = b_0 b_1 b_2 b_3 \ldots b_b, \tag{2.84}$$

where b_0 is the sign bit and where $b_1 b_2 b_3 \ldots b_b$ represent the modulus using a binary code. For digital filtering, the most widely used binary code is the **two's complement** representation, where for positive numbers $b_0 = 0$ and for negative numbers $b_0 = 1$. The fractionary part of the number, called x_2 here, is represented as:

$$x_2 = \begin{cases} x & \text{if } b_0 = 0. \\ 2 - |x| & \text{if } b_0 = 1. \end{cases} \tag{2.85}$$

The discussion here concentrates in the fixed-point implementation.

A finite word length multiplier can be modeled in terms of an ideal multiplier followed by a single noise source $e(n)$ as shown in Figure 2.24.

For product quantization performed by rounding and for signal levels throughout the filter much larger than the quantization step $q = 2^{-b}$, it can be shown that the power spectral density of the noise source $e_i(n)$ is given by:

$$P_{e_i}(z) = \frac{q^2}{12} = \frac{2^{-2b}}{12}. \tag{2.86}$$

In this case, $e_i(n)$ represents a zero mean white noise process. We can consider that in practice, $e_i(n)$ and $e_k(n+l)$ are statistically independent for any value of n or l (for $i \neq k$). As a result, the contributions of different noise sources can be taken into consideration separately by using the principle of superposition.

The power spectral density of the output noise, in a fixed-point digital-filter implementation, is given by:

$$P_y(z) = \sigma_e^2 \sum_{i=1}^{K} G_i(z) G_i(z^{-1}), \tag{2.87}$$

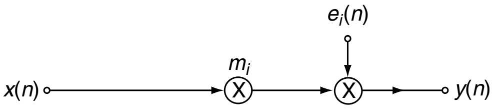

FIGURE 2.24 Model for the Noise Generated after a Multiplication

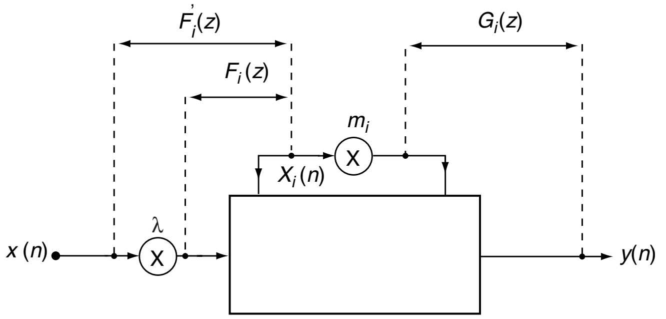

FIGURE 2.25 Digital Filter Including Scaling and Noise Transfer Functions.

where $P_{e_i}(e^{jw}) = \sigma_e^2$, for all i, and each $G_i(z)$ is a transfer function from multiplier output ($g_i(n)$) to the output of the filter as shown in Figure 2.25. The word length, including sign, is $b+1$ bits, and K is the number of multipliers of the filter.

2.11.3 Overflow Limit Cycles

Overflow nonlinearities influence the most significant bits of the signal and cause severe distortion. An overflow can give rise to self-sustained, high-amplitude oscillations known as **overflow limit cycles**. Digital filters, which are free of zero-input limit cycles, are also free of overflow oscillations if the overflow nonlinearities are implemented with saturation arithmetic, that is, by replacing the number in overflow by a number with the same sign and with maximum magnitude that fits the available wordlength.

When there is an input signal applied to a digital filter, overflow might occur. As a result, input signal scaling is required to reduce the probability of overflow to an acceptable level. Ideally, signal scaling should be applied to ensure that the probability of overflow is the same at each internal node of the digital filter. This way, the signal-to-noise ratio is maximized in fixed-point implementations.

In two's complement arithmetic, the addition of more than two numbers will be correct independently of the order in which they are added even if overflow occurs in a partial summation as long as the overall sum is within the available range to represent the numbers. As a result, a simplified scaling technique can be used where only the multiplier inputs require scaling. To perform scaling, a multiplier is used at the input of the filter section as illustrated in Figure 2.25.

It is possible to show that the signal at the multiplier input is given by:

$$x_i(n) = \frac{1}{2\pi j}\oint_c X_i(z)z^{n-1}dz = \frac{1}{2\pi}\int_0^{2\pi} F_i(e^{j\omega})X(e^{j\omega})e^{j\omega n}d\omega, \quad (2.88)$$

where c is the convergence region common to $F_i(z)$ and $X(z)$.

The constant λ is usually calculated by using L_p norm of the transfer function from the filter input to the multiplier input $F_i(z)$, depending on the known properties of the input signal. The L_p norm of $F_i(z)$ is defined as:

$$\|F_i(e^{j\omega})\|_p = \left[\frac{1}{2\pi}\int_0^{2\pi} |F_i(e^{j\omega})|^p d\omega\right]^{\frac{1}{p}}, \quad (2.89)$$

for each $p \geq 1$, such that $\int_0^{2\pi} |F_i(e^{j\omega})|^p d\omega \leq \infty$. In general, the following inequality is valid:

$$|x_i(n)| \leq \|F_i\|_p \|X\|_q, \left(\frac{1}{p} + \frac{1}{q} = 1\right), \quad (2.90)$$

for p, $q = 1$, 2 and ∞.

The scaling guarantees that the magnitudes of multiplier inputs are bounded by a number $M_{\max}$ when $|x(n)| \leq M_{\max}$. Then, to ensure that all multiplier inputs are bounded by $M_{\max}$ we must choose λ as follows:

$$\lambda = \frac{1}{Max\{\|F_1\|_p, \ldots, \|F_i\|_p, \ldots, \|F_K\|_p\}}, \quad (2.91)$$

which means that:

$$\|F_i'(e^{j\omega})\|_p \leq 1, \text{ for} \|X(e^{j\omega})\|_q \leq M_{\max}. \quad (2.92)$$

The K is the number of multipliers in the filter.

The norm p is usually chosen to be infinity or 2. The L_∞ norm is used for input signals that have some dominating frequency component, whereas the L_2 norm is more suitable for a random input signal. Scaling coefficients can be implemented by simple shift operations provided they satisfy the overflow constraints.

In case of modular realizations, such as cascade or parallel realizations of digital filters, optimum scaling is accomplished by applying one scaling multiplier per section.

As an illustration, we present the equation to compute the scaling factor for the cascade realization with direct-form second-order sections:

$$\lambda_i = \frac{1}{\|\prod_{j=1}^{i-1} H_j(z)F_i(z)\|_p}, \quad (2.93)$$

where:

$$F_i(z) = \frac{1}{z^2 + m_{1i}z + m_{2i}}.$$

The noise power spectral density is computed as:

$$P_y(z) = \sigma_e^2\left[3 + \frac{3}{\lambda_1^2}\prod_{i=1}^{m} H_i(z)H_i(z^{-1}) + 5\sum_{j=2}^{m}\frac{1}{\lambda_j^2}\prod_{i=j}^{m} H_i(z)H_i(z^{-1})\right], \quad (2.94)$$

whereas the output noise variance is given by:

$$\sigma_o^2 = \sigma_e^2 \left[3 + \frac{3}{\lambda_1^2} \| \prod_{i=1}^{m} H_i(e^{j\omega}) \|_2^2 + 5 \sum_{j=2}^{m} \frac{1}{\lambda_j^2} \| \prod_{i=j}^{m} H_i(e^{j\omega}) \|_2^2 \right]. \tag{2.95}$$

As a design rule, the pairing of poles and zeros is performed as explained here: poles closer to the unit circle pair with closer zeros to themselves, such that $\|H_i(z)\|_p$ is minimized for $p = 2$ or $p = \infty$.

For ordering, we define the following:

$$P_i = \frac{\|H_i(z)\|_\infty}{\|H_i(z)\|_2}. \tag{2.96}$$

For L_2 scaling, we order the section such that P_i is decreasing. For L_∞ scaling, P_i should be increasing.

2.11.4 Granularity Limit Cycles

The quantization noise signals become highly correlated from sample to sample and from source to source when signal levels in a digital filter become constant or very low, at least for short periods of time. This correlation can cause autonomous oscillations called granularity limit cycles.

In recursive digital filters implemented with rounding, magnitude truncation,[4] and other types of quantization, limit-cycles oscillations might occur.

In many applications, the presence of limit cycles can be harmful. Therefore, it is desirable to eliminate limit cycles or to keep their amplitude bounds low.

If magnitude truncation is used to quantize particular signals in some filter structures, it can be shown that it is possible to eliminate zero-input limit cycles. As a consequence, these digital filters are free of overflow limit cycles when overflow nonlinearities, such as saturation arithmetic, are used.

In general, the referred methodology can be applied to the following class of structures:

- State-space structures: Cascade and parallel realization of second-order state-space structures includes design constraints to control nonlinear oscillations (Diniz and Antoniou, 1986).
- Wave digital filters: These filters emulate doubly terminated lossless filters and have inherent stability under linear conditions as well as in the nonlinear case where the signals are subjected to quantization (Fettweis, 1986).
- Lattice realization: Modular structures allowing easy limit cycles elimination (Gray and Markel, 1975).

2.12 Real-Time Implementation of Digital Filters

There are many distinct means to implement a digital filter. The detailed description of these implementation methods is beyond the scope of this chapter. The interested reader can refer to Wanhammar (1990) and Diniz (2002) and the references therein.

The most straightforward way to implement digital filters relies on general purpose computers by programming their central processing units (CPUs) to execute the operations related to a particular digital filter structure. This type of implementation is very flexible because it consists of writing software, allowing fast prototyping and testing. This solution, however, might not be acceptable in applications requiring high-processing speed, fast data input/output interfaces, or large-scale production.

Efficient software implementations of digital filters are usually based on special-purpose CPUs known as Digital Signal Processors (DSPs). These processors are capable of implementing a sum of product operations, also referred to as multiply-and-accumulate (MAC) operations, in a very efficient manner.

Another implementation alternative is to employ programmable logic devices (PLD) that include a large number of logic functions on a single chip. An advanced version of PLD is the field-programmable gate array (FPGA). An FPGA is an array of logic macro-cells that are interconnected through a number of communication channels configured in horizontal and vertical directions. The FPGAs allow the system designer to configure very complex digital logic that can implement digital signal processing tasks at low cost with reduced power consumption. Usually, high-level software tools are available for the design of digital systems using FPGAs.

Special purpose hardware is also possible for implementing a digital filter. Hardware implementations consist of designing and possibly integrating a digital circuit with logical gates to perform the basic operating blocks inherent to any digital filter structure, namely **multiplications**, **additions**, and **storage elements**. Multiplications and additions can be implemented using bit-serial or bit-parallel architectures. In general, hardware implementations of digital filters are less flexible than software (CPU-based) implementations. Special purpose hardware, however, is usually necessary when high cost of development is offset by a large production and a DSP-based solution is too expensive or is incapable of meeting sampling frequency specifications.

Consider a heuristic related to the computational complexity of digital filters in a full custom design (Dempster, 1995). Figure 2.26 shows an intuitive plot of complexity as a function of filter order for all digital filter implementations meant to satisfy a given set of specifications. The complexity of a digital filter is measured in terms of number of bits used in the

[4] Truncation here refers to the magnitude of the number is reduced, which leads to the decrease of its energy.

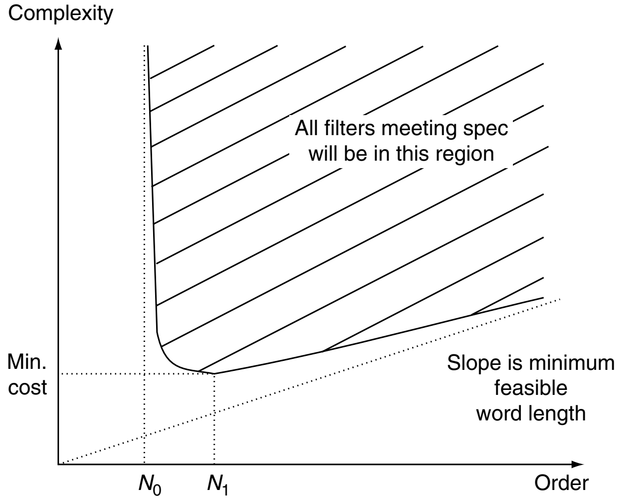

FIGURE 2.26 Complexity of a Digital Filter

coefficients and number of multiplier operations.[5] For a prescribed set of frequency specifications and a particular filter structure, a certain order N_0 may be capable of meeting the specifications with infinite precision. For filters with an order lower than N_0, it is not possible to meet the prescribed specifications. Infinite precision is translated as very high complexity because an infinite number of bits is required. If higher order is used, the number of bits necessary for multiplier coefficients may be reduced, implying lower complexity. An order N_1 in Figure 2.26 is the order of the implementation with the lowest possible complexity. Orders higher than N_1 will necessarily imply higher complexity. The heuristic introduced here, when applied to the case of FIR filter designs using direct-form realizations, leads to complexity curves that are very flat around their minimum point, indicating that almost minimum complexity can be achieved for a wide range of values for the filter order. On the other hand, for IIR filters, the complexity curve is rather sharp, implying that a more careful choice for the filter order should be made.

2.13 Conclusion

In this chapter the main steps for the design and implementation of linear and time-invariant digital filters are introduced. These filters are very important building blocks for signal processing systems implemented in discrete-time domain. In particular, the widely available digital technology allows the implementation of very fast and sophisticated filters in a cheap and reliable manner. As a result, the digital filers are found in numerous commercial products such as audio systems, biomedical equipment, digital radio, and TV just to mention a few.

Methods, Models, and Algorithms for Modern Speech Processing

John R. Deller, Jr.* and
John Hansen
Department of Electrical and Computer Engineering, Michigan State University, East Lansing, Michigan, USA

3.1 Introduction

In this chapter, we address digital speech processing, one of the most important applications of modern signal processing (SP). Speech technologies have become fundamental to the development of many products and services that influence the way we live and work. The enormous commercial potential for speech-based products has been a major impetus for research and development of two broad application areas: **speech communications** and **speech recognition**. Public awareness of speech technologies is based largely on direct experience with speech recognition (and related) products and through marketing of communications services with novel speech features. Internet-based telephony and other audio services have also brought speech processing into the homes and offices of consumers. Underlying the more recent commercial manifestations of speech technology are several decades' worth of ongoing research into fundamental aspects of speech processing at government, military, industry, and university laboratories. These efforts address a broad interdisciplinary span of issues, ranging from basic physiology and speech science, to acoustic modeling and processing algorithms, to higher level language concepts probing questions of intelligence and meaning.

The purpose of this chapter is to present an overview of some salient methods and tools of modern speech processing with the aim of familiarizing the reader with the key vocabulary and main concepts and the most important models and algorithms. In many instances, we will necessarily direct the reader to literature sources for a deeper study of topics. Several current and comprehensive textbooks on speech processing are available (Deller *et al.*, 2000; Rabiner and Juang, 1993), and these texts contain extensive references lists to original citations.[1] The most current developments in the field are often found in conference proceedings, notably in *Proceedings of the IEEE International Conference on Acoustic, Speech, and Signal Processing, Proceedings of the International Conference on Spoken Language Processing*, and *Proceedings of Eurospeech.* Many relevant background topics are treated elsewhere in this book.

* This work was supported in part by the National Science Foundation (NSF) under Cooperative Agreement No. IBIS-9817485. Opinions, findings, or recommendations expressed are those of the author and do not necessarily reflect the views of the NSF.

[1] Space constraints, rather than any lack of deference to the original researchers, make it impossible to cite all relevant original research papers and to give detailed historical accounts.

3.2 Modeling Speech Production

3.2.1 Essential Interdisciplinary Aspects of Speech Production

Basic Anatomy and Physiology

To fully appreciate the engineering systems used to model speech, it is necessary to have a basic understanding of the living system that produces it. We first give a very brief overview of the anatomical structures that comprise the human **speech production system**. Then, with the aid of some primitive processing of a speech waveform, we discuss the physiology of speech production. The principal aim of this cursory treatment of speech "biology" is to provide justification for the discrete-time (DT) model used pervasively in contemporary speech processing.

Figure 3.1 portrays the speech system anatomy midway through the human upper torso as viewed from the left. The gross components of the system are the **lungs**, **trachea** ("windpipe"), **larynx** (organ of voice production), **pharyngeal cavity** (throat), **oral** (or **buccal**) **cavity** (mouth), and **nasal cavity** (nose). In technical discussions, the pharyngeal and oral cavities are grouped into one unit referred to as the **vocal tract** and the nasal cavity is often called the **nasal tract**[2]. Accordingly, the vocal tract begins at the output of the larynx and terminates at the input to the lips. The nasal tract begins at the velum and ends at the nostrils of the nose. Finer anatomical features that are critical to speech production include the **vocal folds** or **vocal cords**, **soft palate** or **velum**, **tongue**, **teeth** and **lips**. The **uvula** is the soft tip of the velum that hangs down in the back of the oral cavity. The **glottis** is the name given to the opening between the vocal folds, and the adjective *glottal* is frequently used to refer to laryngeal or vocal phenomena (e.g., "glottal waveform"). These finer anatomical components move to different positions to produce various speech sounds and are known as **articulators** by speech scientists. The **mandible** (jaw) is also considered to be an articulator because it is responsible for both gross and fine movements that affect the size and shape of the vocal tract as well as the positions of the other articulators.

Speech-processing engineers view speech production in terms of an acoustic filtering operation. Let us associate the anatomy with such a technical model. The three main cavities of the speech production system (vocal plus nasal tracts) compose the main acoustic filter. Much of the information in speech is encoded in the spectral peaks associated with given sounds. The size and shape of the vocal tract (pharyngeal and oral cavities) at a given instant are the principal determiners of the resonant structures in the short-term speech spectrum. In particular, the resonances associated with a speech sound are a consequence of the articulators having formed various acoustical cavities and subcavities out of the vocal tract cavities, much like concatenating different lengths of organ pipe in various orders. Thus, the center frequencies of these resonances depend on the shape and physical dimensions of the vocal tract. Conversely, each vocal-tract shape is characterized by a set of resonant frequencies. From a modeling point of view, the vocal-tract articulators determine the important "pole" properties of the speech system. Since these resonances tend to "form" (impose an envelope upon) the spectrum, speech scientists refer to them as **formants**. This term is often used to refer to the nominal center frequencies of the resonances, so formant may be used interchangeably with **formant frequency**. The formants in the spectrum are denoted[3] as $F_1, F_2, F_3, \ldots, F_N$, beginning with the lowest frequency. In practice, there are usually three to five discernable formants in the Nyquist band for typical sampling rates (8–16 kHz).

Spectral "valleys" (antiresonances) in speech spectra are not nearly as prevalent or prominent (i.e., they tend to be of wider bandwidth) as spectral peaks (resonances). Nevertheless, there are speech sounds for which zeros in the production model seem warranted both empirically (by spectral analysis) and physically (by analysis of the anatomy and physiology). The degree to which the nasal cavity is coupled to the vocal tract (as a "side cavity") determines, in part, the antiresonance structure. Generally, any component of the vocal and/or nasal tract systems that creates a cavity with the potential to "trap" energy (which is nominally on a direct path from "lungs to lips") will manifest some degree of antiresonant spectral character. The spectral dip will appear in the frequency region of the resonance of the trapping cavity.

The articulators are used to change the properties of the acoustic filter over time. The filter is loaded at its main output by a radiation impedance ("flow-to-pressure converter") due to the lips. The vocal tract (and/or nasal tract, when appropriate) is excited in two principal ways in most natural languages.[4] The main function of the larynx in speech is to provide a periodic flow waveform (called the **voice** or **phonation**) as input to the acoustic system in the production of **voiced** speech sounds. The voice waveform is a periodic lowpass pulse train whose fundamental frequency, usually denoted F_0, reflects the frequency of glottal vibration.[5] Voiced speech

[2] The term **vocal tract** is often used in imprecise ways by engineers. Sometimes it is used to refer to the combination of all three cavities and even more often to the entire speech production system. We will be careful in this chapter not to use vocal tract when we mean speech production system, but, as is conventionally done in the literature, we will sometimes use the term vocal tract when we actually mean vocal tract *plus* nasal tract. Whether vocal tract implicitly includes the nasal tract will be clear from context, or explicitly stated.

[3] Uppercase F and Ω are used throughout to denote real frequencies (in hertz and radians per second, respectively), while lowercase f and ω are used to represent "normalized" frequencies (dimensionless and in radians, respectively); that is, frequencies normalized to the sample frequency are $f = F/F_s$ and $\omega = 2\pi/F_s$.

[4] The term **natural language** refers to any of the world's human languages. This will be contrasted with a technical meaning of the term **formal language** in the material on language modeling in Section 3.4.2 and beyond.

[5] The improper use of the term *voice* to mean *speech* seems irrevocably entrenched in the technical lexicon (e.g., voice channel) just as it is in common use (e.g., a singer with a "beautiful voice").

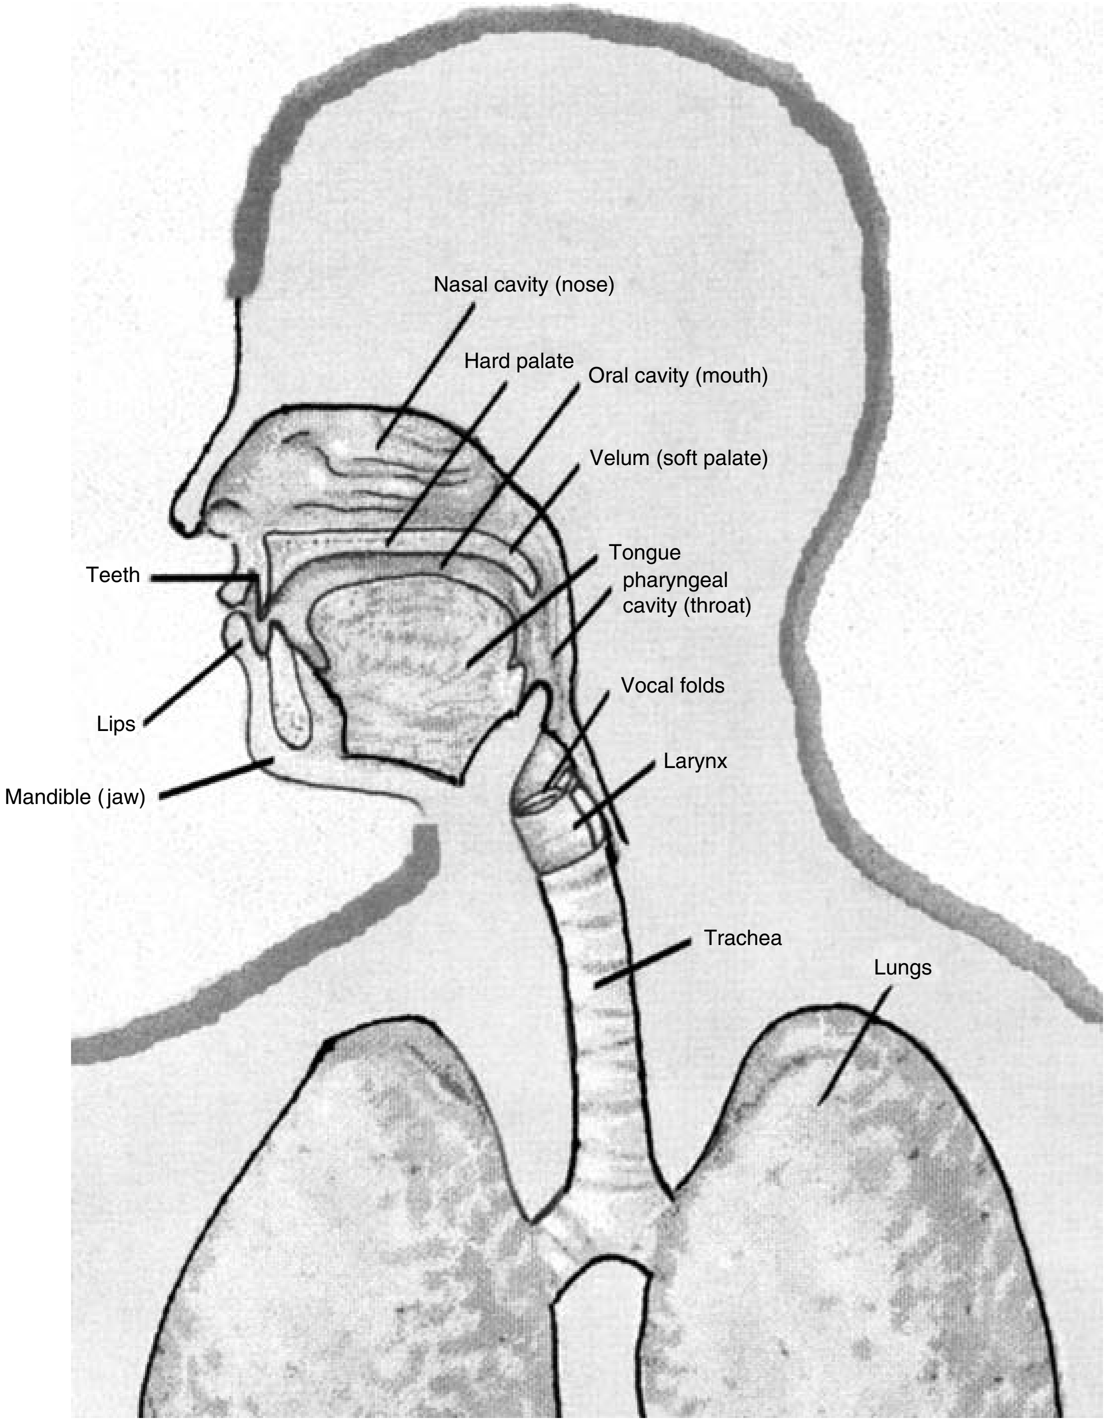

FIGURE 3.1 Gross Anatomy of the Human Speech Production System

waveforms are short-term quasiperiodic, with the period determined by the frequency of vocal-fold vibration—the **pitch** frequency.[6] Accordingly, voice speech is modeled as a deterministic process. **Unvoiced** speech sounds are produced by exciting the vocal tract by turbulent airflow at some constriction in the vocal tract. The excitation source is often modeled

[6] **Pitch** is actually a psychoacoustic rather than a waveform-domain concept. Pitch is precisely defined as the *perceived* fundamental frequency of an audible stimulus, whether or not that fundamental frequency is actually present in the acoustic waveform. In a telephone conversation, each conversant perceives the fundamental voicing frequency of the other even though that frequency is ordinarily not in the telephone channel bandwidth.

as white noise. Unvoiced waveforms are usually lower in energy than voiced utterances, and their noisy character necessitates modeling them as stochastic processes. In addition, some sounds are created using **mixed** voiced and unvoiced excitations. Examples of voiced and unvoiced sounds are given below. The sound made by the letter *z* in *zoo* (denoted /*z*/ by phoneticians) is the result of mixed excitation.

Some of the differences between voiced and unvoiced speech segments are evident in the time waveform for the utterance of the letter *X* in Figure 3.2. The leading voiced sound *eh* (written /*E*/ by phoneticians—see discussion concerning Table 3.1) is higher in amplitude and contains strong periodic structure. The final unvoiced sound /*s*/ is low in amplitude and noise-like. Figure 3.3 shows corresponding magnitude spectra of the steady-state portions of /*E*/ and /*s*/ in Figure 3.2. In Figure 3.3, we note that in each spectrum (and especially for the vowel sound), there are well-defined frequency ranges of emphasis (resonances) and de-emphasis (antiresonances).

Other forms of input to the vocal tract include **plosive** excitation and **whisper**. Because there are pauses[7] in speech, we also include **silence** as a form of "excitation" for modeling completeness. Plosive sounds are formed by making a complete closure (normally toward the front of the vocal tract), building air pressure behind the closure, and suddenly releasing it. The word *pat* begins with the **voiced plosive** /*p*/ (silence, then voiced), and ends with the **unvoiced plosive** /*t*/ (silence, then unvoiced). The whisper excitation is formed by forcing air through a partially constricted glottis.

One of the main challenges in speech processing is that the dynamics of the speech system are constantly changing. This is evident in Figure 3.2. A conservative rule of thumb is that speech frames remain quasistationary for intervals of 10 to 20 ms. Moreover, speech is not a string of discrete, well-formed sounds but rather a series of steady-state or target sounds (sometimes quite brief, if achieved at all) with intermediate transitions. The preceding and/or succeeding sound in a string can affect whether a target is reached, how long it is held, and other finer acoustic details. This interplay among sounds in an utterance is called **coarticulation**. Changes witnessed in the speech waveform are a direct consequence of movements of the speech system articulators that rarely remain fixed for any sustained period of time. On the other hand, the articulators have mass and cannot be moved instantaneously from one target to the next without a period of transition.

Since the vocal-tract shape is varied as a function of time to produce desired speech sounds, so must the spectral properties of the speech signal be time-varying. In contemporary SP, it is possible to exhibit these changes using a three-dimensional plot of magnitude spectra over time (sometimes called a "waterfall plot") This information was historically gleaned from the **speech spectrograph** (Flanagan, 1972; Koenig *et al.*, 1946; Potter *et al.*, 1966).

Phonetics and Linguistics

Phonemes and Phones

Speech processing engineers rely heavily on research into the complex sounds of speech (phonetics) and into the characterization of the higher-level "rules" by which those sounds are combined to transmit information (linguistics).

The basic theoretical unit for describing how speech conveys linguistic meaning is called a **phoneme**. For American English, there are about 42 phonemes which are made up of **vowels**, **semivowels**, **diphthongs**, and **consonants**, including **nasals**, **stops**, **fricatives**, and **affricates**. Each phoneme can be considered to be a code that consists of a unique set of **articulatory gestures**. These articulatory gestures include the type and location of sound excitation as well as the position or movement of the vocal-tract articulators. We can view a phoneme as an ideal sound unit with a set of corresponding articulatory gestures. If speakers could exactly and consistently produce (in the case of English) these 42 phonemes, then speech would amount to a stream of discrete codes. Many different factors, including accents, gender, and coarticulatory effects, ensure that a given phoneme will have a variety of acoustic manifestations in the course of flowing speech. From an acoustical point of view, therefore, the phoneme represents a **class** of sounds whose elements convey the same meaning. Accordingly, the phonemes of a language compose a minimal theoretical set of distinct units which are sufficient to convey all meaning in the language. This is to be juxtaposed with the actual *sounds* that can be produced which speech scientists call **phones**. Associated with each phoneme is a collection of **allophones** (phone variations) that represent slight acoustic variations of the basic unit.

The study of the abstract units and their relationships in a language is called **phonemics**, while the study of the actual sounds of the language is called **phonetics**. Moreover, each of three branches of phonetics approaches the subject somewhat differently. **Articulatory phonetics** is concerned with the manner in which speech sounds are produced by the articulators of the vocal system; **acoustic phonetics** research explores the sounds of speech through analysis of acoustic waveforms; and, **auditory phonetics** research focuses on perceptual responses to speech sounds as reflected in listener trials. Our cursory explorations into phonetics below will represent a blend of articulatory and acoustic analysis.

A string of symbols representing the phonemes is called **phonemic transcription**. When the transcription also includes **diacritical marks** on the phonemic symbols that indicate allophonic variations, then the result is a **phonetic transcription**. Although the term phonetic transcription is commonly used, speech processing engineers tend to think about speech more at the level of phonemic transcriptions even though allophonic variations are inherently modeled in many systems.

[7] In addition to "long" pauses that can occur, for example, as a person stops to think, there are also very short regions of naturally occurring silence in continuous speech. Read on, for example, to the discussion of plosives.

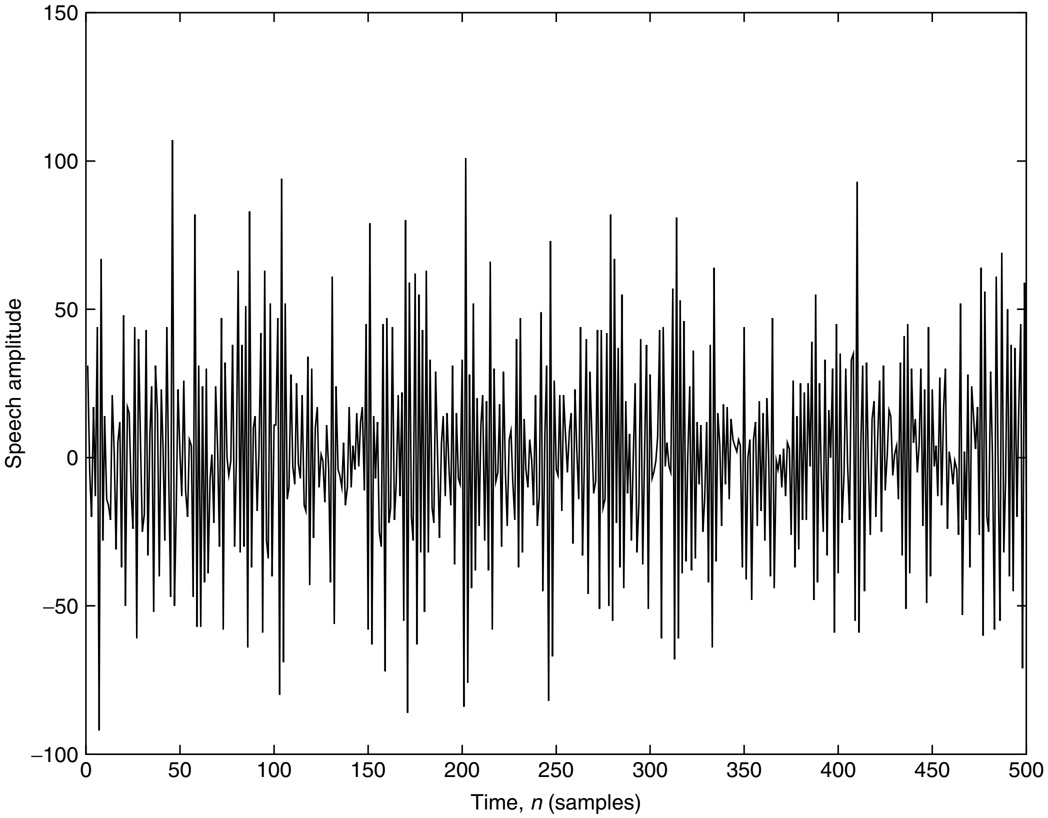
FIGURE 3.2 Differences Between Voiced and Unvoiced Speech Segments



(C) Blowup of Fricative Portion of Fricative /*s*/ in Utterance of (A)

FIGURE 3.2 Difference Between Voiced and Unvoiced Speech Segments (*Continued*)

Three "phonetic alphabets" are widely used; the two noted in this paragraph are preferred by most speech engineers. The **International Phonetic Alphabet** (IPA) was developed by European phoneticians in the late 19th century, and it remains the standard for basic science writing on phonetics. The complete IPA has entries covering phonemes in all the world's languages (Ladefoged, 1975). To facilitate keyboard entry of phonetic transcriptions, a more recent phonetic alphabet was developed under the auspices of the United States Defense Advanced Research Projects Agency (DARPA) and is accordingly called the **ARPAbet**. There are two versions of the ARPAbet, one that uses single letter symbols and one that uses all uppercase symbols. The use of all uppercase necessitates some double letter designators. When transcription is necessary in this discussion, we will employ the single-letter ARPAbet symbols. In general, phonemic or phonetic transcriptions are shown between two forward slashes as we did when denoting the phonemes /*E*/ and /*s*/ for Figures 3.2 and 3.3.

Classification of Phonemes

There are many methods for classifying phonemes. Phonemes can be categorized based on properties related to the time waveform, frequency characteristics, manner of articulation, place of articulation, type of excitation, and the stationarity of the phoneme. We mention only a few salient facts about the various of phoneme classes, leaving detailed study to the reader's further pursuit (Deller *et al.*, 2000; Ladefoged, 1975).

A phoneme is **continuant** if the speech sound is produced by a steady-state vocal-tract configuration and **noncontinuant** if a change in the vocal-tract configuration is required. The phonemes in Table 3.1 are classified based on the continuant/noncontinuant property. Noncontinuant phonemes are generally more difficult to characterize and model.

Vowels are voiced speech sounds involving a constant vocal-tract shape. There are twelve principle vowels in American English. A thirteenth vowel, called a **schwa**, is a sort of "degenerate vowel" to which many others gravitate when articulated hastily in the course of flowing speech. The initial vowel in "ahead" is a schwa vowel. All vowels are voiced and are normally among the phonemes of largest amplitude. Vowels can vary widely in duration (typically from 40 to 400 ms). From an articulatory point-of-view, vowels are differentiated by the tongue-hump position and the degree of constriction at that position. The tongue position is largely responsible for the variation of cross-sectional area along the vocal tract which, in turn, determines the formants of the vowel. From an acoustic point-of-view, therefore, the sets of formant frequencies are fairly reliable discriminators of the various vowels.

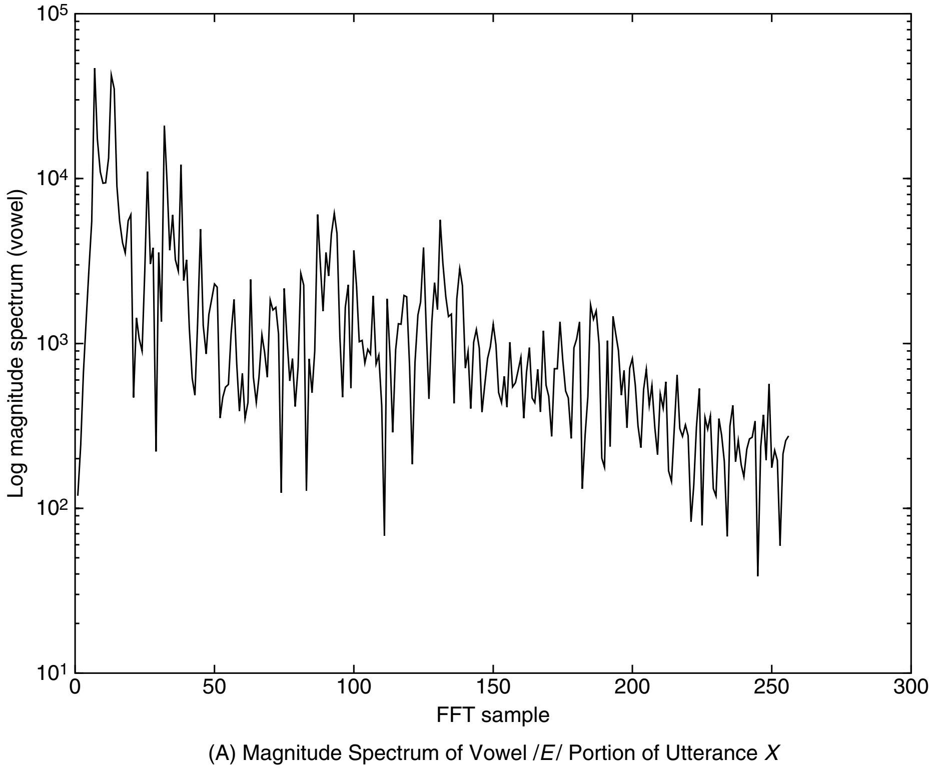
f	F	five			

† *vocalic l,m,n* ‡ *flapped t* § *glottal stop*

There are two further categories of "vowel-like" phonemes. A **diphthong** involves an intentional movement from one vowel toward another vowel. The three diphthongs that are universally accepted are /*Y*/, /*W*/, and /*O*/ (corresponding examples occur in *pie*, *out*, and *toy*). The other group of vowel-like phonemes consists of /*w*/, /*l*/, /*r*/, and /*y*/, which are called **semivowels**. Semivowels are classified as either **liquids** (/*w*/ in *wet* and /*l*/ in *lawn*) or **glides** (/*r*/ in *ran* and /*y*/ in *yam*).

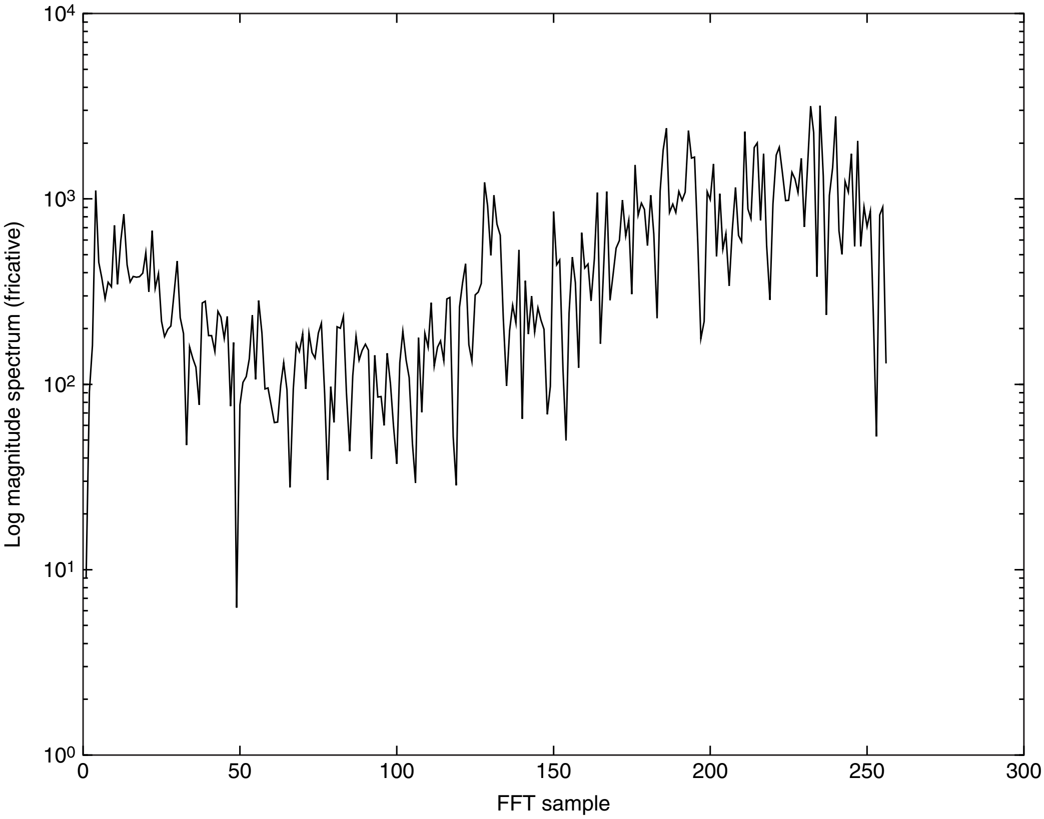
The second broad class of phonemes, the **consonants**, consists of speech sounds that are produced with a constricted vocal tract. Some consonants require precise dynamic movement of the articulators for their production. Other consonants, however, may not require articulator motion, so their sounds, like vowels, are sustained (hence, continuants). Consonants are subclassified as fricatives, affricates, stops, and nasals.

The **fricatives** are produced by exciting the vocal tract with a steady airstream that becomes turbulent at some point of constriction. The constriction in the vocal tract or glottis results in an unvoiced excitation. However, some fricatives also have a simultaneous voicing component (hence, mixed excitation). Those with simple unvoiced excitation are usually called **unvoiced fricatives** whereas those of mixed excitation are called **voiced fricatives**. In the unvoiced case, the constriction causes a noise source anterior to the constriction. The location of the



(A) Magnitude Spectrum of Vowel /*E*/ Portion of Utterance *X*

FIGURE 3.3 Corresponding Magnitude Spectra



(B) Magnitude Spectrum of Final Fricative /*s*/ Portion of Utterance *X*

FIGURE 3.3 Corresponding Magnitude Spectra (*Continued*)

constriction serves to determine the fricative sound produced. Unvoiced fricatives include /*f*/ (free), /*T*/ (thick), /*s*/ (cease), /*S*/ (mesh), and /*h*/[8] (heat). The voiced fricatives /*v*/ (vice), /*D*/ (then), /*z*/ (zephyr), and /*Z*/ (measure) are the voiced counterparts of the unvoiced fricatives /*f*/, /*T*/, /*s*/, /*S*/, respectively. Voiced fricatives possess the usual frication noise source at the point of major constriction but also have periodic glottal pulses exciting the vocal tract.

Similarly to glides, liquids, and diphthongs, **affricates** are formed by transitions from a stop to a fricative. The two affricates found in American English are the unvoiced affricate /*C*/ (stop /*t*/, followed by unvoiced fricative /*S*/) as in *change* and the voiced affricate /*J*/ (stop /*d*/, followed by the voiced fricative /*Z*/) as in jam.

The **stops**, or **plosives**, are transient, noncontinuant consonants produced by building up pressure behind a total constriction of the vocal tract and suddenly releasing this pressure. The constriction can be at the lips (/*b*/ in *be* and /*p*/ in *pea*), at the gum ridge (/*d*/ in *day*, and /*t*/ in tea), or at the soft or hard palate (/*g*/ in *go*, /*k*/ in *key*). The consonants /p, t, k/ are unvoiced stops; /b, d, g/ are voiced.

The **nasals** are voiced consonants produced with the glottal waveform exciting an open nasal cavity. Their waveforms resemble vowels but are normally weaker in energy due to limited ability of the nasal cavity to radiate sound. In forming a nasal, a complete closure is made toward the front of the vocal tract, either at the lips (/*m*/ as in *more*), with the tongue resting on the gum ridge (/*n*/ as in *noon*), or by the tongue pressing at the soft or hard palate (/*G*/ as in *sing*).

Prosodic Features

Expressive uses of speech depend on tonal patterns of pitch, syllable stresses, and timing to form rhythmic patterns. Timing and rhythm contribute significantly to the formal linguistic structure of speech. The tonal and rhythmic aspects of speech, called **prosodic features**, are created by special manipulations of the speech production system during the normal sequence of phoneme production. The glottal source excitation conveys important prosodic cues such as **intonation** and **stress**. Stress is used to distinguish similar phonetic sequences or to highlight a syllable or word against a background of unstressed syllables. Intonation refers to the distinctive use of patterns of pitch. The same utterance, for example, can often be changed from a statement into a question by use of intonation.

[8] The *whisper* sound /h/ is normally referred to as a unvoiced glottal fricative.

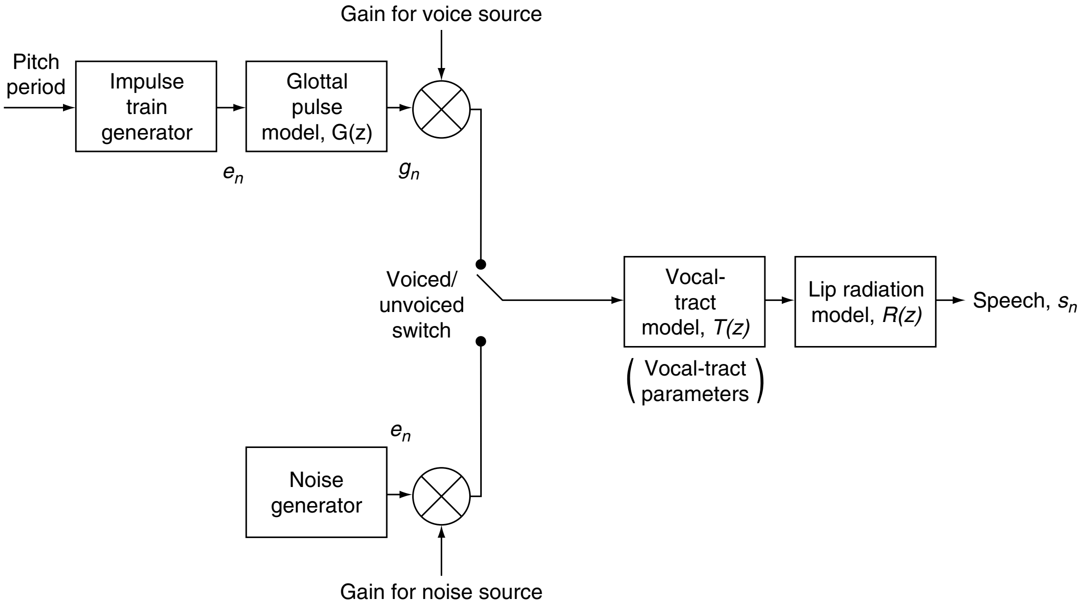


FIGURE 3.4 A General Discrete-Time Model for Speech Production

A detailed discussion of prosodics is found, for example, in Chomsky and Halle (1968) and Lieberman (1967).

3.2.2 Discrete-Time Model of Speech Production

Efforts to model speech production have focused principally on the "source–filter" view of the physiologic system in which, over short stationary intervals of an utterance, speech is modeled as a linear, time-invariant, acoustic filtering operation on an appropriate excitation (the "source"). The process of producing the source input is assumed to be decoupled from the dynamics of the acoustic filter. The prominent discrete-time (DT) source-filter model of speech, known variously as the "all-pole" or "linear prediction" model, is essentially a DT version of classic analog acoustic models. The linear-prediction model underlies a majority of the modern speech products and services.

The history of the developments leading up to modern DT models for speech production is interesting and informative, and it has great value in illuminating the present models (Flanagan, 1972; Klatt, 1987; Morgan and Gold, 1999; Shafer and Markel, 1979; Dudley, 1939). Circuit models developed early in the 20th century, consisting mainly of band-pass filters (resonators) to simulate formant spectra, represent the first attempts of the modern era to model speech production. The primary goal of this work was speech synthesis, and there was no assertion that the models bore any internal similarity to the physiologic system. Such models are often called **terminal–analog** models because they are analogous to the real system only at the terminus. Work on acoustic tube models in the 1960s (Fant, 1960) represents an attempt to model the internal physics of the speech system. Tube models and their differential equations of wave propagation proved to be remarkably useful tools in understanding the speech production system. Although the prevailing DT "all-pole" model of speech production was not derived directly from the acoustic tube theory, important insights and interpretations of the DT model have been obtained from classical theory (Deller, 2000; Rabiner and Schafer, 1978).

A general linear, time-invariant DT model for speech production is shown in the block-diagram form in Figure 3.4. The model is a terminal analog, and it is understood to represent only short intervals of speech over which signal dynamics are assumed to be stationary. Frequent updating or adaptation of model parameters is necessary to properly model the quickly time-varying nature of speech. With this caveat, such a system produces reasonable quality speech for coding and synthesis purposes and serves as a useful analysis model for recognition and related tasks, in spite of the fact that there are no provisions for coupling or nonlinear effects among subsystems in the model.

In the general DT model, a vocal-tract system $T(z)$ is cascaded with a radiation model $R(z)$. [We henceforth include any nasal-tract dynamics in the vocal-tract model $T(z)$.] This system is excited by an uncorrelated excitation signal, say $\{e_n\}$, or by a filtered version of $\{e_n\}$. During unvoiced speech activity, the excitation $\{e_n\}$ is a flat-spectrum **noise** source that excites the vocal tract model directly. During periods of voiced speech activity, the excitation is a periodic DT impulse train whose period corresponds to the desired fundamental frequency.[9] A more realistic voicing signal is created by using

[9] The $\{e_n\}$ is uncorrelated as assumed only as the pitch period becomes infinite (i.e., only when $e_n = \delta_n$).

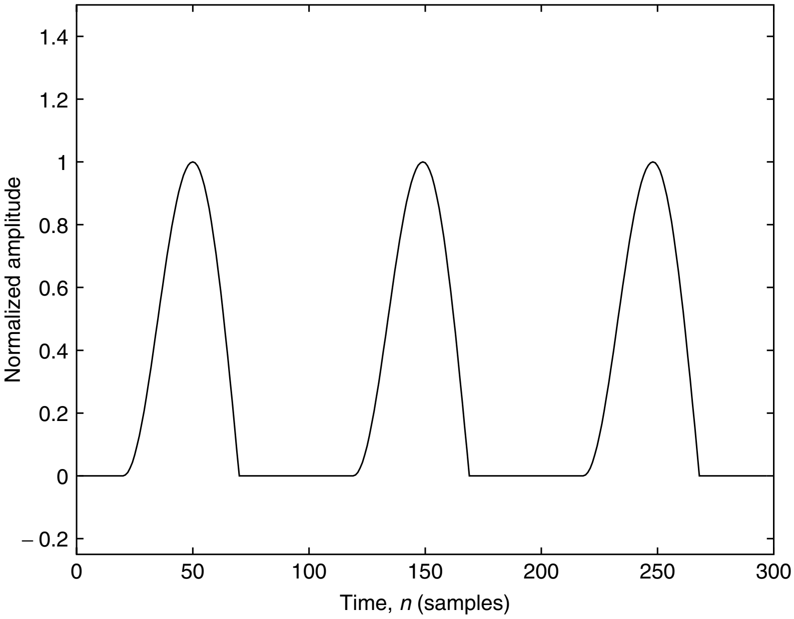

FIGURE 3.5 Idealized Low-Pass Pulse Train. This figure shows three cycles of the glottal volume–velocity waveform during voiced speech.

the pulse train as input to a glottal pulse shaping filter, $G(z)$. In principle, we would like $G(z)$ to produce a low-pass pulse waveform similar to that shown in Figure 3.5. The filter $G(z)$ is further discussed in upcoming paragraphs.

Assuming that the vocal-tract system has a spectrum that is well-modeled by pure resonances, its model is taken to be all pole:[10]

$$T(z) = \frac{T_o}{1 - \sum_{k=1}^{N} b_k z^{-k}} = \frac{T_o}{\prod_{k=1}^{N} (1 - \rho_k z^{-1})}, \tag{3.1}$$

where T_o represents an overall gain term and ρ_k the (generally complex) pole locations for the model. Based on our knowledge of phonetics, we might suspect that the model is inadequate for certain classes of phonemes. We have noted that some phonemes (e.g., the nasals) exhibit spectral nulls, strongly suggesting the need for zeros in the model. We will return to the issue of zeros in the model below. A strong impetus to justify an all-pole model is the availability of powerful analytical methods that follow from its use.

Each pair of poles in the z-plane at complex conjugate locations (ρ_i, ρ_i^*) roughly corresponds to a formant in the spectrum of $T(z)$. Since the $T(z)$ should be a stable system, all poles are inside the unit circle in the z-plane. If the poles in the z-plane are well-separated, estimates for formant frequencies and bandwidths can be obtained from the pole locations.

Now let us further characterize the glottal filter $G(z)$. In keeping with the desire to have an all-pole speech model, it is sometimes suggested that the two-pole signal:

$$g_n = [\alpha^n - \beta^n]u_n, \quad \beta < \alpha < 1, \, \alpha \approx 1, \tag{3.2}$$

in which $\{u_n\}$ is the unit step sequence; the signal is an appropriate impulse response for the filter. An all-pole impulse–response model for $\{g_n\}$ (regardless of the number of poles used), however, is incapable of producing the realistic pulse shapes that are observed in many experiments because an all-pole model is constrained to be of minimum phase (otherwise it would be unstable). More realistic pulse signals have been suggested in the literature. The Rosenberg pulse [18] is given by:

$$g_n = \begin{cases} \frac{1}{2}[1 - \cos(\pi n/P)], & 0 \leq n \leq P, \quad P = \text{time of pulse peak.} \\ \cos[\pi(n-P)/2(K-P)], & P \leq n \leq K, \quad K = \text{final sample before complete closure.} \\ 0, & \text{otherwise.} \end{cases} \tag{3.3}$$

Equation 3.3 is popular because it can flexibly represent many realistic pulse shapes by adjusting its parameters. The Rosenberg pulse, however, cannot be approximated well using a model with only poles, so we add another concern for the discussion of zeros below.

The radiation component, $R(z)$, is a low-impedance load that terminates the vocal-tract and converts the volume velocity at the lips to a pressure wave in the far field. The radiation load has been observed to have a high-pass filtering effect that is well-modeled by a simple differencer:

[10] Describing a system function as "all pole" is strictly improper and can be misleading. The term means that all zeros of the system function are at $z = 0$ or $z = \infty$ in the z-plane. In other words, the system function has a "denominator polynomial (in z^{-1}) only."

$$R(z) = Z_{\text{lips}}(z) = 1 - \zeta_o z^{-1}, \quad \zeta_o < 1, \zeta_o \approx 1. \tag{3.4}$$

We must finally come to terms with the apparent contradiction between the need for zeros in the model and the desire to avoid them. Indeed, $R(z)$ itself is composed of a single zero and no poles. Some of the early writings on this subject argued that if equation 3.2 is a good model for the glottal dynamics, then one of the poles of $G(z)$ will approximately cancel the zero ζ_o in $R(z)$. This does not, however, resolve the question of whether $G(z)$ should contain zeros, or whether, in certain cases, $T(z)$ should include zeros to appropriately model a phoneme. The answer to these questions depends largely on what aspect of speech we are trying to model. In most applications, correct *spectral magnitude* information is all that is required of the model. Generally speaking, this is because the human auditory system is "phase deaf" (Milner, 1970), so information gleaned from the speech is extracted from its magnitude spectrum. While a detailed discussion is beyond our current scope (Deller *et al.*, 2000), the critical fact that justifies the all-pole model is that a magnitude (but not a phase) spectrum for any rational system function can be modeled to an arbitrary degree of accuracy with a sufficient number of stable poles. Therefore, the all-pole model can exactly preserve the magnitude spectral dynamics (the "information") in the speech but might not retain the phase characteristics. In fact, for the speech model to be stable and all pole, it must necessarily have a *minimum phase* spectrum, regardless of the true characteristics of the signal being encoded. Ideally, the all-pole model will have the correct magnitude spectrum but minimum phase characteristic with respect to the "true" model. If the objective is to code, store, resynthesize, and perform other such tasks on the magnitude spectral characteristics but not necessarily on the temporal dynamics, the all-pole model is perfectly adequate. One should not, however, anticipate that the all-pole model can preserve time-domain features of speech waveforms because such features depend explicitly on the phase spectrum.

Let us summarize these important results. Ignoring the technicalities of z-transform existence, we assume that the output (pressure wave) of the speech production system is the result of filtering the appropriate excitation by two (in the unvoiced case) or three (voiced) linear, separable filters. Ignoring the developments above momentarily, let us suppose that we know "exact" or "true" linear models of the various components. By this we mean that we (somehow) know models that will exactly produce the speech waveform under consideration. These models are only constrained to be linear and stable and are otherwise unrestricted. In the unvoiced case $S(z) = E(z)T(z)R(z)$, where $E(z)$ represents a partial realization of a white noise process. In the voiced case, $S(z) = E(z)G(z)T(z)R(z)$, where $E(z)$ represents a DT impulse train of period P, the pitch period of the utterance. Accordingly, the true overall system function is as follows:

$$H(z) = \frac{S(z)}{E(z)} = \begin{cases} T(z)R(z), & \text{unvoiced case.} \\ G(z)T(z)R(z), & \text{voiced case.} \end{cases} \tag{3.5}$$

With enough painstaking experimental work, we could probably deduce reasonable "true" models for any stationary utterance of interest. In general, we would expect these models to require zeros as well as poles in their system functions. Yet, an all-pole model exists that will at least produce a model/speech waveform with the correct magnitude spectrum (Deller *et al.*, 2000), and a waveform with correct spectral magnitude is frequently sufficient for coding, recognition, and synthesis.

We henceforth assume, therefore, that during a stationary frame of speech, the speech production system can be characterized by a z-domain system function of the form:

$$H(z) = \frac{H_0}{1 - \sum_{i=1}^{M} a_i z^{-i}} \text{ with } H_0 > 0, \tag{3.6}$$

which is driven by an excitation sequence:

$$e_n = \begin{cases} \sum_{q=-\infty}^{\infty} \delta_{n-qP}, & \text{voiced case.} \\ \text{zero mean, unity variance, uncorrelated noise,} & \text{unvoiced case.} \end{cases} \tag{3.7}$$

In equation 3.6, $0 < M < \infty$. A block diagram for this system is shown in Figure 3.6.

3.3 Fundamental Methods and Algorithms Used in Speech Processing

3.3.1 Parametric and Feature-Based Representations of the Speech Signal

Speech processing algorithms rarely work directly with the (sampled) speech waveform but rather with a sequence of quantified **features** that are extracted from the signal, usually at regularly-spaced intervals. In a typical scenario, features are computed periodically in time over 256-point **frames** that are intentionally overlapped by 128 samples. For a 10-kHz sampling rate, this represents feature computations using 25.6 ms segments of speech that overlap by 12.8 ms as the processing moves through time. Using the rule of thumb that speech signal dynamics remain stationary for blocks of 10 to 20 ms, the frame duration is chosen with this in mind, balanced against the need to represent the waveform with the smallest possible number of feature computations (for economy of computation and storage, adherence to bandwidth requirements, and other factors). Increased duration of the frame results in enhanced **spectral resolution** of the feature being computed, while sequences of features computed over shorter windows provide better **time resolution** (Deller *et al.*, 2000). Overlapping frames are used to smooth the transitions of features from one stationary region to the next.

Speech features are often **vector-valued.** An example would be (estimates of) the set of filter coefficients $\{a_i\}$ associated with the DT model of speech in equation 3.6. As we detail in Section 3.3.2, these coefficient estimates, typically 14 in number, are the result of "linear prediction" analysis of speech. Such a set of features is called a **parametric** representation of the frame because it consists of values for the parameters associated with a predetermined model. In the present example, the set of 14 model parameters might be complemented by an estimate of the system gain (H_0 in equation 3.6) and a binary valued feature to indicate a voiced or unvoiced frame. Each frame, therefore, would be represented by a real vector of dimension 16.

Features that have been used to characterize speech usually convey information about spectral properties. These include direct spectral measures (FFT based), mappings or transformations of spectral information (see the cepstrum in Section 3.3.3.), correlation information, zero-crossing measures (crude frequency content information), model parameter estimates (as in the linear-prediction example, or the "reflection coefficients," discussed in Section 3.3.2.), and various transformations of such parameters. Energy measures are also used as conveyors of information about, for example, the presence of voicing or for "silence/speech" decisions.

3.3.2 Linear Prediction Analysis

LP Model and the Normal Equations

The time-domain implication of the all-pole system function is that the difference equation governing the system includes memorized values for the output only; given these output lags, only the present sample of the input is needed to determine s_n to within a gain factor at each n. In particular:

$$s_n = a_1 s_{n-1} + a_2 s_{n-2} + \cdots + a_M s_{n-M} + H_0 e_n = \boldsymbol{a}^T s_n + H_0 e_n, \tag{3.8}$$

where we have defined vectors $\boldsymbol{a} \overset{\text{def}}{=} [a_1 \; a_2 \cdots a_M]^T$ and $s_n \overset{\text{def}}{=} [s_{n-1} \; s_{n-2} \; \cdots \; s_{n-M}]^T$.

A model of form equation 3.8 driven by a zero-mean, uncorrelated (white) sequence, it is called an **autoregressive** (AR) **model** by time-series analysts. The output of an AR model of order M, denoted AR(M), is said to "(linearly) regress on itself," meaning that the present value s_n is a linear combination of (or a **prediction** based on) its past M values plus a component, $H_0 e_n$, which is not predictable from any data, past or future.

Let us assume for the moment that $\{e_n\}$ is indeed stationary white noise, so $\{s_n\}$ is a stationary random process. In light of the difference equation 3.8, a natural way to estimate the parameters of a signal believed to follow an AR(M) model is to design an FIR filter that attempts to "predict" s_n from its past M values. Let us denote the estimated filter parameters by $\{\hat{a}_i\}_{i=1}^{M}$ and the prediction at time n by $\hat{s}_n$:

$$\hat{s}_n = \hat{a}_1 s_{n-1} + \hat{a}_2 s_{n-2} + \cdots + \hat{a}_M s_{n-M} = \hat{\boldsymbol{a}}^T s_n, \tag{3.9}$$

in which the vector $\hat{\boldsymbol{a}} \in \mathbb{R}^M$ is defined similarly to $\boldsymbol{a}$ in equation 3.8. In accordance with the AR model, the parameters, $\hat{\boldsymbol{a}}$, should be chosen to account for all but an unpredictable component, $\{H_0 e_n\}$, in $\{s_n\}$. That is, we seek $\hat{\boldsymbol{a}}$ such that:[11]

$$\hat{e}_n = s_n - \hat{\boldsymbol{a}}^T s_n \approx H_0 e_n \quad \text{(a white-noise sequence of variance } H_0^2\text{)}. \tag{3.10}$$

The sequence $\{\hat{e}_n\}$, which represents the error in prediction at each n, is called the **prediction residual**.

Using the **orthogonality principle** from optimization theory (Haykin, 1996), it can be shown that selecting parameters $\{\hat{a}_i\}$ such that $\{\hat{e}_n\}$ has minimum power (i.e., minimum $\mathcal{E}\{\hat{e}_n^2\}$ in which $\mathcal{E}$ denotes the statistical expectation) will also result in the desired spectral whiteness of $\{\hat{e}_n\}$. Therefore, we seek $\hat{\boldsymbol{a}}$ that minimizes the **mean squared error** (MSE) in prediction; that is:

$$\begin{aligned}\hat{\boldsymbol{a}} &= \underset{\boldsymbol{a}}{\operatorname{argmin}}\; \mathcal{E}\{\hat{e}_n^2\} = \underset{\boldsymbol{a}}{\operatorname{argmin}}\; \mathcal{E}(s_n - \boldsymbol{a}^T \boldsymbol{s}_n)^2 \\ &= \underset{\{a_i\}}{\operatorname{argmin}}\; \mathcal{E}\left(s_n - \sum_{i=1}^{M} a_i s_{n-i}\right)^2\end{aligned} \tag{3.11}$$

[11] The approximation should be taken to mean that $\{\hat{e}_n\}$ and $\{H_0 e_n\}$ are approximately the "same stochastic process."

The well-known solution is the unique parameter vector solving the system of **normal equations**:

$$\bar{\boldsymbol{R}}_s \hat{\boldsymbol{a}} = \bar{\boldsymbol{r}}_s, \qquad (3.12)$$

in which $\bar{\boldsymbol{R}}_s \in \mathbb{R}^{M<M}$ is the **autocorrelation matrix** for the process $\{s_n\}$ [i.e., a matrix whose (i, k) element is $\bar{r}_{s;k-i} = \mathcal{E}\{s_{n-i}s_{n-k}\}$] and $\bar{\boldsymbol{r}}_s \in \mathbb{R}^M$ is an auxiliary vector of autocorrelations $\bar{\boldsymbol{r}}_s = \left[\bar{r}_{s;1} \ \cdots \ \bar{r}_{s;M}\right]^T$. The overbars are to distinguish the correlation quantities as statistical expectations rather than time averages.

In the voiced case, where $\{e_n\}$ is modeled as a periodic DT impulse train, the normal equations are used without modification except that the statistical autocorrelations must be replaced by long-term time averages because the speech waveform is deterministic. This approach can be shown to produce unbiased results as the pitch period becomes infinite. Generally speaking, the analysis works satisfactorily for voiced speech for most pitch ranges encountered in applications although performance predictably degrades for very high-pitched utterances that are more typical of women's and children's voices (Deller *et al.*, 2000).

Practical Solutions of the Normal Equations

Frame-Wise Normal Equations

In practice, the parameters must be identified using finite signal records with nominally constant dynamics—typically 10 to 20 ms. Let us denote the block of samples over which the analysis takes place by $n \in \{0, N-1\}$. There are two methods conventionally used to estimate the LP parameters in speech processing.

In the **autocorrelation method**, the solution takes the form of equation 3.12, with the statistical autocorrelations estimated by values of the **autocorrelation sequence**:

$$r_{s;k} = \sum_{n=0}^{N-1} s_n^w s_{n-k}^w, \quad k = 0, 1, \ldots, M, \qquad (3.13)$$

in which $s_n^w = s_n w_n$, where w_n is a data window (e.g., Hamming) of duration $N \geq M$ beginning at the time origin, $n = 0$. For future purposes, let us write the resulting system of equations in vector–matrix form as:

$$\boldsymbol{R}_s \hat{\boldsymbol{a}} = \boldsymbol{r}_s, \qquad (3.14)$$

in which the overbars have been dropped with respect to equation 3.12 to indicate the short-term temporal solution.

In the so-called **covariance method** the same solution form applies, but the statistical autocorrelations are estimated by values of the **covariance sequence**:

$$\phi_{s;i,k} = \sum_{n=0}^{N-1} s_{n-1} s_{n-k}, \quad i, k = 0, 1, \ldots, M. \qquad (3.15)$$

The $\bar{r}_{s;k-i}$ is estimated by $\phi_{s;i,k}$. The data are *not windowed* in this case. Let us denote the corresponding vector–matrix equation by:

$$\boldsymbol{\Phi}_s \hat{\boldsymbol{a}} = \phi_s. \qquad (3.16)$$

In addition to its interpretation as a temporally estimated version of the stochastic normal equations, each LP result can be derived as the solution to a short-term optimization problem (Deller *et al.*, 2000).

Autocorrelation Method and Lattice Structures

In either the autocorrelation or covariance solution, obtaining the final LP parameter estimate, $\hat{\boldsymbol{a}}$, ultimately requires the solution of a matrix–vector equation of the form $\boldsymbol{Ax} = \boldsymbol{b}$, in which $\boldsymbol{A}$ is a square matrix that is reasonably assumed to be of full rank, M. This is a widely studied problem for which numerous methods exist (Golub and van Loan, 1989). Solutions to general problems of this form tend to be of $\mathcal{O}(M^3)$ computational complexity.

In the autocorrelation case, the symmetric and Toeplitz structure of the correlation matrix $\boldsymbol{R}_s$ is exploited to obtain numerical and computational $[\mathcal{O}(M^2)]$ benefits as well as an alternative view of the solution that leads to the so-called **lattice** methods. The basis for the more efficient solution is the **Levinson-Durbin** (L-D) **recursion** (Deller *et al.*, 2000; Haykin, 1996; Golub and van Loan, 1989), a **recursive-in-model-order** solution (see Figure 3.7). By this we mean that, using the fixed block of windowed data at each iteration, $\{s_n^w\}_{n=0}^{N-1}$, the solution for the desired order M model is successively built up from lower order models, beginning with the "zero order predictor," which is no predictor at all ($\hat{s}_n = 0$ for every n). Associated with the ith iteration for each $i \in [0, M]$ is a sequence, say $\{\hat{e}_n^i\}$, that can be interpreted as the error in prediction associated with the ith order filter as well as a "backward" prediction error, say $(\hat{b}_n^i)$, corresponding to an attempt to predict the waveform on a reversed time axis (i.e., "backward prediction" in time). Each stage is also characterized by a **parcor** (short for *partial correlation*) **coefficient** or **reflection coefficient**, the ith one of which, say k_i, can be interpreted as a proportion of the amount of "forward error" from stage i that is reflected back as backward error as the forward error propagates into the $(i+1)$st stage. Figure 3.8 illustrates the **analysis lattice**, so-named because it takes the speech as input, sequentially analyzes its dynamics to return only the unpredictable error sequence as output. It is a simple matter to reverse the flow of the lattice to create a **synthesis lattice** that reconstructs the speech from the (forward) error signal (Deller *et al.*, 2000).

As the name suggests, reflection coefficients, $\{\kappa_i\}_{i=1}^M$, bear a strong formal relationship to acoustic reflection coefficients associated with the vocal-tract acoustic-tube model briefly discussed in Section 3.2.2, with the forward and backward errors analogous to similar flow quantities in the model. This

Initialization: For $\ell = 0$,
$\xi^0 =$ scaled total energy in the "error" from an "order-0" predictor
$=$ average energy in the speech frame $\{s_n^w\}_{n=0}^{N-1} = r_{s;\,0}$

Recursion: For $\ell = 1, 2, \ldots, M$:

1. Compute the ℓth reflection coefficient, $\kappa_\ell = \frac{1}{\xi^{\ell-1}}\left\{r_{s;\,\ell} - \sum_{i=1}^{\ell-1} \hat{a}_i^{\ell-1} r_{s;\,\ell-i}\right\}$.
2. Generate the order-ℓ set of LP parameters:

$$\hat{a}_\ell^\ell = \kappa_\ell.$$
$$\hat{a}_i^\ell = \hat{a}_i^{\ell-1} - \kappa_\ell \hat{a}_{\ell-i}^{\ell-1},\ i = 1, \ldots, \ell - 1.$$

3. Compute the error energy associated with the order-ℓ solution, $\xi^\ell = \xi^{\ell-1}\{1 - \kappa_\ell^2\}$.
4. Return to step 1 with ℓ replaced by $\ell + 1$ if $\ell < M$.

FIGURE 3.7 The Levinson-Durbin Recursion. The recursion is applied to the time frame $n = 0, 1, \ldots, N - 1$.

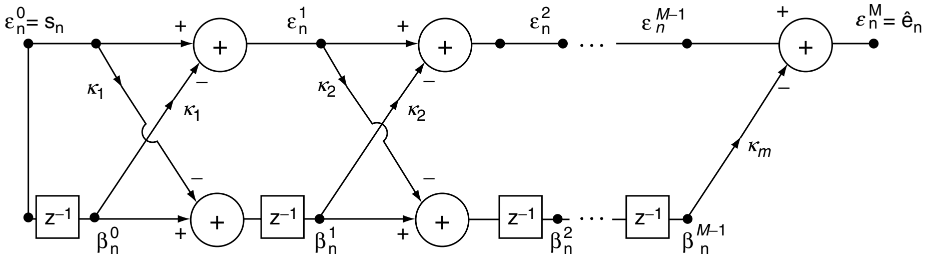

FIGURE 3.8 Analysis Lattice Structure

is a manifestation of the physics of the all-pole system in the mathematics of the DT model. The set $\{\kappa_i\}_{i=1}^M$ contains equivalent information to the set of LP coefficients, as is evident from the fact that the reflection coefficients can be used to reconstruct the speech from the error signal $\{\hat{e}_n\}$. The reflection coefficients are often used as alternatives to the LP parameters in compression and coding schemes because of their desirable numerical property of having a restricted dynamic range (in theory), $|\kappa_i| < 1$ for all i. (Deller *et al.*, 2000). Checking the reflection coefficients for this property on an iteration-by-iteration basis in the L-D recursion offers a convenient check for numerical stability.

Further topics related to lattice structures and reflection coefficients include formulations that compute reflection coefficients independently of the LP parameters (Itakura and Saito, 1969; Burg, 1967) sets of parameters that are related to, or are transformations of, reflection coefficients (Deller *et al.*, 2000; Viswanathan and Makhoul, 1975; and Itakura, 1975); and more efficient lattice structures (Makhoul, 1977; Strobach, 1991).

Decomposition Methods for the Covariance Solution

The covariance method equations to be solved are of the form of equation 3.16. Similar to the autocorrelation matrix $\boldsymbol{R}_s$, the covariance matrix $\boldsymbol{\Phi}_s$ is symmetric and positive definite. Unlike $\boldsymbol{R}_s$, however, $\boldsymbol{\Phi}_s$ it is not Toeplitz, so there is less structure to exploit the solution. The most common solution methods are based on the decomposition of the covariance matrix into lower and upper triangular matrices, say $\boldsymbol{L}$ and $\boldsymbol{U}$, such that $\boldsymbol{\Phi}_s = \boldsymbol{LU}$. Given this decomposition, equation 3.16 can be solved by sequentially solving $\boldsymbol{Ly} = \phi_s$ and $\boldsymbol{U}\hat{\boldsymbol{a}} = y$ in each case using simple algorithms (Golub and van Loan, 1989). The most efficient algorithms for accomplishing the $\boldsymbol{LU}$ decomposition are based on two methods from linear algebra (for symmetric matrices): the $\boldsymbol{LDL}^T$ **decomposition** and the **Cholesky** or **square root decomposition**. For details, see Golub and van Loan (1989). Specific algorithms are found in Deller *et al.* (2000) and Golub and van Loan (1989).

Comparisons and Further Notes

When approached as "batch" (i.e., nonlattice) solutions to the $\boldsymbol{Ax} = \boldsymbol{b}$ problem according to the methods described above, the solution methods are of $\mathcal{O}(M)$ complexity, with the autocorrelation method being slightly, but insignificantly, more efficient. Variations exist on the general algorithms discussed above, some being more efficient than others (Markel and Gray, 1976), but all commonly used methods are of $\mathcal{O}(M)$ complexity.

Factors other than computational burden must be considered in choosing between the two general methods. Stability of the solution, for example, can be an important consideration. The autocorrelation solution is theoretically guaranteed to represent a stable filter if infinite precision arithmetic is used. In practice, the L-D recursion contains a built-in check

($|\kappa_i| \leq 1$) for instabilities arising from finite-precision computations. No such theoretical guarantee nor numerical check is available in the covariance case.

The lattice approaches are the most computationally expensive of the conventional methods but are among the most popular because they offer the inherent ability to directly generate the parcor coefficients to monitor stability and to deduce appropriate model orders "online".

Finally, the popularity of the autocorrelation method notwithstanding, the covariance method has an important property that can be very significant in certain applications. In fact, the covariance approach is precisely equivalent to the classical least square error (LSE) solution of an overdetermined system of equations (Golub and van Loan, 1989). This fact can be exploited to develop alternative solutions (Deller *et al.*, 2000; McWhiter, 1983; Deller and Odeh, 1993).

Estimating the Model Order and Gain

In practice, the "true" order of the system of equation 3.6 is unknown. A generally accepted rule of thumb is to allocate one pole pair per kilohertz of Nyquist bandwidth; then, if the segment is voiced, one can add an additional four or five (whichever makes the total even) (Markel and Gray, 1976). Since the order of the model would ordinarily not be changed from frame to frame, the "extra" four or five would be included for unvoiced speech frames. Hence, we choose:

$$M = F_s + \{4 \text{ or } 5\} \quad (F_s = \text{sampling frequency in kHz}). \tag{3.17}$$

The pole-pair per kHz rule is based on the fact that speech spectra tend to have about one formant (which can ordinarily be modeled by a resonant pole pair) per kHz (Fant, 1956). The supplemental poles are needed in the voiced case to account for the glottal shaping filter and to generally allow some flexibility in fitting the model to the speech spectrum.

An experimental technique for determining an appropriate value for M is to study the sum of squared errors, either $\xi_{\text{autoc}} = \sum_{n=0}^{N+M-1} (\hat{s}_n^w - s_n^w)^2$ (autocorrelation method) or $\xi_{\text{cov}} = \sum_{n=0}^{N-1} (\hat{s}_n - s_n)^2$ (covariance), as a function of M. Each is a nonincreasing function of M, and each will tend to reach a point of diminishing returns in the neighborhood of the value of M suggested in equation 3.17. For unvoiced speech, the asymptote will be reached before the four or five supplemental poles in this equation are added. In the unvoiced case, ξ_{autoc} and ξ_{cov} will also tend to level off at a higher final value than the respective values in the voiced case, suggesting that the LP model is not as accurate for the former. Note that ξ_{autoc} as a function of M is a byproduct of the L-D recursion so that the solution method itself can be used to ascertain an appropriate model size.

Finally, to have a completely specified model, we need a means for estimating the gain parameter, H_0. The relative gain from frame to frame is clearly important for proper resynthesis of a speech waveform, for example. By some straightforward manipulations involving the difference equations 3.8 and 3.9, two sets of approximations are obtained (Deller *et al.*, 2000). These are as follows:

$$\hat{H}_0 = \begin{cases} \sqrt{r_{s;0} - \sum_{i=1}^{M} \hat{a}_i r_{s;i}}, & \text{unvoiced case.} \\ \sqrt{P[r_{s;0} - \sum_{i=1}^{M} \hat{a}_i r_{s;i}]}, & \text{voiced case, } (P = \text{pitch period}). \end{cases} \tag{3.18}$$

$$\hat{H}_0 = \begin{cases} \sqrt{r_{\hat{e};0}} = \sqrt{\xi_{\text{autoc}}}, & \text{unvoiced case.} \\ \sqrt{P r_{\hat{e};0}} = \sqrt{P \xi_{\text{autoc}}}, & \text{voiced case, } (P = \text{pitch period}). \end{cases} \tag{3.19}$$

Each of these expressions assumes that the autocorrelation method is used. For the covariance method, the values $\phi_{s;o,i}$, are inserted in place of the $r_{s;i}$ in equation 3.18. In equation 3.19, $\phi_{\hat{e};0,0}$ and ξ_{cov} are similarly substituted.

3.3.3 Cepstral Analysis

The Cepstrum

As its name suggests, **cepstral analysis** represents a variation on speech **spectral** analysis. The nominal goal of cepstral processing is a representation of a voiced speech signal, the **cepstrum**, in which the excitation information is separated, or **deconvolved** from the dynamics of the speech system impulse response. With such a representation, the speech system dynamics and the excitation signal can be studied, coded, and manipulated separately. Applications of the cepstrum have included pitch detection (using the voice component) and "homomorphic" vocoding (using the speech production system component of the cepstrum to derive an efficient representation of the speech dynamics) (Deller *et al.*, 2000; Rabiner and Huang, 1993). The history of the cepstrum is interesting and the details of the theory are extensive. The objective of this treatment is to present an overview of the main concepts and then focus on a modern application of the cepstrum in which most of the connections to the original motivations and theoretical underpinnings are obscured.

Cepstral analysis is a special case within a class of methods collectively known as **homomorphic signal processing**. Historically, the discovery and use of the cepstrum by Bogert, Healy, and Tukey (1963) and Noll (1967) predate the formulation of the more general homomorphic SP approach by Oppenheim and Schafer (1968). In fact, the earlier cepstrum is a special case of a more general cepstrum, which, in turn, is a special instance of homomorphic processing. When it is not clear from context, the cepstrum derived from homomorphic processing is called the **complex cepstrum** (even though the version of it used is ordinarily *real*-valued!), while the original Bogert–Tukey–Healy cepstrum is called the **real cepstrum**.

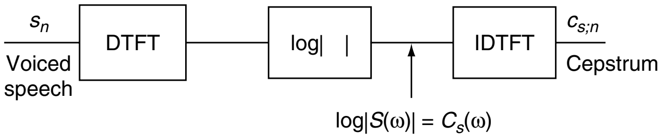

FIGURE 3.9 Computation of the Real Cepstrum

We use the term *cepstrum* and restrict attention to the simpler *real cepstrum*. In fact, there are various definitions of the real cepstrum, but all are equivalent to the even part of the complex cepstrum to within a scale factor.

In spite of its connection to the spectrum, the cepstrum is actually a sequence indexed by time, say $\{c_{s;n}\}$, representing the speech sequence $\{s_n\}$. The set of operations leading to $\{c_{s;n}\}$ is depicted in Figure 3.9. The first two operations can be interpreted as an attempt to transform the signal $\{s_n\}$ into a "linear" domain in which the two parts of the signal that are convolved in the unaltered signal have representatives that are added in the new domain. Let us denote by $\mathcal{Q}$ the operation corresponding to the first two boxes in the figure. Then:

$$\begin{aligned} C_s(\omega) &= \mathcal{Q}\{s_n\} = \log|S(\omega)| = \log|E(\omega)H(\omega)| \\ &= \log|E(\omega)| + \log|H(\omega)| = C_e(\omega) + C_h(\omega). \end{aligned} \tag{3.20}$$

In the linear domain, we are able to apply familiar linear techniques to the new signal, $C_s(\omega)$. In particular, we might wish to apply Fourier analysis to view the frequency domain properties of the new signal. Because $C_s(\omega)$ is a *periodic* function of ω, it is appropriate to compute the Fourier series coefficients for the "harmonics" of the signal. These would take the form:[12]

$$\alpha_n = \frac{1}{2\pi}\int_{-\pi}^{\pi} C_s(\omega)e^{-j\omega n}d\omega. \tag{3.21}$$

Now, according to the definition:

$$c_{s;n} = \frac{1}{2\pi}\int_{-\pi}^{\pi} C_s(\omega)e^{j\omega n}d\omega, \tag{3.22}$$

but $C_s(\omega)$ is a real, even function of ω, so that equations 3.21 and 3.22 produce equivalent results.[13] Therefore, the cepstrum can be interpreted as the Fourier series "line spectrum" of the "signal" $C_s(\omega)$.

In practice, the cepstrum would be computed over a frame of, say, length N, using a DFT–IDFT pair. Suppose that we seek the cepstrum of the frame (possibly windowed) $\{s_n\}_{n=0}^{N-1}$. Then, we would compute:

$$C_{s;k} = \log\left|\sum_{n=0}^{N-1} s_n e^{-j\frac{2\pi}{N}kn}\right|, \quad \text{for } k = 0, 1, \ldots, N-1 \quad \text{(log magnitude spectrum).} \tag{3.23}$$

$$c_{s;n} = \sum_{k=0}^{N-1} C_{s;k}e^{j\frac{2\pi}{N}kn}, \quad \text{for } n = 0, 1, \ldots, N-1 \quad \text{(cepstrum).} \tag{3.24}$$

Because the cepstrum is an infinitely long sequence, care must be taken to avoid aliasing in the cepstral domain (by zero padding, often unnecessary) and to account for the artificial periodicity of the result.

In the introduction above, quotation marks appear around terms that are used in an unusual manner. The signal that is being transformed into the frequency domain is, in fact, *already* in what we ordinarily consider the frequency domain. Therefore the "new" frequency domain was dubbed the **quefrency domain** by Tukey in the earlier work on the cepstrum, and the *cepstrum* was so named because it plays the role of a *spectrum* in the quefrency domain. The index of the cepstrum (which actually represents DT) is called the **quefrency axis**. The harmonic frequencies of $C_s(\omega)$, which are actually time indices of the cepstrum, are called **rahmonics**. There is an entire vocabulary of amusing terms that accompanies cepstral analysis [see the title of the paper by Bogert *et al.* (1996)], but only the terms *cepstrum* and *quefrency* (and sometimes *liftering*, a concept discussed next, are widely used by speech processing engineers.

The stated purpose of the cepstrum is to resolve the two convolved pieces of the speech, $\{e_n\}$ and $\{h_n\}$, into two additive components, then to analyze those components with spectral (cepstral) analysis. From equation 3.20:

$$c_{s;n} = c_{e;n} + c_{h;n}, \tag{3.25}$$

and if the nonzero parts of $c_{e;n}$ and $c_{h;n}$, occupy different parts of the quefrency axis, we should be able to examine them as separate entities—something that we are unable to do when they are convolved in $\{s_n\}$. In fact, the excitation component, $\{c_{e;n}\}$, tends to have most of its energy at relatively large (and "rahmonically spaced") values of n, since its quefrency domain counterpart manifests fast, periodic variations. The use of a time window to select out the component due to the excitation, $\{c_{e;n}\}$, has been called **high-time liftering** to stress the analogy to high-pass filtering. For similar reasons, the vocal

[12] Note that function $C_s(\omega)$ is periodic on the ω axis where its fundamental "period" is $\omega_s = 2\pi$. The role of the fundamental "frequency" in this formulation is the quantity $T_s = \omega_s/2\pi = 1$. Hence, the harmonic frequencies are the numbers $nT_s = n$, $n \geq 0$.

[13] In fact, since $C_s(\ \omega)$ is even, the IDTFT in the definition can be replaced by a **cosine transform**:

$$c_{s;n} = \frac{1}{2\pi}\int_{-\pi}^{\pi} C_s(\omega)\cos(\omega n)d\omega = \frac{1}{\pi}\int_{0}^{\pi} C_s(\omega)\cos(\omega n)d\omega.$$

system component, $\{c_{h;n}\}$, appears at very low quefrencies and can be extracted using a **low-time lifter.**

Mel Cepstrum

In the 1980s, the cepstrum began to supplant the direct use of the LP parameters as the premier features in speech recognition because of two convenient enhancements that improve performance (Davis and Mermelstein, 1980). The first is the ability to easily smooth the spectrum using the liftering process described above. This process removes the inherent variability of the LP-based spectrum due to the excitation. A second improvement over direct use of the LP parameters can be obtained by use of the so-called **mel-cepstrum**.

In principle, the mel cepstrum represents a set of features that are more similar (than those derived uniformly over the frequency spectrum) to those used by the human auditory system in sound perception. A **mel** is a unit of measure of **perceived pitch** or **frequency** of a tone. It does not correspond linearly to the physical frequency of the tone because the human auditory system does not perceive pitch in this linear manner (Stevens and Volkman, 1940; Koenig, 1949). The mapping between real frequencies, say F_{Hz}, and perceived frequency, say F_{mel}, is approximately (Fant, 1959):

$$F_{\text{mel}} \simeq \frac{1000}{\log 2}\left[1 + \frac{F_{\text{Hz}}}{1000}\right], \tag{3.26}$$

in which F_{mel} (F_{Hz}) is the perceived (real) frequency in mels or Hz.

The cepstrum is particularly well-suited to working with a warped frequency axis since it is based directly on the magnitude spectrum of the speech. Suppose one desires to compute the cepstral parameters at frequencies distributed linearly on the range 0–1 kHz and logarithmically above 1 kHz. One approach is to "oversample" the frequency axis with the DFT–IDFT pair by using, say, a $N' = 1024$ or 2048 point DFT, then selecting those frequency components in the DFT that represent the appropriate distribution. The remaining components can be set to zero, or, more commonly, a second psychoacoustic principle is invoked.

Loosely speaking, it has been found that the perception of a particular frequency by the auditory system, say F', is influenced by energy in a **critical band** of frequencies around F' (O'Shaughnessy, 1987). Further, the bandwidth of these critical bands varies with frequency, beginning at about 100 Hz for frequencies below 1 kHz, then increasing logarithmically above 1 kHz. Therefore, rather than simply using the mel-distributed log magnitude frequency components to compute the cepstrum, it has become common to use the **log total energy** in critical bands around the mel frequencies as inputs to the final DFT. The energy components in each critical band are weighted by a **critical band filter** to account for their relative influences in the band (Davis and Mermelstein, 1980; Dautrich *et al.*, 1983). A detailed description of this computastion is found in Chapter 6 of Deller *et al.* (2000).

Delta Cepstrum

Another popular feature in speech recognition is the delta cepstrum. If $\{c^m_{s;n}\}$ denotes the (mel-) cepstrum or for the mth frame of the signal $\{s_n\}$, then the **delta** or **differenced cepstrum** at frame m is defined as:

$$\Delta c^m_{s;n} \overset{\text{def}}{=} c^{m+\delta}_{s;n} - c^{m-\delta}_{s;n}, \tag{3.27}$$

for all n. The parameter δ is chosen to smooth the estimate and typically takes a value of 1 or 2 (look forward and backward one or two frames). A vector of such features at relatively low ns (quefrencies) intuitively provides information about spectral changes that have occured since the previous frame although the precise meaning of $\Delta c^m_{s;n}$ for a particular n and m is difficult to ascertain.

A generalization and enhancement on the delta cepstrum is represented by the **shifted delta cepstrum** (SDC) (Bielefeld, 1994) in which a set of flexible parameters is used to construct enhanced cepstral vectors. The SDC has been shown to be beneficial in limited study (Bielefeld, 1994; Torres-Carrasquillo *et al.*, 2002).

Typically, 8 to 14 cepstral coefficients and their differences are used as features for speech recognition (Deller *et al.*, 2000; Rabiner and Juang, 1993; Juang *et al.*, 1987).

Log Energy

The measures $c_{s;0}$ and $\Delta c_{s;0}$ are often used as relative measures of spectral energy and its change. For the cepstrum, inserting $\log|S(\omega)|$ for $C_s(\omega)$ in equation 3.22, then evaluating at $n = 0$, we see that $c_{s;0}$ differs by a factor of two from the area under the log energy density spectrum. In the practical case in which the IDFT is used in the final operation, this becomes $c_{s;0} = N^{-1}\sum_{k=0}^{N-1}\log|S_k|$ that has a similar interpretation. In the case of the mel-cepstrum, the sum of all critical band energies provides a measure of total spectral energy.

3.3.4 Traditional Search and Pattern Matching Algorithms

Introduction

Pattern recognition and matching and related problems in optimal search play key roles in speech processing. In this subsection, we examine some critical algorithms related to these tasks. The main objective of this material is to introduce the **hidden Markov model** (HMM), a critical technology that serves as a foundation for many aspects of modern speech recognition systems. The HMM can be considered to be a stochastic form of the widely used (across many disciplines and applications) search method known as **dynamic programming** (DP). After treating some general issues in pattern recognition, we begin by studying the DP foundation, then progress to the specific DP-based speech algorithms.

Similarity Measures and Clustering

Underlying all statistical pattern matching problems is the need to have objective measures of similarity among objects and the related problem of grouping objects into clusters whose elements are similar in some sense. Here, we touch on four interrelated classes of pattern-matching problems that occur in specific contexts in speech processing. We return to the clustering problem at the end of the section.

The first problem involves the relatively straightforward task of determining a measure of similarity between sets of features resulting from the analysis of two frames of speech. When features composing the feature vectors represent uncorrelated pieces of information with similar scales (e.g., outcomes of uncorrelated random variables with equal variances), then the widely used Euclidean distance is an appropriate measure of similarity between the vectors. Such is the case, for example, with cepstral coefficients because the parameters are coefficients of a Fourier series and, therefore, represent an expansion on an orthogonal set of basis functions. Determining the "distance" between (models represented by) two sets of LP parameters, however, is a common task for which the Euclidean distance is not appropriate because the LP parameters are highly correlated. For this problem, some variation of the **Itakura distance** measure (Itakura, 1975) (discussed next) is often used.

The LP parameter-matching problem can be considered as an example of the first class of pattern-matching problem—that of assessing the similarity between two feature vectors. It also, however, belongs to a second class of problems important to speech processing, that of assessing similarity between two *models*.[14] The Itakura distance is used to measure intermodel distance reflected in LP vectors. To understand the Itakura distance, consider two LP models, say $\hat{\boldsymbol{a}}$ and $\hat{\boldsymbol{b}}$, derived using two different windowed sequences of data, say $\mathcal{X} = \{x_n^{\omega}\}_{n=0}^{N-1}$ and $\mathcal{Y} = \{y_n^{\omega}\}_{n=0}^{N-1}$. The Itakura distance is given by:

$$d_1(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}}) \overset{\text{def}}{=} \log \frac{\tilde{\boldsymbol{b}}^T \tilde{\boldsymbol{R}}_x \tilde{\boldsymbol{b}}}{\tilde{\boldsymbol{a}}^T \tilde{\boldsymbol{R}}_x \tilde{\boldsymbol{a}}}, \tag{3.28}$$

where

$$\tilde{\boldsymbol{R}}_x \overset{\text{def}}{=} \begin{bmatrix} r_{x;0} & \boldsymbol{r}_x^T \\ \boldsymbol{r}_x & \boldsymbol{R}_x \end{bmatrix}, \quad \tilde{\boldsymbol{a}} \overset{\text{def}}{=} \begin{bmatrix} 1 \\ -\hat{\mathbf{a}} \end{bmatrix}, \quad \text{and } \tilde{\boldsymbol{b}} \overset{\text{def}}{=} \begin{bmatrix} 1 \\ -\hat{\boldsymbol{b}} \end{bmatrix}, \tag{3.29}$$

in which $\boldsymbol{R}_x$ and $\boldsymbol{r}_x$ have as elements the short-term autocorrelations of the data (i.e., $\mathcal{X}$) used to estimate $\hat{\boldsymbol{a}}$ (Schafer and Markel, 1979). If we let $\xi_{\hat{a}}$ be the total squared error incurred in predicting $\mathcal{X}$ using $\hat{\boldsymbol{a}}$ and $\xi_{\hat{b}}$ be the total squared error in predicting $\mathcal{X}$ using $\hat{\boldsymbol{b}}$, then it is not difficult to show that $d_I(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}}) = \log(\xi_{\hat{b}}/\xi_{\hat{a}})$; hence, the measure gives an indication of how "far" from optimal is the estimate of $\hat{\boldsymbol{b}}$. The Itakura distance is always positive because the denominator yields the smallest possible value of ξ.

The sense of the Itakura distance is to measure similarity between models, but it is based, in fact, on the measurements of the distances from *sequences* to models. These measurements indirectly provide the intermodel distance. Assessment of **sequence-to-model** similarity is a third important class of pattern-matching problems occurring in speech processing. Such problems figure prominently in an array of modern speech-processing technologies, including speech and speaker recognition, speaker identification, speaker verification, language identification, and accent recognition (Rabiner and Juang, 1993). In nearly every case, the model is a statistical representation of the production of sequences associated with that model's class or entity (e.g., a word, a language, a speaker). The "distance" between a sequence consists of some likelihood measure that the model in question is coherent with the given sequence. The discussion later in this chapter of speech recognition using the HMM provides a prime example of this strategy.

A fourth important class of pattern-matching problems occurring in speech processing is that of assessing similarity between two **sequences**. The line between this class and the one immediately preceeding is not distinct because one may consider a particular sequence as a "model" for a given class or entity (e.g., a word), or several sequences may be combined in some manner to produce a "model sequence" for a particular entity. Older techniques in speech recognition and related problems in particular, "dynamic time warping" (discussed later) rely on such direct measures of intersequence distance. Coding and decoding problems in speech processing routinely deploy such techniques as well. The upcoming discussions will provide ample illustration.

Finally, we return to the clustering problem. **Clustering** refers to the act of categorizing J objects into $K \leq J$ classes or categories according to strategies that maximize intraclass similarity and minimize interclass similarity. Clustering methods are numerous and varied depending on the application, types of measurements available, similarity measures used, as well as other factors (Devijver and Kittler, 1982). Although cluster formation often employs feature-to-feature matching (i.e., "objects" represented by features or feature vectors), the "objects" can be sequences or models as well. Thus, any of the pattern-matching problems already discussed may figure into the clustering procedure.

The need for clustering arises in many speech processing applications. Again, the HMM provides two important examples. These include clustering procedures for "codebook" formation for the so-called discrete-observation HMM and

[14] A second important example of model-to-model distance occurs in the assessment of the similarity of HMMs. These models are discussed later in this chapter.

clustering for Gaussian mixture model formation for continuous-observation HMMs. In each case, the **K-means algorithm** (Deller *et al.*, 2000; Devijver and Kittler, 1982) is ordinarily used. In this popular method, the initial measurements are subdivided into K distinct groups. The average feature vector, or **centroid** in each group is used as the exemplar feature for that group. The entire population of measurements is then assigned to the group to which it is closest according to the similarity measure used. The centroids are recomputed. The process is repeated until no measurement changes classes.

Dynamic Programming

Dynamic programming (DP) has a rich and varied history in mathematics (Silverman and Morgan, 1990; Bellman, 1957). DP as we discuss it here is actually a special class of DP problems that is concerned with discrete sequential decisions.

Let us first view DP in a general framework. Consider a "grid" in the plane where discrete points or **nodes** of interest are, for convenience, indexed by ordered pairs of non-negative integers as though they are points in the first quadrant of the Cartesian plane. The basic problem is to find a "shortest distance" or "least cost" path through the grid that begins at a designated **original node**, (0,0), and ends at a designated **terminal node**, (I, J). A **path** from node (i_0, j_0) to node (i_N, j_N) is an ordered set of nodes (index pairs) of the form $(i_0, j_0), (i_1, j_1), (i_2, j_2), (i_3, j_3), \ldots, (i_N, j_N)$, where the intermediate (i_k, j_k) pairs are not, in general, restricted.

Distances, or **costs**, may be assigned to nodes or transitions (arcs connecting nodes) along a path in the grid, or both. Suppose that we focus on a node with indices (i_k, j_k). Let us define the notation as:

$$\begin{aligned}
D[(i_0, j_0), (i_1, j_1), \ldots, (i_N, j_N)] &\overset{\text{def}}{=} \text{distance associated with the path } (i_0, j_0), (i_1, j_1), \ldots, (i_N, j_N);\\
D_{\min}(i_k, j_k) &\overset{\text{def}}{=} \text{distance from}(0,0) \text{ to } (i_k, j_k) \text{ over the best path; and}\\
d[(i_k, j_k)|(i_{k-1}, j_{k-1})] &\overset{\text{def}}{=} \textbf{transition cost} \text{ from node } (i_{k-1}, j_{k-1}) \text{ to node } (i_k, j_k)\ \odot\ \textit{node cost} \text{ incurred upon entering node } (i_k, j_k),
\end{aligned} \tag{3.30}$$

where "$\odot$" indicates the rule (usually addition or multiplication) for combining these costs. This total cost is first-order Markovian in its dependence on the immediate predecessor node only. The distance measure d is ordinarily a non-negative quantity, and any transition originating at (0,0) is usually costless. Let us further define the notation:

$$(i_0, j_0) \rightarrow (i_N, j_N): \quad \text{best path (in the sense of optimal cost) from } (\mathrm{i}_0, \mathrm{j}_0) \text{ to } (i_N, j_N) \tag{3.31}$$

$$(i_0, j_0) \xrightarrow{(i', j')} (i_N, j_N): \quad \text{best path}(i_0, j_0) \text{ to } (i_N, j_N) \text{ that also passes through } (i', j'). \tag{3.32}$$

In these terms, the **Bellman Optimality Principle** (BOP) implies the following (Deller *et al.*, 2000; Bellman, 1957).

$$\left[(i_0, j_0) \xrightarrow{(i', j')} (i_N, j_N)\right] = \left[(i_0, j_0) \rightarrow (i', j')\right] \oplus \left[(i', j') \rightarrow (i_N, j_N)\right], \tag{3.33}$$

for any i_0, j_0, i', j', i_N, and j_N, such that $0 \le i_0, i', i_N \le I$ and $0 \le j_0, j', j_N \le J$; the $\oplus$ denotes concatenation of the path segments. In words, the BOP asserts that the best path from node (i_0, j_0) to node (i_N, j_N) that includes node (i', j') is obtained by concatenating the best paths from (i_0, j_0) to (i', j') and from (i', j') to (i_N, j_N).

Because it is consistent with most path searches encountered in speech processing, let us assume that a viable search path is always "eastbound" in the sense that for sequential pairs of nodes in the path, say $(i_{k-1}, j_{k-1}), (i_k, j_k)$, it is true $i_k = i_{k-1} + 1$; that is, each transition involves a move by one positive unit along the abscissa in the grid. DP searches generally have similar **local path constraints** to this assumption (Deller *et al.*, 2000). This constraint, in conjunction with the BOP, implies a simple, sequential update algorithm for searching the grid for the optimal path. To find the best path to a node (i, j) in the grid, it is simply necessary to try extensions of all paths ending at nodes with the previous abscissa index, that is, extensions of nodes $(i-1, p)$ for $p = 1, 2, \ldots, J$ and then choose the extension to (i, j) with the least cost. The cost of the best path to (i, j) is:

$$D_{\min}(i, j) = \min_{p \in [1,\, j]} \{D_{\min}(i-1, p) \odot d[(i, j)|(i-1, p)]\}. \tag{3.34}$$

Ordinarily, there will be some restriction on the allowable transitions in the vertical direction so that the index p above will be restricted to some subset of indices $[1, J]$. For example, if the optimal path is not permitted to go "southward" in the grid, then the restriction $p \not< j$ applies.

Ultimately, node (I, J) is reached in the search process through the sequential updates, and the cost of the globally optimal path is $D_{\min}(I, J)$. To actually locate the optimal path, it is necessary to use a **backtracking** procedure. Once the optimal path to (i, j) is found, we record the immediate predecessor node, nominally at a memory location attached to (i, j). Let us define:

$$\psi(i, j) \overset{\text{def}}{=} \text{index of the predecessor node to } (i, j) \text{ on the minimum cost path from } (0, 0) \text{ to } (i, j). \tag{3.35}$$

```
Initialization:  "Origin" of all paths is node (0,0).
                 For $j = 1, 2, \ldots, J$.
                 $D_{\min}(1, j) = d[(1, j)|(0, 0)]$.
                 $\psi(1, j) = (0, 0)$.

Recursion:       For $i = 2, 3, \ldots, I$.
                     For $j = 1, 2, \ldots, J$.
                     Compute $D_{\min}(i, j)$ according to equation 3.34.
                     Record $\psi(i, j)$ according to equation 3.35.
                     Next $j$
                 Next $i$

Termination:     Distance of optimal path from (0,0) to $(I, J)$ is $D_{\min}(I, J)$.
                 Best path is found by backtracking.
```

FIGURE 3.10 Example Dynamic Programming Algorithm for the Eastbound Salesperson Problem.

If we know the predecessor to any node on the path from (0, 0) to (i, j), then the entire path segment can be reconstructed by recursive backtracking beginning at (i, j).

As an example of how structured paths can yield simple DP algorithms, consider the problem of a salesperson trying to traverse a shortest path through a grid of cities. The salesperson is required to drive eastward (in the positive i direction) by exactly one unit with each city transition. To locate the best route into a city (i, j), only knowledge of optimal paths ending in the column just to the west of (i, j), that is, those ending at $\{(i-1, p)\}_{p=1}^{J}$, is required. A DP algorithm that finds the optimal path for this problem is shown in Figure 3.10.

There are many application-dependent constraints that govern the path search region in the DP grid. We mentioned the possibility of local path constraints that govern the local trajectory of a path extension. These local constraints imply **global constraints** on the allowable region in the grid through which the optimal path may traverse. Further, in searching the DP grid, it is often the case that relatively few partial paths sustain sufficiently low costs to be considered candidates for extension to the optimal path. To cut down on what can be an extraordinary number of paths and computations, a **pruning** procedure is frequently employed that terminates consideration of unlikely paths. This procedure is called a **beam search** (Deller *et al.*, 2000; Rabiner and Juang, 1993; Lowerre and Reddy, 1980).

3.4 Specialized Speech Processing Methods and Algorithms

3.4.1 Applied Dynamic Programming Methods

Dynamic Time Warping

Time alignment is the process by which temporal regions of a test utterance are locally matched with appropriate regions of a reference utterance. The need for time alignment arises not only because different utterances of the same word generally have different durations but also because phones within words are also of different durations across utterances. In this section, we will focus on discrete utterances as the unit to be recognized. For the sake of discussion, we will assume the usual case in which these discrete utterances are words although there is nothing that precludes the use of these principles on subword or superword units.

Dynamic time warping (DTW) is a feature-matching scheme that uses DP to achieve time alignment between sequences of reference and test features. The brief description of DTW presented here is mostly of historical interest and for its value in introducing the HMM (Deller *et al.*, 2000; Rabiner and Juang, 1993; Silverman and Morgan, 1990) DTW has been successfully employed in simple applications requiring relatively straightforward algorithms and minimal hardware. The technique had its genesis in **isolated-word recognition** (IWR) in which words are deliberately spoken in isolation but has also been applied in a limited way to **continuous-speech recognition** (CSR) in which speech is produced naturally without concern for the recognition process. The approach to CSR using DTW has been called **connected-speech recognition** a sort of hybrid approach in which the continuous speech (spoken naturally or with minimal "cooperation" by the talker), is assumed to have been uttered as isolated words. The DTW process essentially concatenates isolated-word templates against which to match the flowing speech feature stream. Details and algorithms used in connected-speech recognition are found in Chapter 11 of Deller *et al.* (2000). Because DTW requires a template (or concatenation of templates) to be available for any utterance to be recognized, the method does not generalize well to accommodate the numerous sources of variation in speech. Therefore, DTW is not used for complex tasks involving large vocabularies.

Generally speaking, DTW is used to match an incoming **test word** (represented by a string of features) with numerous **reference words** (also represented by feature strings). The reference word with the best match score is declared the "recognized" word. In fairness to the correct reference string, the test features should be aligned with it in the manner that gives the best matching score to prevent time differences from unduly influencing the match. On the other hand, constraints on the matching process prevent unreasonable alignments from taking place.

The procedure by which a test word is assigned an optimal match score with respect to a reference string is straightforward. Both the test and reference utterances are reduced to strings of features extracted from the acoustic speech waveform. Let us denote the test utterance feature vectors by $\{\mathbf{t}_i\}_{i=1}^{I}$ and those of the reference utterance by $\{\mathbf{r}_j\}_{j=1}^{J}$, where i and j index the frames as we progress in time. The test and reference features are (conceptually, at least) laid out on the abscissa and ordinate of a grid much like that discussed previously in Section 3.3.4. Although the indices i and j denumerate frame numbers rather than absolute sample times, it is customary to refer to the i and j axes as "time" axes. Costs are assigned to each node in the grid, say node (i, j), according to some measure of distance between the feature vectors $\mathbf{t}_i$ and $\mathbf{r}_j$. With an appropriate set of transition costs for the grid, the feature mapping problem can clearly be posed as a minimum-cost path search through the $i - j$ plane, and we can solve the problem using DP.

Transition costs are sometimes explicitly or implicitly used to control the general trend of the candidate paths as well as the local trajectories at each step along a path.[15] For example, a horizontal transition into a node corresponds to the association of two sequential test frames with a single reference frame, whereas a unity slope transition into a node corresponds to the pairing of sequential frames in both the test and reference strings. The latter may be given a lower cost, for example, to promote a more linear path. Such local costs are often dependent on the short-term history of the path (e.g., one or two steps back) so that, for example, excessive numbers of test string features are not associated with a single reference feature vector. In addition to the local trajectory costs, hard constraints (effectively infinite transition costs) are placed on the search. These may include, for example, strict endpoint matching constraints [nodes (1, 1) and (I, J) must appear on any valid path] and a **monotonicity** requirement that a path may never take a "westward" trajectory at any step. The latter requirement ensures proper time sequencing of events in the utterance. These "soft" and "hard" **local constraints** on path trajectories imply **global constraints** on the overall search space. In turn, the restricted search space implies computational savings as certain node costs need not be computed. For further details on local and global constraints and conditions, see Deller *et al.* (2000), Rabiner and Juang (1993), and Myers *et al.* (1980).

A final issue of significance in the use of DTW is the development of an appropriate set of reference strings—the so-called **training problem**. DTW training is a problem to which there is no simple or well-formulated solution, and this fact represents one of the central contrasts between the DTW method and the pervasive HMM approach. Unlike the DTW reference models, the HMM can be trained in a "supervised" paradigm in which the model can learn the statistical makeup of the exemplars. The application of the HMM to speech recognition in the 1980s was a revolutionary development, largely because of the supervised training aspect of the model. For more information on DTW training, see Deller *et al.* (2000).

Viterbi Decoding

Occurring in many important engineering tasks is a problem that can be solved by the DP search procedure when modified to accommodate stochastic node or transition costs or both. Such problems arise when the test or reference sequence, or both, are modeled by stochastic process(es) so that the search costs are random variables whose values depend on the outcome(s) of the stochastic process(es) to be matched. Given random test and reference sequences, the search costs can only be modeled as random variables. Once realizations of the test and reference sequences are available, however, the search can proceed as in the deterministic case with costs determined "online." Such a modified search procedure, called the **Viterbi algorithm** (Viterbi, 1967), plays a key role in the training and decoding of the HMM, to which we now turn.

3.4.2 The Hidden Markov Model

Introduction

In the 1970s and 1980s, speech researchers began to turn to stochastic approaches to modeling of speech in an effort to address the problem of variability, particularly in large-scale systems (Baker, 1975; Jelinek *et al.*, 1975). The term **stochastic approach** is used to indicate that models are employed that inherently characterize some of the variability in the speech. This is to be contrasted with the straightforward "deterministic" use of the speech data in template-matching (e.g., DTW) approaches in which no probabilistic modeling of variability is present.

Two very different types of stochastic methods have been researched. The first, the **hidden Markov model** (HMM), is amenable to computation on conventional sequential computing machines. Speech research has driven a majority of the engineering interest in the HMM in the last three decades, and the HMM has been the basis for several successful large-scale laboratory and commercial speech recognition systems. In contrast, the second class of stochastic techniques in speech recognition based on the **artificial neural network** (ANN) has been a small part of a much more general research effort to explore alternative computing architectures with some superficial resemblances to the massively parallel computing of biologic neural systems. ANNs have had relatively little impact on the speech field, and we will not pursue this topic here. Interested readers can refer to Morgan and Scofield (1991).

HMM Structure and Formulation

The HMM as an Automaton

An HMM can be viewed as a **stochastic finite-state automaton**—a type of abstract "machine" used to model the generation of a sequence of events or observations (Hopcroft and Ullman, 1979), in this case representing a speech utterance. The utterance may be a word, a subword unit, or, in principle, a sentence or paragraph. In small vocabulary systems, the HMM tends to be used to model words, whereas in larger vocabulary systems, the HMM is used for subword units like phonemes and for more abstract language information (see Section 3.4.3.). To introduce the operation of the HMM,

[15] Normalization of **path lengths** (i.e., sum of the transition costs along a path) is required to prevent undue penalty to longer reference strings. In a DP algorithm, where optimization is done locally, a path-dependent normalization is clearly inappropriate, and we must resort to the use of an arbitrary normalization factor (Myers *et al.*, 1980).

however, it is sufficient to assume that the speech unit is a word.

The HMM models an utterance in the form of a string of features (or feature vectors) to which the corresponding analog waveform has been reduced. In HMM literature, it is customary to refer to the string of test features as the **observations** or **observables** because these features represent information that is "observed" from the speech utterance to be modeled. Let us denote a string of observations by $\{y_t\}_{t=1}^{T}$.

During the **training phase** an HMM is "taught" the statistical makeup of the observation strings for its dedicated word. Training an HMM can be thought of as an attempt to create the automaton (the HMM) that "produces" a given word, in the sense that the HMM will tend to generate strings of features that are similar (statistically) to those produced by a human speaker uttering the given word. In producing the word, the human's vocal tract, roughly speaking, progresses through a sequence of "states" (corresponding to phonemes, for example) that are not directly observable to a listener who must recognize the utterance. The listener can observe the speech features but generally does not know the exact state of the speaker's vocal system that produced a given observation. The HMM is likewise composed of a set of interconnected states, a sequence through which the HMM progresses in the production of a feature string. As in the case of the human generator, the states of the HMM are "hidden" from the observer of the feature string, and the number of discrete states composing the HMM is usually very small compared with the number of feature vectors in a string of observables. In modeling a word, for example, the HMM might have six states corresponding to a like number of phonemes that compose the word being modeled, whereas an acoustic utterance of the word could result in a hundred or more feature vectors.

During the **recognition phase** given an incoming observation string, it is imagined that one of the trained HMMs produced the observation string. Then, for each HMM, the question is asked: How likely (in some sense) is it that *this* HMM produced this incoming observation string? The word associated with the HMM of highest likelihood is declared to be the recognized word. Note carefully that it is *not* the purpose of an HMM to generate observation strings. We *imagine*, however, that one of the HMMs *did* generate the observation string to be recognized as a gimmick for performing the recognition.

The "Hidden" and Observable Random Processes Associated with an HMM

A diagram of a typical HMM with six states is shown in Figure 3.11. The states are labeled by integers. The **structure, or topology**, of the HMM is determined by its allowable state transitions, and speech-related HMMs almost always have a left-to-right or **Bakis** (Bakis, 1976) topology in keeping with the natural temporal ordering of events in an utterance. Two slightly different forms of the HMM are used. The one usually (but not always) discussed for acoustic processing (modeling the signal, as we are doing here) emits an observation upon arrival at each successive state. (It also emits one from the initial state at the outset.) The alternative form, generally employed in language processing, emits an observation *during* the transition. The state emitter form of the model is called a **Moore machine** in automata theory, while the transition emitter form is a **Mealy machine** (Hopcroft and Ullman, 1979). Throughout the rest of this discussion, we will discuss the Moore form. The differences in algorithms associated with the two forms are largely a matter of interpretations of quantities.

The HMM is imagined to "produce" strings of features as follows. At each observation time (corresponding to the times at which we extract observations), a state transition is assumed to occur in the HMM. Upon entering the next state, an observation is emitted. Accordingly, there are two main stochastic processes for which the characterizations must be learned (inferred from data) during training. The first random process models the (hidden) sequence of states that occurs en route to generating a given observation sequence. The second models the generation of observations by the various states.

The state sequence random process is governed by the **state-transition probabilities**, which appear as labels on the arcs connecting the states. Suppose that we call the state random process $\underline{x}$. The associated random variables are $\{\underline{x}_t\}_{t=-\infty}^{\infty}$. We then have that:

$$a(i|j) \overset{\text{def}}{=} P(\underline{x}_t = i | \underline{x}_{t-1} = j), \tag{3.36}$$

for arbitrary t. By assumption, the state transition at time t does not depend on the history of the state sequence prior to time $t-1$; hence, the random sequence is called a (first-order) *Markov process* (Leon-Garcia, 1989). The matrix of state transition probabilities is the **state-transition matrix** $\boldsymbol{A} \in \mathbb{R}^{S \times S}$,

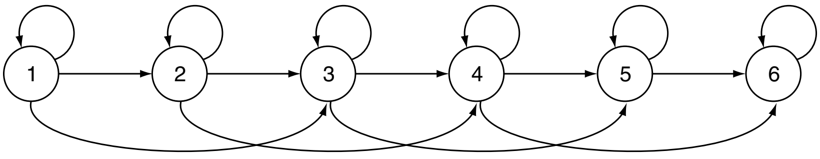

FIGURE 3.11 Typical HMM with Six States

that has $a(i|j)$ as its (i,j) element, where S is the total number of states in the model. Since the random variables of the Markov process take only discrete values (integers), the state process is called a **Markov chain**. Further, since the state-transition probabilities do not depend on t, the Markov chain is said to be homogeneous in time.

The second stochastic process characterized in the learning phase models the generation of observations by the HMM. Let us denote this (generally vector-valued) random process by $\underline{\boldsymbol{y}} = \left\{ \underline{y}_t \right\}_{t=-\infty}^{\infty}$, and let $\mathcal{Y}$ be the assumed set of all possible observations (e.g., features, feature vectors, or some mapping of features) that can be produced by a human talker. If $\mathcal{Y}$ is a finite discrete set, then the model is called a **discrete-observation** HMM, whereas if $\mathcal{Y}$ is a continuum, then the model is a **continuous-distribution** HMM. Associated with state i in the HMM, for $i \in [1, S]$, is a probability distribution (discrete) or density (continuous) over the set $\mathcal{Y}$, $f_{y_t|\underline{x}_t}(\xi|i)$. (We henceforth use the abbrevation pdf for this function). Both y_t and ξ are, in general, M-dimensional vectors, where M is the dimension of the feature vector extracted from the speech. For mathematical tractability, it is customary to make the unrealistic assumption that the random process $\underline{\boldsymbol{y}}$ has conditionally independent and identically distributed random variables, $\left\{ y_t \right\}$, where the conditioning is upon the state sequence. This means that $f_{y_t|\underline{x}_t(\xi|i)}$ is not dependent on t, and we write:

$$f_y|_{\underline{x}}(\xi|i) \overset{\text{def}}{=} f_{y_t|\underline{x}_t(\xi|i)} \quad \text{for arbitrary } t. \tag{3.37}$$

Two auxiliary pieces of information are needed to complete the characterization of the HMM—the initial probability vector, say $\boldsymbol{\pi}_1$, and the number of states, S. The ith element of $\boldsymbol{\pi}_1 \in \mathbb{R}^S$ is the probability that state i is the initial state in any path that produces an observation string. In the left-to-right model, the starting state is naturally taken to be the "leftmost" one, ordinarily numbered "state 1." Accordingly, $\boldsymbol{\pi}_1 = [1 \quad 0 \quad 0 \; \ldots \; 0]$. Formally, then, a Moore-form HMM, say $\mathcal{M}$, is comprised of the set of elements:

$$\mathcal{M} = \left\{ S, \boldsymbol{\pi}_1, \boldsymbol{A}, \left\{ f_{y|\underline{x}}(\xi|i), 1 \leq i \leq S \right\} \right\}. \tag{3.38}$$

The Discrete-Observation Model

The discrete-observation HMM, a special case of model set 3.38, is restricted to the production of a finite set of observations. In this case, the naturally occurring observation vectors are quantized into one of the permissible sets using a technique known as **vector quantization** (VQ). In the VQ process, a large population of continuous-observation vectors, assumed to be statistically representative of all the features to be encountered in a speech-recognition task, is partitioned into a fixed number of clusters, say K, typically using the K-means algorithm (Deller *et al.*, 2000; Devijver and Kittler, 1982). The centroids of the clusters are assumed to be representative of the sounds associated with the respective clusters. Only the centroids are kept, and collectively they are called a **codebook** for the vector quantizer. Subsequently, any observation vector used for either training or recognition is quantized (assigned to the nearest code) using this codebook; hence, each feature vector suffers some degree of quantization in the feature space. If there are K possible vectors (observations) in the codebook, then it is sufficient to assign to an observation a single integer, say k, where $1 \leq k \leq K$. Formally, the vector random process $\underline{\boldsymbol{y}}$ is replaced by a scalar random process, say $\underline{y}$, where each of the random variables $\underline{y}_t$ may take only integer values in $[1, K]$.

For the discrete-observation HMM, the quantized observation pdf for state i takes the form of K impulses on the real line. In this case, it is sufficient to know the probability distribution over the K symbols for each state (weights on the impulses), which we shall denote as:

$$b(k|i) \overset{\text{def}}{=} P(\underline{y}_t = k|\underline{x}_t = i), \quad \text{for } k \in [1, K], i \in [1, S]. \tag{3.39}$$

These **observation probabilities** are clearly defined to be dependent on the state but are assumed independent of time t. In general, we will not know the value assumed by a particular observation, $\underline{y}_t$, and we will write:

$$b(y_t|i) \overset{\text{def}}{=} P(\underline{y}_t = y_t|\underline{x}_t = i). \tag{3.40}$$

Similar to the definition of the transition probability matrix, $\boldsymbol{A}$, we define the **observation probability matrix**, $\boldsymbol{B} \in \mathbb{R}^{K \times S}$, with (k, i) element $b(k|i)$. The general mathematical specification of the HMM of equation 3.38 can be modified to reflect the discrete observations:

$$\mathcal{M} = \{S, \boldsymbol{\pi}_1, \boldsymbol{A}, \boldsymbol{B}, \mathcal{Y}_{\text{VQ}}\}, \tag{3.41}$$

where $\mathcal{Y}_{\text{VQ}} \overset{\text{def}}{=} \{y_k, 1 \leq k \leq K\}$, the set of K vectors in the VQ codebook.

Recognition Using the HMM

Discrete-Observation Case

We assume that we have a population of M HMMs, say $\{\mathcal{M}_\ell\}_{\ell=1}^{M}$, each of which represents a word and each of which has been trained (we will discuss how in subsequent paragraphs) with appropriate probabilities. Every HMM represents a word in a vocabulary, $\mathcal{V}$. Given a (vector-quantized) observation sequence, say $y \overset{\text{def}}{=} \{y_1, y_2, \ldots, y_t, \ldots, y_T\}$, which is a realization of random process $\underline{y}$, we seek to deduce which of the words in $\mathcal{V}$ is represented by y. That is, we want to determine the *likelihood* with which each of the $\mathcal{M}_\ell$ produces y.

Available data will generally not allow us to characterize the more intuitive *a posteriori* probability $P(\mathcal{M}|\underline{y} = y)$ to use as a likelihood measure, so the measure $P(\underline{y} = y|\overline{\mathcal{M}})$, the probability that the observation sequence y is produced given the model $\mathcal{M}$, is used instead. If the model probabilities are equal, then Bayes rule implies that the two approaches will produce the same result.

First, we consider an approach based on the likelihood that the observations could have been produced using *any* state sequence (path) through a given model. The most common technique applied to this problem is the so-called the **forward–backward** (F–B) **algorithm**, also called **Baum-Welch reestimation**. The full F–B algorithm was developed in the series of papers by Baum and colleagues (Baum, 1972). The underlying principles described in these papers are well beyond the scope of this treatment. The interested reader is referred, for example, to Deller *et al.* (2000) and Rabiner and Juang (1993). We simply note that the method represents an enormous savings in computation with respect to the effort required by exhaustive evaluation of all paths in each model. For $S = 5$ and $T = 100$, for example, the F–B method yields an improvement of 69 orders of magnitude with respect to the same computation carried out directly.

The second approach evaluates the likelihood be based on only the *best* state sequence through $\mathcal{M}$. A Viterbi search provides a slightly more cost-efficient alternative to the F–B method, with typically 10 to 25% fewer computations required. Recalling that the Viterbi algorithm amounts to a DP search with stochastic costs, it is not surprising that Viterbi search returns a total cost based on the single best state path through the HMM. Formally, given observation string y of length T and HMM $\mathcal{M}$, the Viterbi search returns the likelihood $P(y, \mathcal{I}^*|\mathcal{M})$, where $\mathcal{I}^* \overset{\text{def}}{=} \arg\max_{\mathcal{I} \in \Sigma_T} P(y, \mathcal{I}|\mathcal{M})$ in which Σ_T represents the set of legal state sequences (paths) of duration T.

The formulation of the Viterbi problem as a DP grid search is straightforward. In principle, the observations (indexed by time, t) are laid out along the abscissa of the search grid and the states along the ordinate. Each point in the grid is indexed by a time, state pair (t,i). Two natural restrictions are imposed on the search. The first involves **sequential grid points** along any path that must be of the form $(t,\ i)$, $(t+1,\ j)$, where $1 \leq i, j \leq S$. This says that every path must advance in time by one, and only one, time-step for each path segment. The second refers to **final grid points** on any path that must be of the form $(T,\ i_f)$, where i_f is a legal final state in the model. For a left-to-right HMM, this means that the ordinate of the grid point at time T must be the final ("rightmost") state in the model.

The stochastic cost assigned to node (t,i) in the grid is simply $b(y_t|i)$, and the transition cost, given that the state occupied at time $t-1$ is j, is taken to be $a(i|j)$ for any i and j and for arbitrary $t > 1$. In addition, to account for initial state probabilities, all paths are assumed to originate at a fictitious and costless node (0,0), which makes a transition of cost $P(\underline{x}_1 = i)$ to any initial node of the form $(1,i)$. Upon arriving at the initial node, the path will also incur a node cost of the form $b(y_1|i)$. The total cost associated with any transition, say $(t-1,\ j)$ to $(t,\ i)$, is therefore $a(i|j)b(y_t|i)$ for $t > 1$ and $P(\underline{x}_1 = i)b(y_1|i)$ when $t = 1$. We note that multiplication is the natural operation ($\odot$ in equation 3.30) by which node and transition costs are combined in this case. Also note that a *large* "distance" (i.e., probability) is desirable, so we will apparently want to seek a *maximum* cost path if such measures are used. With these cost assignments, and a minor adjustment to seek the maximum rather than minimum cost path, the Viterbi procedure is applied in the usual way.

```
Initialization: "Origin" of all paths is node (0,0).
                For $i = 1, 2, \ldots, S$.
                    $D_{\min}(1,\ i) = -\ln[a(i|0)b(y_1|i)] =$
                    $-[\ln P(\underline{x}_1 = i) + \ln b(y_1|i)]$.
                    $\psi(1,\ i) = 0$.
                Next $i$

Recursion:      For $t = 2, 3, \ldots, T$
                    For $i_t = 1, 2, \ldots, S$.
                    Compute $D_{\min}(t, i_t) = \min_{p \in [1,S]} \{D_{\min}(t-1, p)$
                    $- \ln a(i_t|p) - \ln b(y_t|i_t)\}$.
                    Record backtracking information at the present node,
                    $\psi(t,\ i_t)$.
                    Next $i_t$
                Next $t$

Termination:    Distance of optimal path from (0,0) to $(T,\ i_T^*)$ is $D_{\min}(T,\ i_t^*)$.
                Best state sequence, $\mathcal{I}^*$, is found as follows:
                    Terminal state is $i_T^*$, then:
                    For $t = T-1,\ I-2, \ldots, 0$.
                        $i_t^* = \psi(t+1,\ i_{t+1}^*)$.
                    Next $t$
```

FIGURE 3.12 Computation of $P(y, \mathcal{I}^*|\mathcal{M})$ Using the Viterbi Algorithm.

To reduce the computational load and to mitigate the numerical problems arising from many products of probabilities, it is common to *sum* negative log probabilities rather than to *multiply* probabilities directly. If this strategy is used, the problem reverts to a *minimal* cost path search because high probabilities result in small negative logs. The steps of a Viterbi search algorithm based on this cost strategy are shown in Figure 3.12. Note that a provision for state backtracking is included in the algorithm.

Continuous-Observation Cases

The F–B and Viterbi methods already described are applicable to the continuous-observation case with a simple modification. We define the likelihood of generating observation $\boldsymbol{y}_t$ in state i as $b(\boldsymbol{y}_t|i) \overset{\text{def}}{=} f_y|x(\boldsymbol{y}_t|i)$. With this substitution for the observation probabilities, the methods developed for the discrete-observation case can be applied directly. The resulting measure computed for a model, say $\mathcal{M}$, and an observation string, say $\boldsymbol{y} \overset{\text{def}}{=} \{\boldsymbol{y}_1, \ldots, \boldsymbol{y}_T\}$, will be $P(\boldsymbol{y}|\mathcal{M})$ for the F–B approach and $P(y, \mathcal{I}_{\min}|\mathcal{M})$ in the Viterbi case. These measures will no longer be proper probabilities, but they provide meaningful likelihood measures with which appropriate relative comparisons across models can be made.

HMM Training

Discrete-Observation Case

Next we address the question of training a particular HMM to correctly represent its designated word or other utterance.[16] We assume that we have one or more feature strings of the form $y = \{y_1, \ldots, y_t\}$ extracted from training utterances of the word (this assumes that we already have the codebook that will be used to deduce symbols), and the problem is to use these strings to find an appropriate model of form 3.38. In particular, we must find the matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ and the initial state probability vector $\boldsymbol{\pi}_1$. There is no known way to analytically compute these quantities from the observations in any optimal sense. However, an extension to the F–B algorithm provides an iterative estimation procedure for computing a model, $\mathcal{M}$, corresponding to a local maximum of the likelihood $P(y|\mathcal{M})$. This method is most widely used to estimate the HMM parameters, and for algorithm details, the reader is referred to Deller *et al.* (2000) and Rabiner and Juang (1993). Repeated re-estimation of the model (by repeated iterations of the F–B algorithm) is guaranteed to converge to an HMM corresponding to a local maximum of $P(y|\mathcal{M})$ (Baum and Sell, 1968). The model improves with each iteration unless its parameters already represent a local maximum. F–B training, therefore, does not necessarily produce the globally best possible model. Accordingly, it is common practice to run the algorithm several times with different sets of initial parameters and to take as the trained model the $\mathcal{M}$ that yields the largest value of $P(y|\mathcal{M})$.

Training using the Viterbi algorithm is much simpler and more computationally efficient, though equally effective. Beginning with an initial model estimate, we implement the recognition procedure on the training sequence. Once the optimal path is discovered, backtracking information is used to determine the number of transitions into and out of each state and the number of times each symbol is produced in each state. The tallies are used to reestimate the state and observation probabilities, and then the process is repeated. The algorithm can be shown to converge to a proper characterization of the underlying probabilities (Fu, 1982).

Continuous-Observation Case

The state-transition and initial-state probabilities in the continuous-observation case have exactly the same meaning and structure as in the discrete-observation case and can be found in exactly the same manner.

The pdf most widely used to model continuous observation outcomes is the **Gaussian mixture density**, which is of the form:

$$f_{\boldsymbol{y}|\boldsymbol{x}}(\xi|i) = \sum_{m=1}^{M} c_{im}\mathcal{N}(\xi;\, \mu_{im},\, C_{im}), \tag{3.42}$$

in which c_{im} is the **mixture coefficient** for the mth component for state i, and $\mathcal{N}(\cdot)$ denotes a multivariate Gaussian pdf with mean vector μ_{im} and covariance matrix $\boldsymbol{C}_{im}$. The mixture coefficients must be non-negative and satisfy the constraint $\sum_{m=1}^{M} c_{im} = 1,\ 1 \leq i \leq S$. For a sufficiently large number of mixture densities, M, equation 3.42 can be used to approximate arbitrarily accurately any continuous pdf.

Modified Baum-Welch reestimation formulas have been derived for the three quantities c_{im}, μ_{im}, and $\boldsymbol{C}_{im}$ for mixture density m in state i (Liporace, 1982; Juang *et al.*, 1986). As in the discrete-observation case, the use of these formulas will ultimately lead to a model, $\mathcal{M}$, that represents a *local* maximum of the likelihood $P(\boldsymbol{y}|\mathcal{M})$. However, finding a *good* local maximum depends rather critically on a reasonable initial estimate of the vector and matrix parameters μ_{im} and $\boldsymbol{C}_{im}$ for each i and m. We now describe a convenient procedure for deriving good separation of the mixture components for use with a Viterbi procedure.

In the Viterbi approach, the mean vectors and covariance matrices for the observation densities are reestimated by simple averaging, similarly to what is done in the discrete-observation procedure. This is easily described when there is only one mixture component per state. In this case, for a given $\mathcal{M}$, the recognition experiment is performed on the observation sequence. Each observation vector is then assigned to the state that produced it on the optimal path by examining the backtracking information. The vectors assigned to each state are then used to update the mean vector and covariance matrix for that state, and the process is repeated.

When $M > 1$ mixture components appear in a state, then the observation vectors assigned to that state must be subdivided into M subsets prior to averaging. This is done by clustering, using, for example, the K-means algorithm with $K = M$. If there are N_{im} vectors assigned to the mth mixture in state i, then the mixture coefficient c_{im} is reestimated as $c_{im} = N_{im}/N_i$.

Practical Considerations in the Use of the HMM

Features

Thus far, we have discussed the HMM in principally abstract terms. Here, we briefly consider some of the practical aspects of the use of the HMM, turning first to the fundamental acoustical analysis. Many features have been used as observations, but the most prevalent are the LP parameters, cepstral parameters, and related quantities. These are frequently supplemented by short-term time differences that capture the dynamics of the signal as well as supplemented by energy measures, such as short-term energy and differenced energy. A comparative discussion is found in Bocchieri and Doddington (1986) and Nocerino *et al.* (1985).

[16] In addition to the two most prominent training methods described here, gradient search techniques (Levinson *et al.*, 1983) and techniques based on the concept of statistical discrimination (Ephraim *et al.*, 1989; Bahl *et al.*, 1988), have been used for training. The latter works includes algorithms for *corrective training* which reinforce model parameters when they achieve successful detection and "negatively train" models with data that cause false recognition.

In a typical application, the speech would be sampled at 8 kHz and analyzed on frames of 256 points with a 156-point overlap. The analysis frame end-times, say 100, 200, ..., M, become observation times $t = 1, 2, \ldots, T$. For a typical word utterance lasting 1 sec, $T = 80$ observations. On each frame, 8 to 10 LP coefficients are computed, which are then converted to 12 cepstral coefficients. Alternatively, 12 mel-cepstral coefficients might be computed directly from the data. To add dynamic information, 12 differenced cepstral coefficients are also included in the vector. Finally a short-term energy measure and a differenced energy measure are included for each frame, for a total of 26 features in the observation.

A related issue is to decide upon the number of symbols (centroids) in the VQ codebook if a discrete-observation model is used. One measure of the quality of a codebook is the average distance of a vector observation in the training data from its corresponding symbol. This figure is often called the **codebook distortion**. The smaller the distortion, the more accurately the centroids represent the vectors they replace. Typically, recognizers use codebooks of size 32–256 with the larger sizes being more common. Since a larger codebook implies increased computation, there is an incentive to keep the codebook as small as possible without decreasing performance. Like the other parametric decisions that must be made about an HMM, this issue is principally guided by experimental evidence.

Model Topology and Size

Some variation of the Bakis topology is almost uniformly used in speech applications because it most appropriately represents the acoustic process. Interestingly, and perhaps not surprisingly, when used with speech, an HMM with no state-transition constraints will often train so that it essentially represents a sequential structure (backward transition probabilities turn out zero).

Experimental evidence suggests that states frequently represent identifiable acoustic phenomena.[17] Therefore, the number of states is often chosen to roughly correspond to the expected number of such phenomena in the utterance. If words are being modeled with discrete observations, for example, 5 to 10 states are typically used to capture the phones in the utterances. Continuous-observation HMMs sometimes use more states. If HMMs are used to model discrete phones or phonemes, three states are often used—one each for onset and exit transitions and one for the steady-state portion of the phone.

The Generality of the HMM and a First View of Language Models

We have generally discussed the HMM above as though it were a model for a single word but stressed that much of what was developed applies to other uses of the model. For large vocabulary systems, it is necessary to use HMMs to model sub-word acoustic units (e.g., phones or phonemes) since appropriate training of thousands of isolated-word models is prohibitive. Regardless of whether we view speech as constructed of phones or words (or some other acoustic unit), the structure of human language is, of course, much more complex than that conveyed by isolated acoustic units. A major part of the information in the speech code is conveyed by the way in which the units are ordered. Still more information is carried in other acoustic cues such as intonation, nonspeech cues like hand gestures and facial expressions, and in abstract notions like the physical environment of the conversation or the meaning of a phrase in the context of the overall message. Generally speaking, a set of rules by which fundamental acoustic units of speech ultimately become complete utterances is called a **language model** (LM). From the earliest efforts to do large vocabulary speech recognition, it has been clear to researchers that a good LM is critical to a successful performance (Lowerre and Reddy, 1980). For large vocabulary systems, acoustic processing will almost never provide satisfactory recognition as a stand-alone technology. LMs have been a very active area of research on speech processing for many years.

We raise the issue of LMs in the present context because the HMM is, in fact, formally equivalent to one of the most prominent LMs used in practice—the so-called "regular" or "finite state" grammar (Hopcroft and Ullman, 1979; Fu, 1982). Because of its simplicity, regular grammar is often used to model the speech production code at several levels of linguistic and acoustic processing. This is why the HMM figures so prominently in the continuous speech recognition (CSR) problem. The general idea is straightforward: an HMM for **syntax** (word ordering) in a speech recognizer would have dynamics (states and transitions) very much like the HMMs we described for the word model. The difference would be that the observations "emitted" by the model would be words, which, in turn, would be represented by an acoustic HMM (probably further decomposed into phonetic HMMs). It is possible, therefore, to envision this type of speech recognizer as a large graph (or grid) consisting of HMMs embedded inside of HMMs several levels "deep."

Not unexpectedly, the training procedures for such an embedded system of models require some enhancement and reconsideration of methods applied to the simple word models. Nevertheless, the basic ideas are the same, and the same F–B and Viterbi reestimation algorithms are applicable. One remarkable property of the HMM is evident in the training process. In working with continuous speech, we must face the problem of not knowing where the temporal boundaries (i.e., phonetic or word) are in the acoustic observation strings used for training (or recognition). The creation of sufficiently large databases marked according to phonetic time boundaries is generally impractical. An important

[17] Perhaps more accurately, assuming that states represent acoustic phenomena seems to provide a good rule of thumb for creating HMMs with successful performance. However, the relationship of the number of states to the performance of the HMM is very imprecise, and in practice, it is often necessary to experiment with different model sizes.

property of the HMM comes to our aid in this situation. Researchers have discovered that HMMs can be trained *in context* (i.e., hooked together in the language graph) as long as reasonable "seed" models are used to initiate the estimation procedure. This means that the entire observation sequence for a sentence can be presented to the appropriate string of HMMs, and the models will tend to "soak up" the parts of the observation sequence corresponding to their words or phones, for example. This ability of the HMM has revolutionized the CSR field because it obviates the time-consuming procedure of temporally marking a database.

3.4.3 Language Modeling

Introduction

The concept of a LM[18] was introduced in the just-completed material on HMMs because these stochastic models play such a prominent role in representing language structure in contemporary speech recognition systems. More generally, however, LM research has a long and interesting history in which numerous and varied systems have been produced. The field remains very active with many challenging unsolved problems. In the scope of this vast history and level of current activity, the goal of this section is very modest—to provide an overview of some of the basic operating principles and terminology of LM'ing[18] particularly those related to the HMM-like formalisms discussed above.

Inasmuch as LMs ultimately imply structure that assists in pattern-matching and search, some of the techniques and algorithms discussed in earlier sections are directly applicable to the LM'ing problem. The field of LM'ing, however, has developed largely outside of the SP discipline—principally in certain areas of computer science, linguistics, and related fields—so the vocabulary and concepts of LM'ing can seem unfamiliar to the traditional SP engineer, even when the techniques are similar to SP methods. Further, the abstraction of some of the problems encountered in LM'ing (e.g., the *meaning* of an utterance) defy the construction of rigorously quantified models, which is another break from the SP engineer's typical approach to problem solving.

The Purpose and Structure of a Language Model

Whether we view phones, phonemes, syllables, or words as the basic unit of speech, LMs are generally concerned with how fundamental speech units may be concatenated: in what order, in what context, and with what intended meaning. This characterization immediately suggests that LMs have both similarities to, and differences from, the sets of "grammatical rules" of a natural language that are typically studied in primary education. "Primary school" grammar is indeed concerned with the rules by which speech components are combined. Such studies rarely, if ever, are concerned with basic sub-word phonetic elements, and seldom do they deal with or higher level abstractions like subtle nuances of meaning. In contrast, an LM often reaches deep into the acoustic structure of speech and sometimes high into the more abstract aspects of intention and meaning. In essence, what primary school students know as "grammar" is the natural-language version of only one of the ingredients of a formal LM used in speech recognition. A LM is a broader framework, consisting of the (often quantified) formalization of some or all of the structure that grammarians, linguists, psychologists, and others who study language can ascribe to a natural language. Indeed, an LM need not conform to the grammatical rules of the natural language it is modeling.

Peirce (Liszka, 1996) identifies four components of the natural-language code: symbolic, grammatical,[19] semantic, and pragmatic. Implicit or explicit banks of linguistic knowledge resident in speech recognizers, sometimes called **knowledge sources** (Reddy, 1976), can usually be associated with a component of Peirce's model. The **symbols** of a language are defined to be the most fundamental units from which all messages are ultimately composed. In the spoken form of a language, for example, the symbols might be words or phonemes, whereas in the written form, the alphabet might serve as the symbols. For the purposes of this discussion, let us consider the phonemes to be the symbols of a natural language. The **grammar** of the language is concerned with how symbols are related to one another to form message units. If we consider the sentence to be the ultimate message unit, then how words are formed from phonemes are part of Peirce's grammar as well as the manner in which words form sentences. How phonemes form words is governed by **lexical** constraints and how words form sentences by **syntactic** constraints. Lexical and syntactic constraints are both components of the grammar.

The grammar of a language is, in principle, arbitrary in the sense that any rule for combining symbols may be posed. On the other hand, **semantics** is concerned with the way in which symbols are combined to form *meaningful* communication. Systems imbued with semantic knowledge sources straddle the line between speech *recognition* and speech *understanding* and draw heavily on artificial intelligence research. Beyond binary unmeaningful or meaningful decisions about symbol strings, semantic processors can be used to impose meaning upon incomplete, ambiguous, noisy, or otherwise hard-to-understand speech.

Finally, the **pragmatics** component of the LM is concerned with the relationship of the symbols to their users and the environment of the discourse. This aspect of language is very difficult to formalize. To understand the nature of pragmatic knowledge, consider the phrase "rocking chair." Depending on the nature of the conversation, the word "rocking" could

[18] In the following please read "LM" as "language model" and "LM'ing" as "language modeling."

[19] We have replaced Peirce's word *syntax* with *grammar* for more consistency with our "engineering" formalisms in the following. We will reserve the word *syntax* to refer to the rules that govern how *words* may combine.

describe either a *type* of chair or the *motion* of a chair or both. A pragmatic knowledge source in a recognizer must be able to discern among the various meanings of symbol strings and, hence, find the correct decoding.

In the 1950s and 1960s, Chomsky further formalized the structure of an LM (Chomsky, 1959), and he and others (Fu, 1982) generalized the concept of *language* and *grammar* to any phenomenon or process that can be viewed as generating structured entities by building them from primitive patterns ("symbols") according to certain "production" rules. The most restrictive type of grammar in Chomsky's hierarchy, and the one that is of most interest in practical application, is the **regular,** or **finite-state, grammar**. In the parlance of the HMM, Chomsky's regular grammar contains production rules that allow any "state" to produce a "symbol" plus a new "state," or to produce a sole "symbol."

In Chomsky's formalism, a **stochastic grammar** is one whose production rules have probabilities associated with them, so each of the strings in the **stochastic language** occurs with a probability that depends on the probabilities of its productions. Clearly, when probabilities are added to the production rules of the regular grammar, the regular grammar can be used as an alternative description of the operation of the Mealy-form HMM. In each "production" (observation time), the HMM produces a symbol and a new state with a certain probability. It is very important to generalize our thinking about the HMM, however, in the present context. Our fundamental descriptions of the HMM involved *acoustic* modeling in which states nominally represented physiologic acoustic states of the vocal systems and in which symbols represented acoustic features. In the LM context, the "HMM" can represent higher level structures as well. For example, the states may represent words while the observations are phonemes, so the model embodies syntactical and lexical information. As noted earlier, the HMM is usually known as a **finite-state automaton** (FSA) in the formal language theory. "HMM" is almost invariantly used to refer to the model at the acoustic level, while "FSA" is more likely to be used for the linguistic models. Regardless of what we call the model, the critical point is the one-to-one correspondence between the model and a regular stochastic grammar.

n-Gram and Other Language Models

While FSA and FSA-like models are prominent among those deployed in practice, other important models have been applied. Notable among these are the *n-gram* LMs in which the occurrence of a string element (usually a word) is characterized by an $(n-1)$-order Markov dependence on past string elements. For example, in a **2-gram** or **bi-gram** LM for syntax, the probability that a particular word appears as the *t*th word in a string is conditioned on the $(t-1)$st word. In the **3-gram** or **tri-gram** LM, the dependency is on two previous elements. For most vocabularies, the use of *n*-gram models for $n > 3$ is prohibitive.

Clearly, the more constrained the rules of language in the recognizer, the less freedom of expression the user has in constructing spoken messages. The challenge of LM'ing is to balance the need for maximally constraining the "pathways" that messages may take in the recognizer while minimizing the degree to which freedom of expression is diminished. A measure of the extent to which an LM constrains permissible discourse is given by the **perplexity**. This term roughly means the average number of branches at any decision point when the decoding of messages is viewed as the search through a graph of permissible utterances.

Training and Searching the Language Model

Training methods akin to those studied in previous sections are available for constructing LMs (e.g., see Chapter 13 of Deller *et al.*, 2000). Both F–B-like and Viterbi-like approaches exist for the inference of the probabilities of the production rules of a stochastic grammar, given the characteristic grammar (rules without probabilities) (Fu, 1982; Levinson, 1985). For a regular grammar, this task is equivalent to the problem of finding the probabilities associated with an HMM or an FSA with a fixed structure. Consequently, the fact that these training algorithms exist is not surprising. In fact, however, any stochastic grammar may be shown to have a correlative doubly stochastic (HMM-like) process. A discussion of this issue and related references are found in Levinson (1985).

3.5 Summary and Conclusions

The focus of this chapter has been on fundamental ideas and algorithms underlying the DT processing of speech. Indeed, it is difficult to find a modern application of speech processing that does not employ one or more of the algorithms discussed here, and virtually all contemporary speech technology begins with some variation of the linear DT model to which we devoted much initial attention in this chapter. As a technology with vast economic significance, the amount of research and development that has been, and continues to be, devoted to speech processing is extraordinary. The commercial, military, forensic, and other driving forces for speech technologies are centered primarily in the broad areas of communications and recognition. Modern communication networks, in their many traditional and emerging forms, have created vast interest in speech processing technologies, particularly with regard to coding, compression, and security. At the same time, modern communications systems have engendered a merging of subspecialties in signal processing as speech technologists find themselves increasingly working with image (and other data) processing engineers, specialists in detection and estimation theory, and computer hardware and software systems developers. Further, the global nature of communications has caused some aspects of speech communications and recognition to merge as well. "Recognition" was once envisioned as a quest for a typewriter that takes dictation, and the field has now broadened to include such issues as **language** and **accent recognition**—motivated, at least in part, as a facilitating technology for multilanguage communications systems and other computer-assisted telephony applications (Waibel *et al.*, 2000). Both as stand-alone technologies and also as part of the communications revolution, security and forensics applications such as **speaker identification** and **speaker verification** have also expanded the activities of "recognition" engineers (Campbell, 1997).

Although the commercial interests have played dominant roles in setting the speech processing agenda, many other applications of speech processing continue to be explored. Biomedicine represents one area, for example, in which speech engineering is playing an important role in the development of diagnostic software, techniques for assessment of speech and hearing therapies, and assistive aids for persons with speech, hearing, and motor disabilities. At the same time, funding agencies continue to support new theories and applications of speech processing, including models of human discourse, theories of hearing and psychoacoustics, and other basic research activities. To explore these emerging technologies and well as the wealth of information about modern applications, the reader is encouraged to explore the literature cited here, the further citations to which it leads, and the ever-increasing amount of information available on the World Wide Web.

4.1 Introduction

Digital image processing consists of the manipulation of images using digital computers. Its use has been increasing exponentially in the last decades. Its applications range from medicine to entertainment, passing by geological processing and remote sensing. Multimedia systems, one of the pillars of the modern information society, rely heavily on digital image processing.

The discipline of digital image processing is a vast one, encompassing digital signal processing techniques as well as techniques that are specific to images. An image can be regarded as a function $f(x, y)$ of two continuous variables x and y. To be processed digitally, it has to be **sampled** and transformed into a matrix of numbers. Since a computer represents the numbers using finite precision, these numbers have to be **quantized** to be represented digitally. Digital image processing consists of the manipulation of those finite precision numbers. The processing of digital images can be divided into several classes: **image enhancement**, **image restoration**, **image analysis**, and **image compression**. In image enhancement, an image is manipulated, mostly by heuristic techniques, so that a human viewer can extract useful information from it. Image restoration techniques aim at processing corrupted images from which there is a statistical or mathematical description of the degradation so that it can be reverted. Image analysis techniques permit that an image be processed so that information can be automatically extracted from it. Examples of image analysis are image segmentation, edge extraction, and texture and motion analysis. An important characteristic of images is the huge amount of information required to represent them. Even a gray-scale image of moderate resolution, say 512×512, needs $512 \times 512 \times 8 \approx 2 \times 10^6$ bits for its representation. Therefore, to be practical to store and transmit digital images, one needs to perform some sort of image compression, whereby the redundancy of the images is exploited for reducing the number of bits needed in their representation.

In what follows, we provide a brief description of digital image processing techniques. Section 4.1 deals with image sampling, and Section 4.2 describes image quantization. In Section 4.3, some image enhancement techniques are given. Section 4.4 analyzes image restoration. Image compression, or **coding**, is presented in Section 4.5. Finally, Section 4.6 introduces the main issues involved in image analysis.

4.2 Image Sampling

An analog image can be seen as a function $f(x, y)$ of two continuous space variables: x and y. The function $f(x, y)$ represents a variation of gray level along the spatial coordinates. Since each color can be represented as a combination of three primaries (R, G, and B), a color image can be represented by the three functions $f_R(x, y)$, $f_G(x, y)$, and $f_B(x, y)$, one for each color component.

A natural way to translate an analog image into the discrete domain is to **sample** each variable; that is, we make $x = n_x T_x$ and $y = n_y T_y$. This way, we get a digital image $f_D(nx, ny)$ such that:

$$f_D(n_x, n_y) = f(n_x T_x, n_y T_y). \tag{4.1}$$

Likewise, for the one-dimensional case, one has to devise conditions under which an analog image can be recovered from its samples. We will first generalize the notions of frequency content and Fourier transform for two-dimensional signals.

One can represent an image in the frequency domain by using a two-dimensional Fourier transform. It is a straightforward extension of the one-dimensional Fourier transform, as can be seen in these equations:

$$F(\Omega_x, \Omega_y) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x, y)e^{-j(\Omega_x x+\Omega_y y)}dxdy. \tag{4.2}$$

$$f(x, y) = \frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} F(\Omega_x, \Omega_y)e^{j(\Omega_x x+\Omega_y y)}d\Omega_x d\Omega_y. \tag{4.3}$$

The function $e^{j(\Omega_x x+\Omega_y y)}$ is a complex sinusoid in two dimensions. It represents a two-dimensional pattern that is sinusoidal both along the x (horizontal) and y (vertical) directions. The Ω_x and Ω_y are the spatial frequencies along the x and y directions, respectively. An example can be seen in Figure 4.1, where a two-dimensional sinusoid is depicted as $\cos(\Omega_x x + \Omega_y y)$, with $\Omega_x = 2\Omega_y$. One can note that there are twice as many cycles in the x direction than in the y direction. The period in the x direction is $2\pi/\Omega_x$ and in the y direction is $2\pi/\Omega_y$.

Therefore, equation 4.3 means that any two-dimensional signal is equivalent to an infinite sum of two-dimensional complex sinusoids. The term that multiplies the sinusoid of frequency (Ω_x, Ω_y) is its Fourier transform, $F(\Omega_x, \Omega_y)$, and is given by equation 4.2.

Having defined the meaning of frequency content of two-dimensional signals, we are now ready to state conditions under which an image can be recovered from its samples. It is well known that most useful digital images have the significant part of the amplitude spectrum concentrated at low frequencies. Therefore, an image in general can be modeled as a bandlimited two-dimensional signal; that is, its Fourier transform $F(\Omega_x, \Omega_y)$ is approximately zero outside a bounded region, as shown in Figure 4.2.

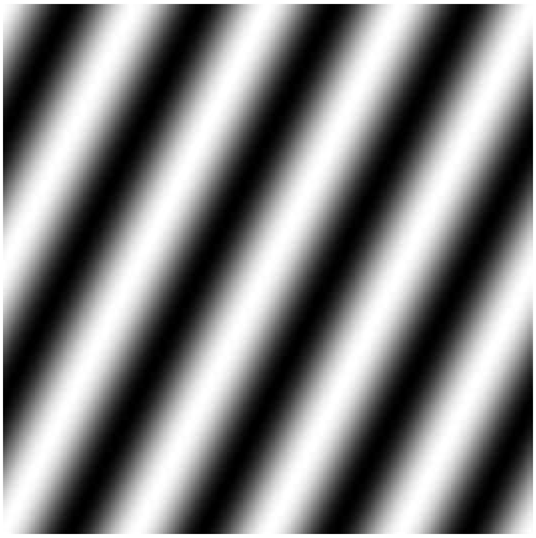

FIGURE 4.1 Two-Dimensional Sinusoid with $\Omega_x = 2\Omega_y$. Its expression is $f(x, y) = 1/2(e^{j(\Omega_x x+\Omega_y y)} + e^{-j(\Omega_x x+\Omega_y y)})$.

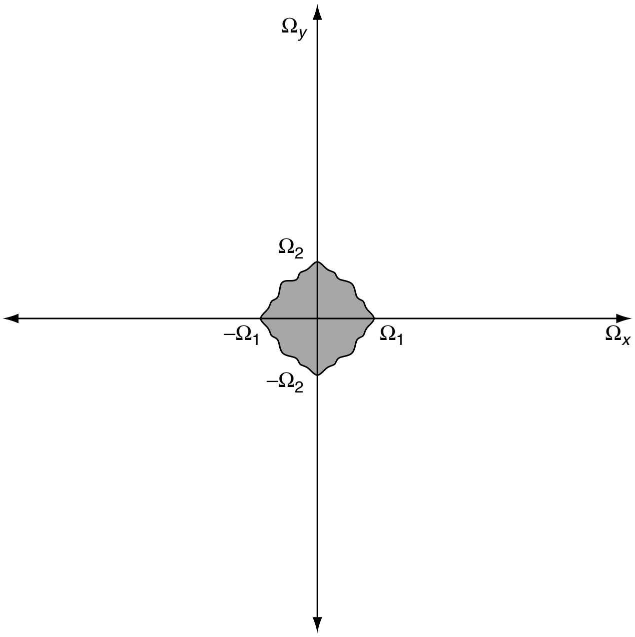

FIGURE 4.2 Support Region of the Fourier Transform of a Typical Image

When the sampling process is performed according to equation 4.1, it is equivalent to sampling the continuous signal using a rectangular grid as in Figure 4.3. As in the one-dimensional case (Oppenheim and Schaffer, 1989), one can show that the spectrum of the digital image is composed of replicas of the analog image spectrum, repeated with a period of $2\pi/T_x$

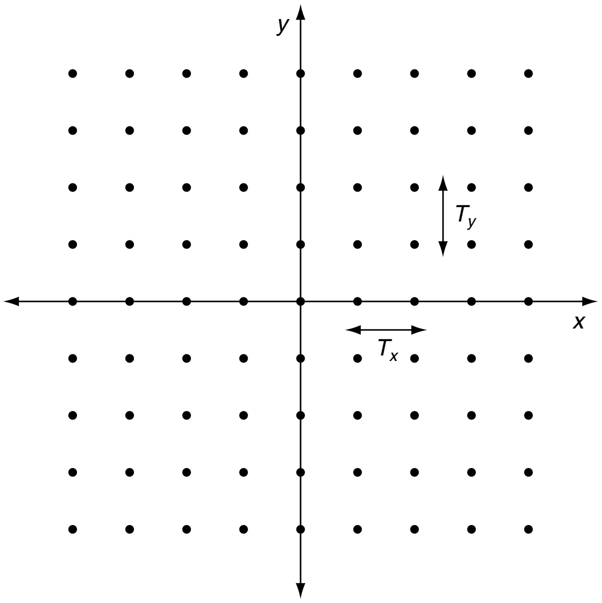

FIGURE 4.3 Sampling a Two-Dimensional Signal Using a Rectangular Grid

along the horizontal frequency axis and $2\pi/T_y$ along the vertical frequency axis, as depicted in Figure 4.4.

The mathematical expression for the spectrum of the sampled signal is then:

$$F_s(\Omega_x, \Omega_y) = \frac{1}{T_x T_y} \sum_{k_x=-\infty}^{\infty} \sum_{k_y=-\infty}^{\infty} F\left(\Omega_x - \frac{2\pi k_x}{T_x}, \Omega_y - \frac{2\pi k_y}{T_y}\right). \quad (4.4)$$

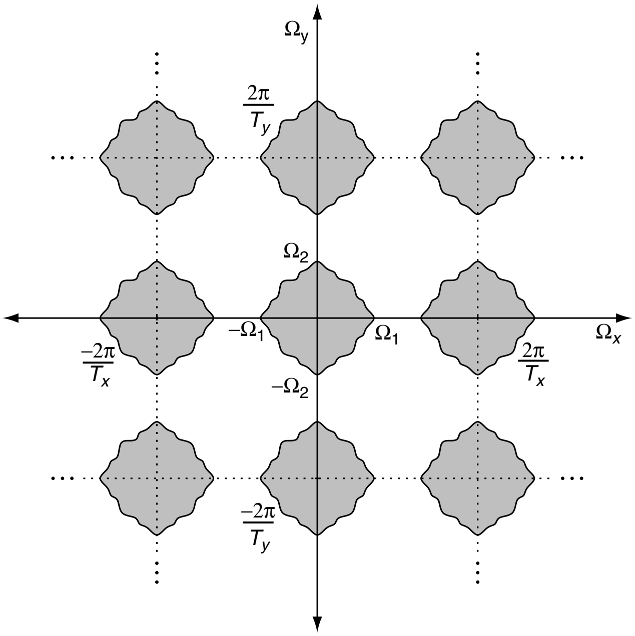

FIGURE 4.4 Spectrum of the Two-Dimensional Discrete Signal Generated by Sampling Using a Rectangular Grid

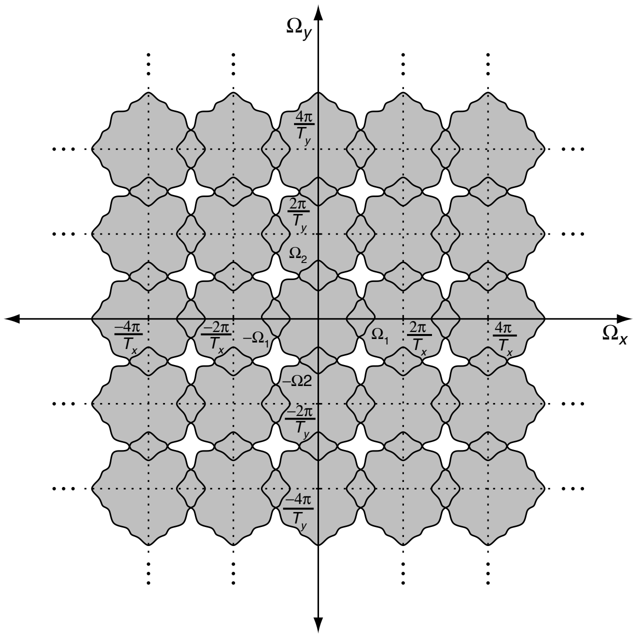

FIGURE 4.5 Aliased Spectrum of the Two-Dimensional Discrete Signal Generated by Sampling Using a Rectangular Grid

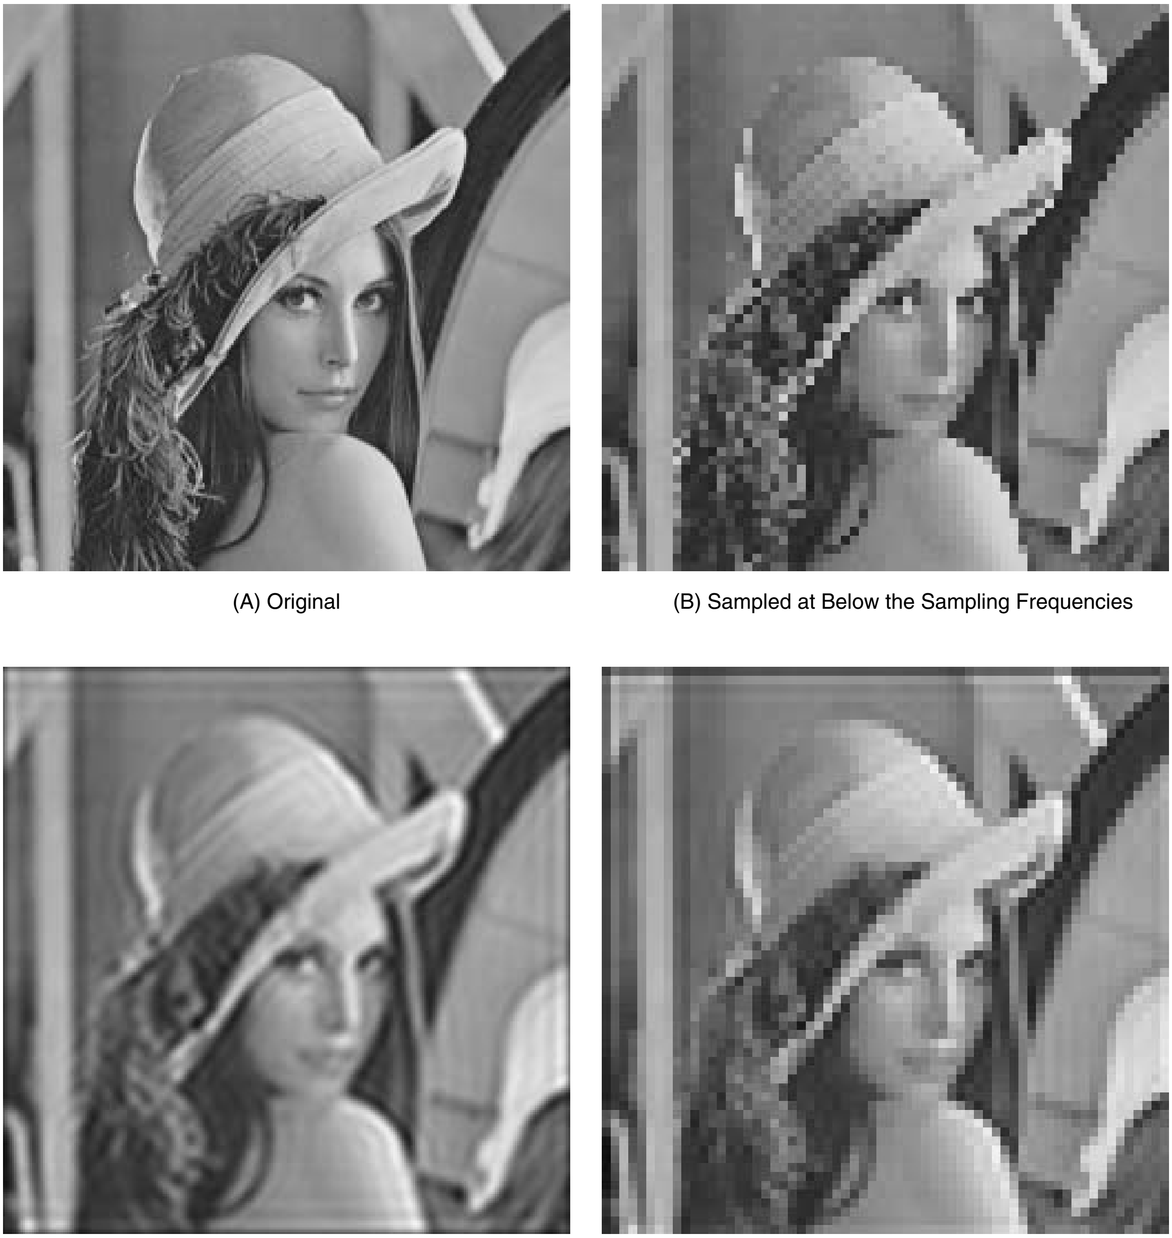
From the above equation and Figure 4.4, we note that if the sampling intervals do not satisfy the Nyquist conditions $\Omega_1 \leq 2\pi/T_x$ and $\Omega_2 \leq 2\pi/T_y$ then the analog signal cannot be reconstructed from its samples. This is due to the overlap of the replicated frequency spectra, which, likewise in the one-dimensional case, is known as aliasing. Aliasing is illustrated in Figure 4.5.

Provided that aliasing is avoided, the sampled signal has to be processed by a two-dimensional low-pass filter to obtain the image signal back into its analog form. This filter should ideally have a transfer function with an amplitude spectrum equal to one in the support region of the Fourier transform of the original image and zero outside that region.

In Figure 4.6(A), we see the original LENA image. It has been sampled without aliasing. Figure 4.6(B) shows the LENA image sampled at a rate much smaller than the minimum sampling frequencies in the horizontal and vertical directions necessary to avoid aliasing. Aliasing can be clearly noted. In Figure 4.6(C), the bandwidth of the image LENA has been reduced prior to sampling so that aliasing is avoided after sampling. Figure 4.6(D) shows the filtered image after sampling. We can notice that despite the blur on the image due to the lower bandwidth, there is indeed less aliasing indicated by the smoother edges.

4.2.1 Nonrectangular Grid Sampling

A two-dimensional signal does not necessarily need to be sampled using a rectangular grid like the one described by equation 4.1 and Figure 4.3.



(A) Original

(B) Sampled at Below the Sampling Frequencies

(C) Low-Pass Filtered

(D) Low-Pass Filtered and Sampled

FIGURE 4.6 LENA Image

For example, a nonrectangular grid as in Figure 4.7 can be used. The nonrectangular grid sampling can be best described by using vector and matrix notation. Let:

$$\boldsymbol{t} = \begin{pmatrix} t_x \\ t_y \end{pmatrix} \; \boldsymbol{n} = \begin{pmatrix} n_x \\ n_y \end{pmatrix} \; \boldsymbol{V} = \begin{pmatrix} v_{xx} & v_{xy} \\ v_{yx} & v_{yy} \end{pmatrix} = \begin{pmatrix} \boldsymbol{v}_x & \boldsymbol{v}_y \end{pmatrix} \; \Omega = \begin{pmatrix} \Omega_x \\ \Omega_y \end{pmatrix}. \tag{4.5}$$

The sampling process then becomes:

$$f_D(\boldsymbol{n}) = f_D(n_x, n_y) = f(n_x \boldsymbol{v}_x + n_y \boldsymbol{v}_y) = f(\boldsymbol{Vn}). \tag{4.6}$$

In the case of Figure 4.7:

$$\boldsymbol{V} = \begin{pmatrix} T_x & T_x \\ T_y & -T_y \end{pmatrix}, \tag{4.7}$$

and it can be shown that the spectrum of the sampled signal becomes (Mersereau and Dudgeon, 1984):

$$F_s(\Omega) = \frac{1}{|\det(\boldsymbol{V})|} \sum_{\boldsymbol{k}} F(\Omega - 2\pi(\boldsymbol{V}^{-1})^t \boldsymbol{k}). \tag{4.8}$$

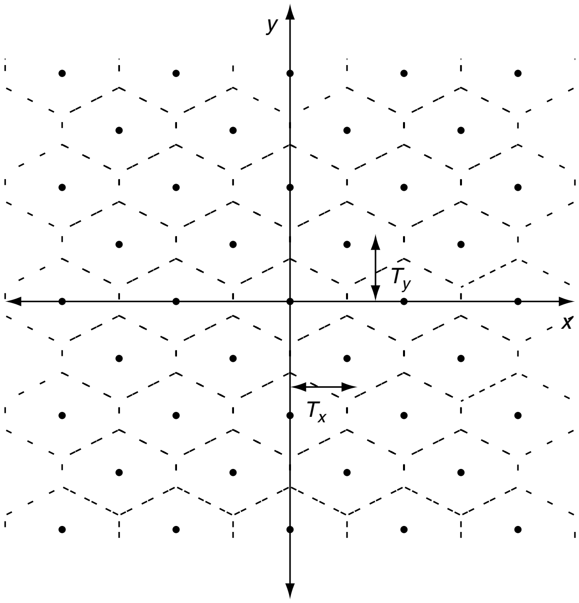


FIGURE 4.7 Sampling a Two-Dimensional Signal Using a Nonrectangular Grid

The matrix $2\pi(\boldsymbol{V}^{-1})^t = \boldsymbol{U}$ gives the periodicity, in the two-dimensional frequency plane, of the spectrum repetitions.

For the sampling grid defined in equation 4.7, we have that the periodicity matrix in the frequency plane is the following:

$$\boldsymbol{U} = \begin{pmatrix} \dfrac{\pi}{T_x} & \dfrac{\pi}{T_x} \\ \dfrac{\pi}{T_y} & -\dfrac{\pi}{T_y} \end{pmatrix}. \tag{4.9}$$

Then, the spectrum becomes like the one shown in Figure 4.8.

One particular nonrectangular grid of interest arises when we make $T_y = \sqrt{3}T_x$. We refer to it as **hexagonal sampling**. One advantage of using such a sampling grid instead of the rectangular one is that, for signals with isotropic frequency response, hexagonal sampling needs 13.4% fewer samples than the rectangular one for representing them without aliasing (Mersereaw and Dudgeon, 1984). Such sampling grid is also useful when the continuous signals have a baseband as in Figure 4.2, as can be observed from Figures 4.4, 4.5, and 4.8. In fact, given the support region of a baseband signal, one can always determine the best sampling grid so that aliasing is avoided with the smallest possible density of samples.

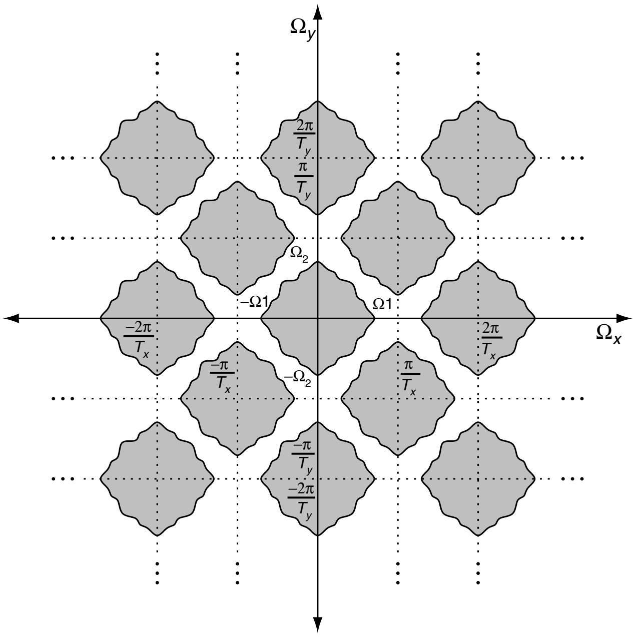

FIGURE 4.8 Spectrum of the Two-Dimensional Discrete Signal Generated by Sampling Using a Nonrectangular Grid

4.3 Image Quantization

To be represented in a digital computer, every signal must be **quantized** once sampled. A digital image, for example, is a matrix of numbers represented with finite precision in the machine being used to process it. More generally, a quantizer is a function $Q(\cdot)$ such that:

$$Q(x) = r_l \text{ for } t_{l-1} < x \leq t_l \text{ for } l = 1, \ldots, L. \tag{4.10}$$

The numbers r_l, $l = 1, \ldots, L$ are referred to as the **reconstruction levels** of the quantizer, and t_l, $l = 0, \ldots, L$ are referred to as its **decision levels**. A typical quantizer is depicted in Figure 4.9.

In many cases, the decision and reconstruction levels of a quantizer are optimized such that the mean-squared error between the quantizer's input and output is minimized. This is usually referred to as a **Lloyd-Max quantizer** (Jain, 1989). In digital image processing, one often uses linear quantizers. For a linear quantizer, the reconstruction and decision levels satisfy the following relations:

$$t_0 = -\infty. \tag{4.11}$$

$$t_{l+1} - t_l = q, \qquad \text{for } l = 1, \ldots, L. \tag{4.12}$$

$$r_{l+1} = t_l + \frac{q}{2} \quad \text{for } l = 1, \ldots, L. \tag{4.13}$$

$$t_L = \infty. \tag{4.14}$$

The parameter q is referred to as the **quantizer step size**.

The mean square error of the linear quantizer, assuming that the quantization error $e(n) = x(n) - Q[x(n)]$ is uniformly distributed, is given by (Jain, 1989):

$$E[e_2(n)] = \frac{q^2}{12}. \tag{4.15}$$

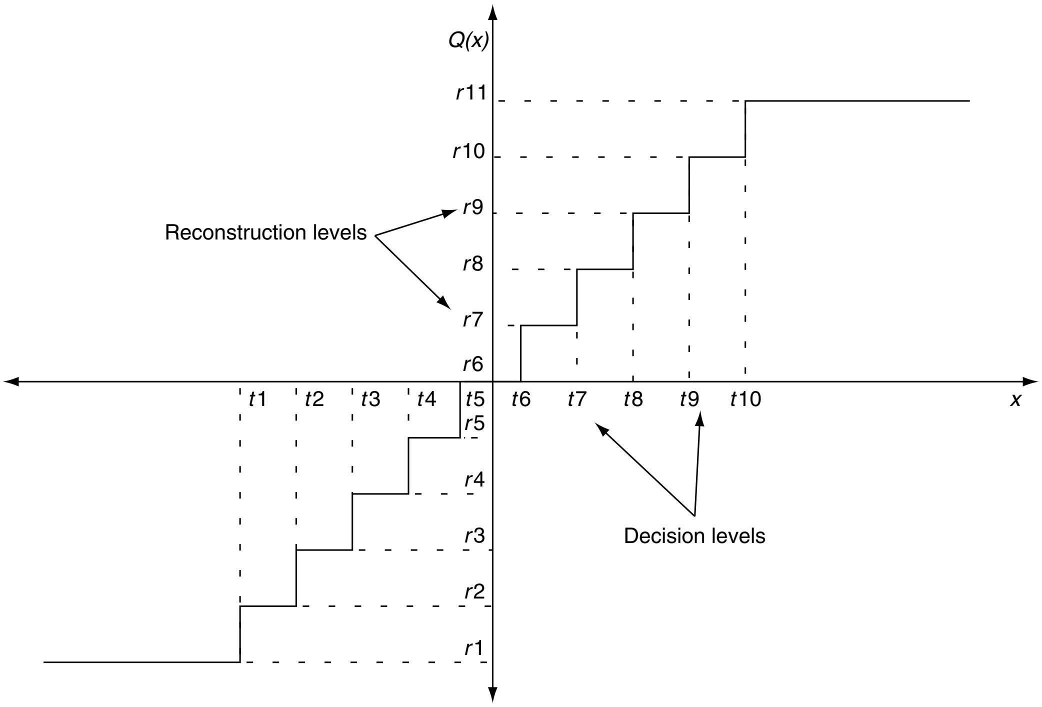

FIGURE 4.9 Typical Quantizer

Since the human eye cannot in general recognize more than around 256 gray levels, usually 8 bits per pixel are enough for representing a gray-scale image. In the case of color images, one uses 8 bits for each color component. For RGB images, this gives 24 bits/pixel.

In many occasions, one needs to quantize an image with less than 8 bits/pixel. Figure 4.10(A) shows the image LENA quantized with 4 bits/pixel. One can notice the effect of false contours. One way to overcome this problem is to perform **dithering** (Jain, 1989). It consists in adding pseudo-random noise to the image prior to quantization. Before display, this noise can be either subtracted from the image or not subtracted. This is illustrated in Figures 4.10(A) to 4.10(C). Figure 4.10(B) shows the LENA image with a pseudo-random noise uniformly distributed in the interval [−25, 25] quantized with 8 levels. Figure 4.10(C) shows the image in Figure 4.10(B) with the pseudo-random noise subtracted from it. One can notice that in both cases there is a great improvement in visual quality when comparing it with Figure 4.10(A). The false contours almost disappear.

4.4 Image Enhancement

Image enhancement is the name given to a class of procedures by which an image is processed so that it can be better displayed or improved for a specific analysis. This can be obtained at the expense of other aspects of the image. There are many enhancement techniques that can be applied to an image.

To provide a flavor of the image enhancement techniques, we will give two examples namely, **histogram manipulation** and **image filtering**.

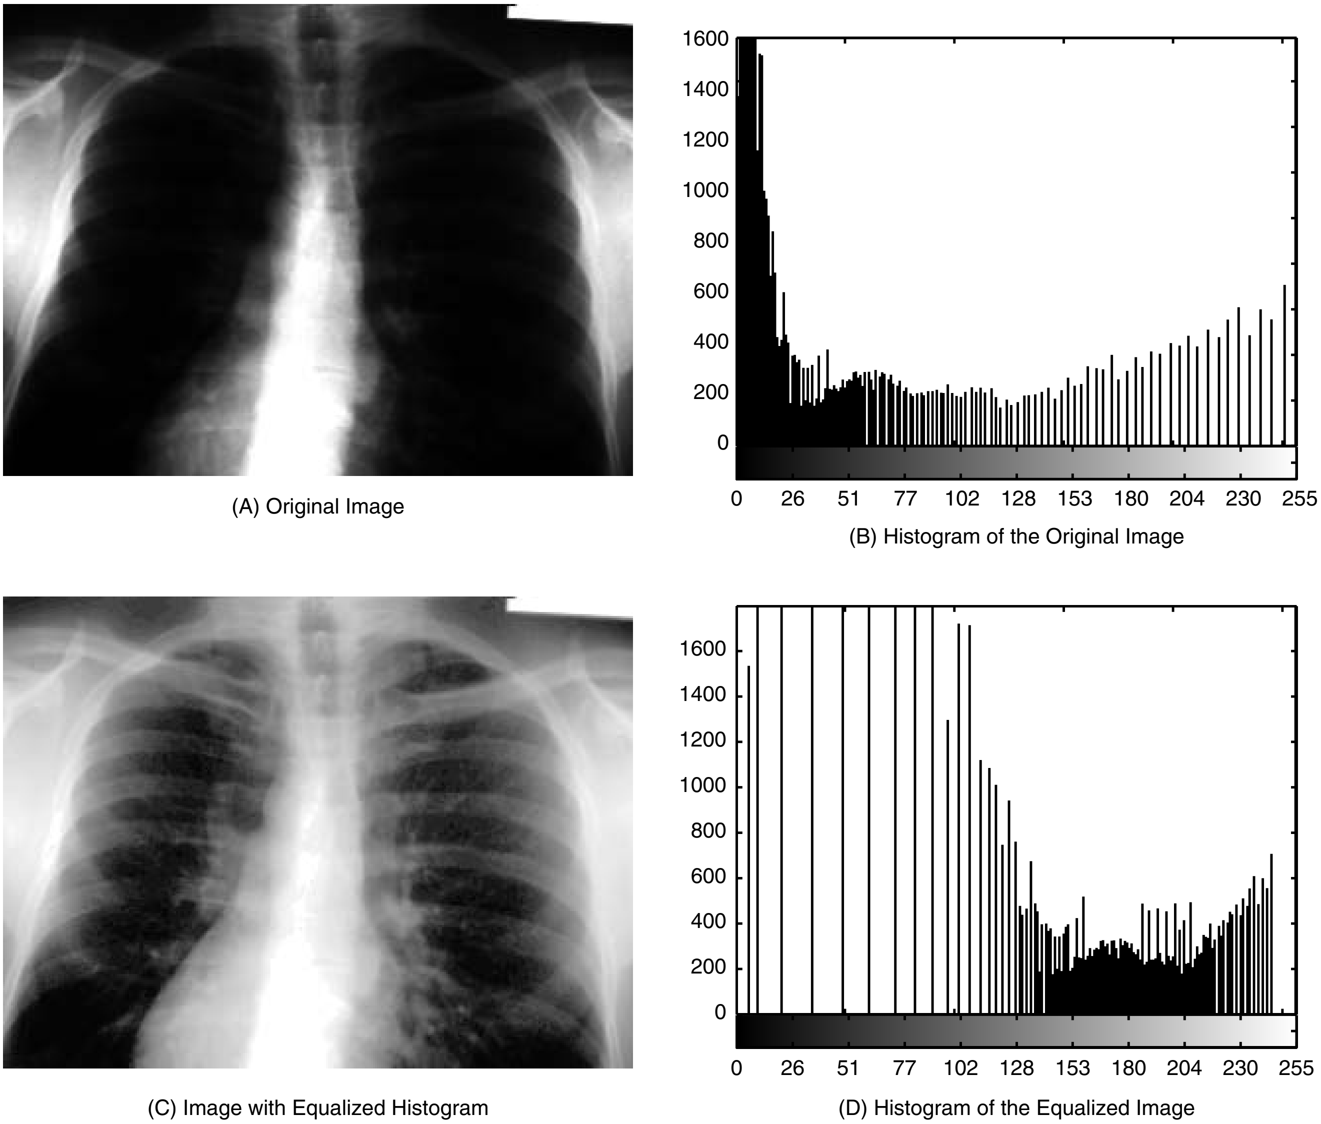
4.4.1 Histogram Manipulation

The histogram of an image is a function that maps each gray level of an image to the number of times it occurs in the image. For example, the image in Figure 4.11(A) has the histogram shown in Figure 4.11(B).

One should note that the pixels have, in general, gray levels in the integer range [0,255].

Histogram Equalization

By looking at Figure 4.11(A), one notices that the image is too dark. This can be confirmed by the image's histogram in Figure 4.11(B), where one can see that the most frequent gray levels have low values. To enhance the appearance of the image, one would need to re-map the image's gray levels so that they become more uniformly distributed. Ideally, one would need to apply a transformation that would make the histogram of the image look uniform. If $F_U(u) = \int_0^u p_U(x)dx$ is the distribution function of the image, then this transformation would



(A) Original Image

(B) Histogram of the Original Image

(C) Image with Equalized Histogram

(D) Histogram of the Equalized Image

FIGURE 4.11 Histogram of an Image

be $y = F^{-1}(x)$ (Gonzalez and Wintz, 1977). In practice, since the pixels can attain only integer values, this operation cannot be performed exactly, and some sort of quantization must be carried out (Jain, 1989).

Figure 4.11(C) shows the image with equalized histogram, and Figure 4.11(D) shows its histogram. Note that the quality of the image is far superior to the original one, and the histogram is much more uniform then the one in Figure 4.11(B).

Another similar histogram manipulation technique is **histogram specification**, where we try to make the histogram of an image as similar as possible to a given one (Gonzalez and Wintz, 1977; Jain, 1989). Some texts refer to **histogram matching**. It is a kind of histogram specification technique in which the histogram of an image is matched to the one of another image. It can be used, for example, when there are two images of the same scene taken from two different sensors.

4.4.2 Linear Filtering

Linear filtering is one of the most powerful image enhancement methods. It is a process in which part of the signal frequency spectrum is modified by the transfer function of the filter. In general, the filters under consideration are linear and shift-invariant, and thus, the output images are characterized by the convolution sum between the input image and the filter impulse response; that is:

$$y(m, n) = \sum_{i=0}^{M} \sum_{j=0}^{N} h(m-i, n-j)x(i, j) = h(m, n) * *x(m, n), \tag{4.16}$$

where the following is true:

- The $y(m, n)$ is the output image.
- The $h(m, n)$ is the filter impulse response.
- The $x(m, n)$ is the input image.

For example, low-pass filtering has the effect of smoothing an image, as can be observed from Figure 4.6(C). On the other hand, high-pass filtering usually sharpens the edges of an image. They can even be used for edge detection, which is used in image analysis algorithms.

The image filtering can be carried out either in the spatial domain, as in equation 4.16, or in the frequency domain, using the discrete Fourier transform (DFT) (Mersereau and Dudgeon, 1984; Oppenheim and Schaffer, 1989). For filtering using the DFT, we use the well known property that the DFT of the circular convolution of two sequences is equal to the product of the DFTs of the two sequences. That is, for $y(m,n)$ defined as in equation 4.16, provided that a DFT of sufficient size is used, we have that:

$$\text{DFT}\{y(m, n)\} = \text{DFT}\ \{h(m, n)\}\ \text{DFT}\ \{x(m, n)\}. \tag{4.17}$$

Therefore, one can perform image filtering in the frequency domain by modifying conveniently the DFT of the image and taking the inverse transformation. This is exemplified in Figures 4.12(A) through 4.12(D).

In Figure 4.12(A), we see an image contaminated with periodic noise. Figure 4.12(B) shows the DFT of this image. One can clearly see the periodic noise as two well-defined points on the DFT of the image. For convenience, arrows are pointing to them. In Figure 4.12(C), one can see the DFT of the image with the periodic noise removed; the frequency locations corresponding to the periodic noise were made equal to zero. Figure 4.12(D) shows the inverse DFT of the image in Figure 4.12(C). One can notice that the noise has been effectively removed, improving the quality of the image a great deal.

Image enhancement is an extensive topic. In this text, we aim at giving a flavor of the topic by providing typical examples. For a more detailed treatment see works by Gonzalez and Wintz (1977) and Jain (1989).

4.5 Image Restoration

In **image restoration**, one is usually interested in recovering an image from a degraded version of it. It is essentially different from image enhancement, which is concerned with accentuation or extraction of image features. Moreover, in image restoration, one usually has mathematical models of the degradation and a statistical description of the ensemble of images used. In this section, we will study one type of restoration problem, namely, the recovery of images degraded by a linear system and contaminated with additive noise. A linear model for degradations is depicted in Figure 4.13. The matrix $u(m, n)$ is the original image, $h(m, n)$ is a linear system representing the degradation, $\eta(m, n)$ is an additive noise, and $v(m, n)$ is the observed degraded image. We can write:

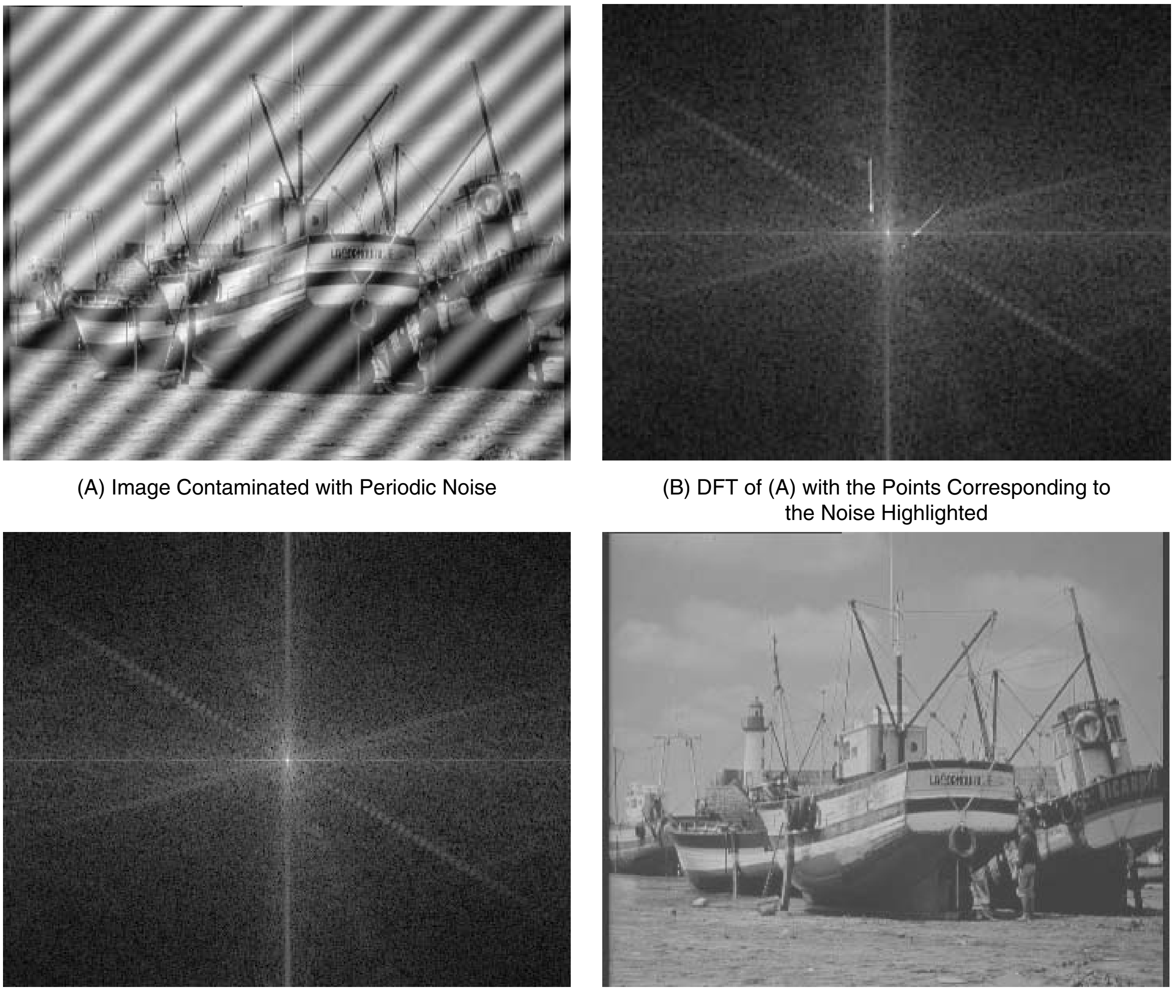
$$v(m, n) = u(m, n) * *h(m, n) + \eta(m, n), \tag{4.18}$$

where $**$ represents a two-dimensional convolution (see equation 4.16).

An illustrative case is when $\eta(m, n) = 0$. In this situation, we can recover $u(m, n)$ from $v(m, n)$ by using a linear filter $g(m, n)$ such that $g(m, n) * *h(m, n) = \delta(m, n)$. In the frequency domain, this is equivalent to having:

$$G(\omega_x, \omega_y) = \frac{1}{H(\omega_x, \omega_y)}. \tag{4.19}$$

This procedure is called **inverse filtering**. The main problem with the inverse filter is that it is not defined in the cases that there is a pair (ω_1, ω_2) such that $H(\omega_1, \omega_2) = 0$. A solution to this problem is the **pseudo-inverse filter** defined as:



(A) Image Contaminated with Periodic Noise

(B) DFT of (A) with the Points Corresponding to the Noise Highlighted

(C) DFT (A) with the Periodic Noise Remove

(D) Recovered Image

FIGURE 4.12 Image Filtering

$$G(\omega_x, \omega_y) = \begin{cases} \frac{1}{H(\omega_x, \omega_y)}, & H(\omega_x, \omega_y) \neq 0. \\ 0, & H(\omega_x, \omega_y) = 0. \end{cases} \tag{4.20}$$

As an example, we analyze now the restoration of images degraded by blur. For image blur caused by excessive film exposure time in the presence of camera motion in the horizontal direction, this degradation can be modeled, in the case of absence of additive noise, as:

$$v(x, y) = \frac{1}{T}\int_0^T u(x - ct, y)dt, \tag{4.21}$$

where the relative speed between the camera and the scene is c and the camera exposure time is T. In the digital domain, this is equivalent to the following operation:

$$v(m, n) = \frac{1}{L}\sum_{t=0}^{L-1} u(m - l, n). \tag{4.22}$$

Figure 4.14(A) shows the ZELDA image, of dimensions 360 × 288, blurred using equation 4.22 with $L = 48$. Applying the pseudo-inverse filter (see equation 4.20) in the frequency

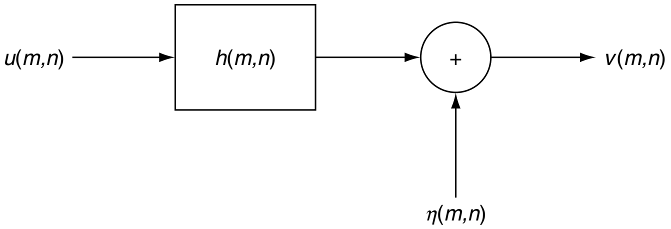


FIGURE 4.13 Image Degradation Model

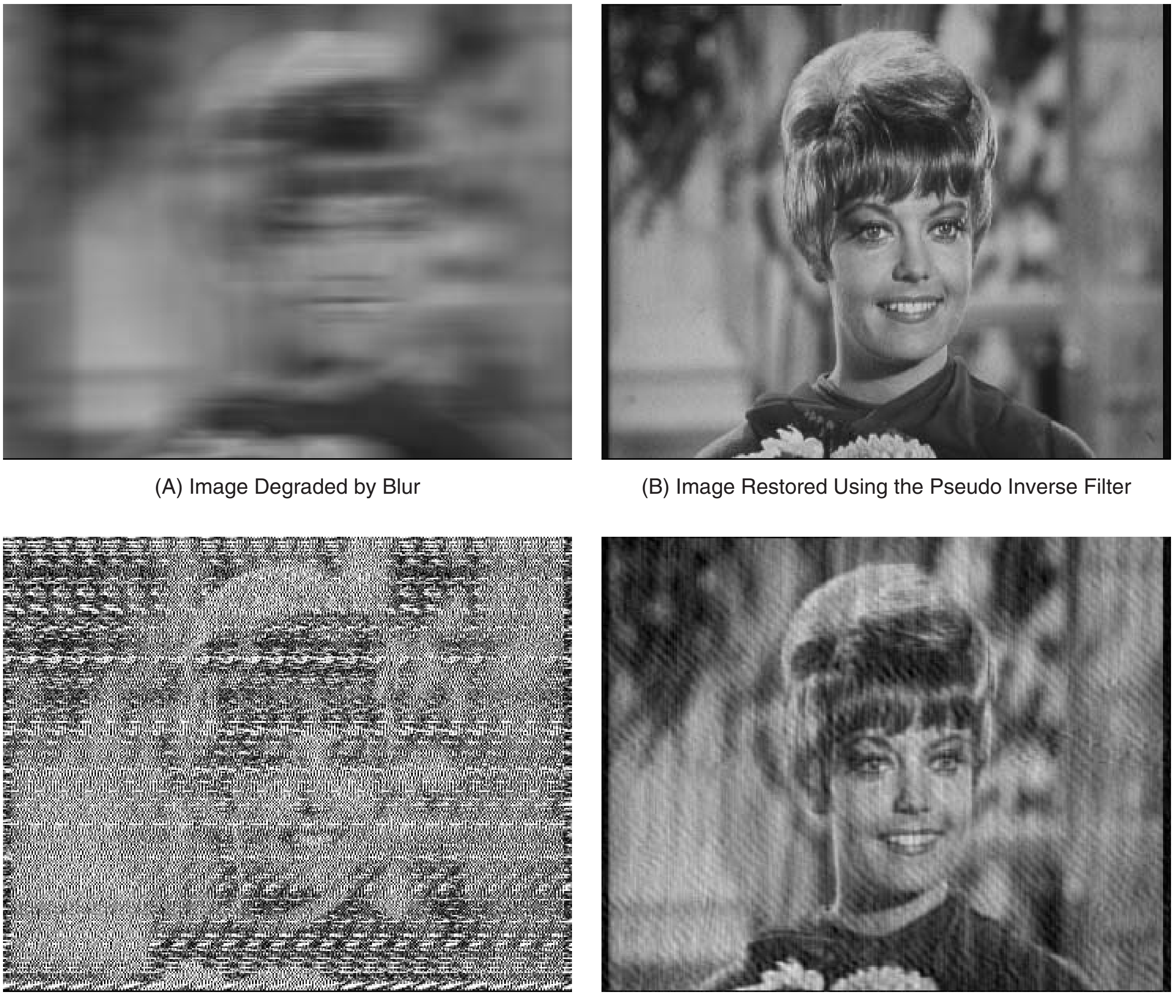

(A) Image Degraded by Blur

(B) Image Restored Using the Pseudo Inverse Filter

(D) Image in (A), Quantized with 256 Levels, after Application of the Wiener Filter

FIGURE 4.14

domain (using a DFT), we obtain Figure 4.14(B). We notice that the recovery can be quite good. It is important to note that, in this case, since the process is supposed to be noiseless, the degradation had to be performed using full machine precision. If we quantize the degraded image using 256 levels, as is usual in image processing applications, a small quantization noise is superimposed on the degraded image. As we explained in Section 4.2, this quantization noise is invisible to the human eye. On the other hand, applying the pseudo-inverse filter to the quantized degraded image, we obtain the image in Figure 4.14(C). We can clearly see that the restoration process has failed completely. The excessive noise present in the restored image results from the fact that, since the quantization noise is relatively white, there is noise information even around the frequencies where $H(\omega_1, \omega_2)$ is very small; as a consequence, $G(\omega_1, \omega_2)$ is very large. This greatly amplifies the noise around these frequencies, thus producing an image like the one in Figure 4.14(C). In fact, one would need a filter that is more or less equivalent to the pseudo-inverse in frequencies where the signal to noise ratio is high but has little effect in regions where the signal to noise ratio is low. One way to accomplish this is using the **Wiener filter** which is optimum for a given image and noise statistics. We describe it in what follows.

4.5.1 Wiener Filter

Given the image degradation model in Figure 4.13, suppose that $x(m, n)$ and $\eta(m, n)$ are zero mean, stationary random processes (Papoulis, 1984). The image restoration problem can be formally stated as: given $v(m, n)$, find the best estimate of $u(m, n)$ and $\hat{u}(m, n)$ such that the mean squared estimation error $E[e^2(m, n)]$ is minimum, where:

$$e(m, n) = u(m, n) - \hat{u}(m, n). \tag{4.23}$$

Such best estimate $\hat{u}(m, n)$ is known to be (Papoulis, 1984; Jain, 1989):

$$\hat{u}(m, n) = E[u(m, n)|v(k, l), \forall(k, l)]. \tag{4.24}$$

In our case, we are looking for linear estimates, that is, $\hat{u}(m, n)$ of the form:

$$\hat{u}(m, n) = v(m, n) * *g(m, n). \tag{4.25}$$

According to the orthogonality principle (Papoulis, 1984), we have the best estimate when:

$$E[e(m_1, n_1)v^*(m_2, n_2)] = 0, \quad \forall m_1, n_1, m_2, n_2, \tag{4.26}$$

where $*$ represents the complex conjugation.

From equation 4.23, we have that the above equation is equivalent to:

$$E[\{u(m_1, n_1) - \hat{u}(m_1, n_1)\}v^*(m_2, n_2)] = 0, \quad \forall m_1, n_1, m_2, n_2. \tag{4.27}$$

For stationary processes, equation 4.27 implies that:

$$r_{uv}(m, n) = r_{\hat{u}v}(m, n), \tag{4.28}$$

where $r_{ab}(m, n)$ is the crosscorrelation (Papoulis, 1984) between signals $a(m, n)$ and $b(m, n)$.

If $S_{ab}(\omega_x, \omega_y)$ is the cross power spectral density (Papoulis, 1984) between signals $a(m, n)$ and $b(m, n)$, the above equation implies that:

$$S_{uv}(\omega_x, \omega_y) = S_{\hat{u}v}(\omega_x, \omega_y). \tag{4.29}$$

Since, from equation 4.25, $\hat{u}(m, n) = v(m, n) * *g(m, n)$, equation 4.29 is equivalent to:

$$S_{\hat{u}v}(\omega_x, \omega_y) = G(\omega_x, \omega_y)S_{vv}(\omega_x, \omega_y). \tag{4.30}$$

From equation 4.29, this implies that:

$$G(\omega_x, \omega_y) = \frac{S_{uv}(\omega_x, \omega_y)}{S_{vv}(\omega_x, \omega_y)}. \tag{4.31}$$

Since, from Figure 4.13 and equation 4.18:

$$v(m, n) = u(m, n) * *h(m, n) + \eta(m, n),$$

and $u(m, n)$ and $v(m, n)$ are considered uncorrelated, we have that:

$$S_{vv}(\omega_x, \omega_y) = S_{uu}(\omega_x, \omega_y)|H(\omega_x, \omega_y)|^2 + S_{\eta\eta}(\omega_x, \omega_y). \tag{4.32}$$

$$S_{uv}(\omega_x, \omega_y) = S_{uu}(\omega_x, \omega_y)H^*(\omega_x, \omega_y). \tag{4.33}$$

Then, from equation 4.31, the above equations imply that the optimum linear estimation filter is as follows:

$$G(\omega_x, \omega_y) = \frac{S_{uu}(\omega_x, \omega_y)H^*(\omega_x, \omega_y)}{S_{uu}(\omega_x, \omega_y)|H(\omega_x, \omega_y)|^2 + S_{\eta\eta}(\omega_x, \omega_y)}. \tag{4.34}$$

This is known as the Wiener filter. Note that the implementation of the Wiener filter requires, besides the knowledge of the degradation process $H(\omega_x, \omega_y)$, the knowledge of the power spectral densities of the ensemble of the original inputs, $S_{uu}(\omega_x, \omega_y)$ and of the noise, $S_{\eta\eta}(\omega_x, \omega_y)$.

Figure 4.14(D) shows the image recovered from the blurred and quantized image. In the implementation of the Wiener filter, it was supposed that the ensemble of the input could be modeled by a first-order Gauss-Markov process [AR(1)] with correlation coefficient equal to 0.95. Since the image has a dynamic range of 256 and was quantized with quantization interval 1, the noise was supposed to be white and uniform with density 1/12 (see equation 4.15). We note that the recovery is far better than the one obtained with the pseudo-inverse filter.

We can rewrite equation 4.34 as:

$$G(\omega_x, \omega_y) = \frac{H^*(\omega_x, \omega_y)}{|H(\omega_x, \omega_y)|^2 + S_{\eta\eta}(\omega_x, \omega_y)/S_{uu}(\omega_x, \omega_y)} \tag{4.35}$$

A couple of interesting conclusions can be drawn from equation 4.35. The first one is that, in regions of the frequency plane where the signal-to-noise ratio is high $\left(S_{\eta\eta}(\omega_x, \omega_y)/S_{uu}(\omega_x, \omega_y) \to 0\right)$, then equation 4.35 is equivalent to equation 4.20, the one for the pseudo-inverse filter. On the other hand, in regions of the frequency plane where the signal-to-noise ratio is low, then the Wiener filter depends on the power spectral densities of both the noise and the input.

In this section, we attempted to provide the reader with a general notion of the image restoration problem, which is still an active area of research (Banham and Katsaggetos, 1997). For a deeper treatment of the subject, the reader is referred to Gonzalez and Wintz (1977), Jain (1989), Lim (1990), Pratt (1978), and Rosenfeld and Kak (1982).

4.6 Image Coding

One of the main difficulties when it comes to image processing applications concerns the large amount of data required to represent an image. For example, one frame of a standard definition digital television image has dimensions 720 × 480 pixels. Therefore, using 256 gray levels (8 bits) for each color component, it requires $3 \times 8 \times 720 \times 480 = 8,294,400$ bits to be represented. Considering that in digital video applications, one uses 30 frames/sec, one second of video needs more than 240 Mbits! Thus, for the processing, storage, and transmission

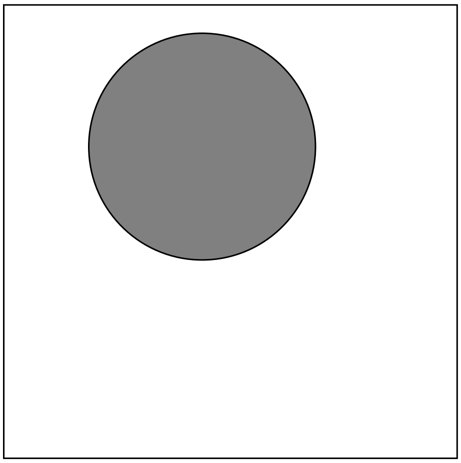

FIGURE 4.15 Illustration of the Image Compression Problem

of images to be feasible, one needs to reduce somehow this number of bits. **Image compression** or **coding**, is the discipline that deals with forms of achieving this. To better understand the image compression problem, consider the 256 × 256 image in Figure 4.15. If we need to represent this image as it is, one would need 8 bits/pixel, giving a total of $8 \times 256 \times 256 = 524{,}288$ bits. Alternatively, if we know that the image in Figure 4.15 is a circle, it would be enough to say that it represents a circle of radius 64, it has a gray level of 102, it has a center coordinates $x = 102$ and $y = 80$, and it is superimposed on a background of gray level 255. Since the radius, x coordinate, and y coordinate are between 0 and 255, one would need 8 bits for specifying each one; since both the gray level of the circle and of the background need 8 bits each, the whole image in Figure 4.15 would only need 40 bits to be specified. This is equivalent to a compression ratio of more than 13,000:1!

The vast majority of images, however, is not as simple as the one in Figure 4.15, and such amount of compression cannot be easily obtained. Fortunately, most useful images are redundant; that is, their pixels carry a lot of superfluous information. This can be better understood by resorting to the images in Figure 4.16.

By looking at Figure 4.16(A), we note that by taking a pixel, for example, at the girl's face, the pixels around it have on average similar values. Certainly there are pixels for which this does not hold, such as at the boundary of the girl's skin and hair. However, this is true of most of the image's pixels. Examining the images in Figures 4.16(B) and 4.16(C), we see that the same reasoning applies to them. In other words, if we know something about one pixel, it is likely that we can guess, with a good probability of success, many things about the pixels around it. This implies that we do not need all the pixels to represent the images, only the ones carrying information that cannot be guessed.

At this point, a question arises: are all images redundant? The answer is no, as one can see in Figure 4.16(D). This image represents uniformly distributed white noise between 0 and 255. To know something about a given pixel does not imply knowing anything about the pixels around it. Such an image, however, is not useful for carrying information and is not of the kind frequently present in nature. Indeed, one can state that most natural images are redundant. Therefore, they are amenable to compression. How to exploit this redundancy to create a compact representation of an image is the main objective of image compression techniques.

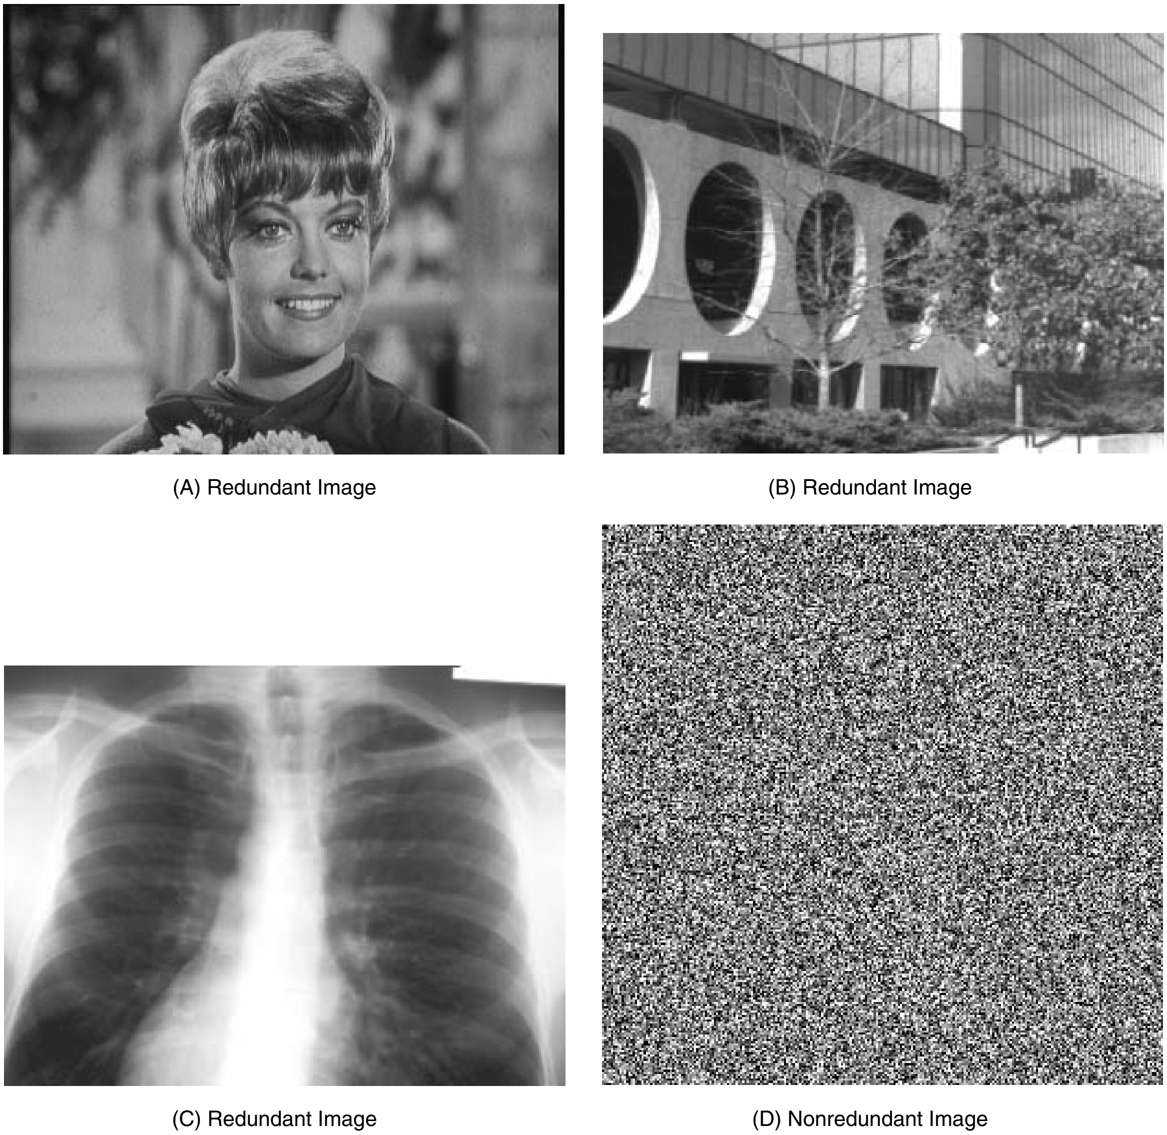
In general, an image compression method can be split into three basic steps, as depicted in Figure 4.17: **transformation**, **quantization**, and **coding**. In the transformation step, a mathematical transformation is applied to the image pixels $x(m, n)$, generating a set of coefficients $c(k, l)$ with less correlation among themselves. Its main objective is to exploit the correlation between the image pixels. For these coefficients $c(k, l)$ to be represented with a limited number of bits, they have to be mapped to a finite number of symbols, $\hat{c}(k, l)$. This mapping is commonly referred to as quantization. In Section 4.2, we introduced some forms of quantization. After the coefficients are mapped to a finite number of symbols, these symbols $\hat{c}(k, l)$ must be mapped to a string of bits $b(s)$ to be either transmitted or stored. This operation is commonly referred to as coding. Actually, we have compression only when the number of bits in $b(s)$, $s = 0, 1, \ldots N$ is smaller than the number of bits needed to represent the pixels $x(m, n)$ themselves. These three steps can be clearly illustrated in the next example, **differential pulse-coded modulation** (DPCM).

4.6.1 DPCM

When looking at the redundant images in Figures 4.16(A) through 4.16(C) one notices, for example, that if we know the value of a pixel $x(m, n-1)$, a good guess for the value of the pixel on its right, $\bar{x}(m, n)$, would be the value of the pixel $x(m, n-1)$. A way to reduce the redundancy on those images would be to transmit or encode only the "part" of the pixel that cannot be guessed. This is represented by the difference between the actual value of the pixel and the guess; that is, one would encode $c(m, n)$ as:

$$c(m, n) = x(m, n) - \bar{x}(m, n) = x(m, n) - x(m, n-1). \quad (4.36)$$

Because the images are redundant, the values of $c(m, n)$ tend to be small. This is illustrated in Figure 4.18, where we can see the histograms of the image LENA [see Figure 4.6(A)] and the histogram of the coefficients generated according to equation 4.36. One can see that the histogram of the original image in Figure 4.18(A) has nothing special about it; it has a more or less random shape. On the other hand, one can see that the histogram of the coefficients $c(m, n)$ has a well-defined shape, tending to a Laplacian distribution. One can also see that indeed the small differences $c(m, n)$ are much more likely than the smaller differences, confirming the redundancy of the LENA



(A) Redundant Image

(B) Redundant Image

(C) Redundant Image

(D) Nonredundant Image

FIGURE 4.16 Redundant and Nonredundant Images: Differences in Pixels

image. A remarkable fact is that the histogram of the differences has a similar distribution for almost any type of natural images. Then, in fact, the transformation we performed, consisting of taking differences between adjacent pixels, has effectively reduced the redundancy of the original image. In addition, because the smaller values are much more probable than the larger ones, if we use a variable-length code to represent the coefficients, where the more likely values are represented with a smaller number of bits and the less likely values are represented with a larger number of bits, we can effectively obtain a reduction on the number of bits used. It is well known from information theory (Thomas and Joy, 1991) that, by properly choosing a code, one can encode a source using a number of bits arbitrarily close to its **entropy**, defined as:

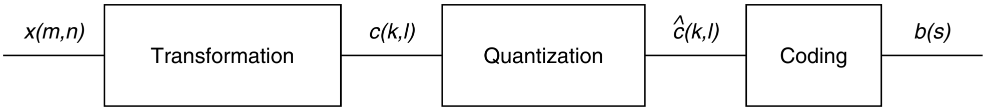


FIGURE 4.17 Three Basic Steps Involved in Image Compression

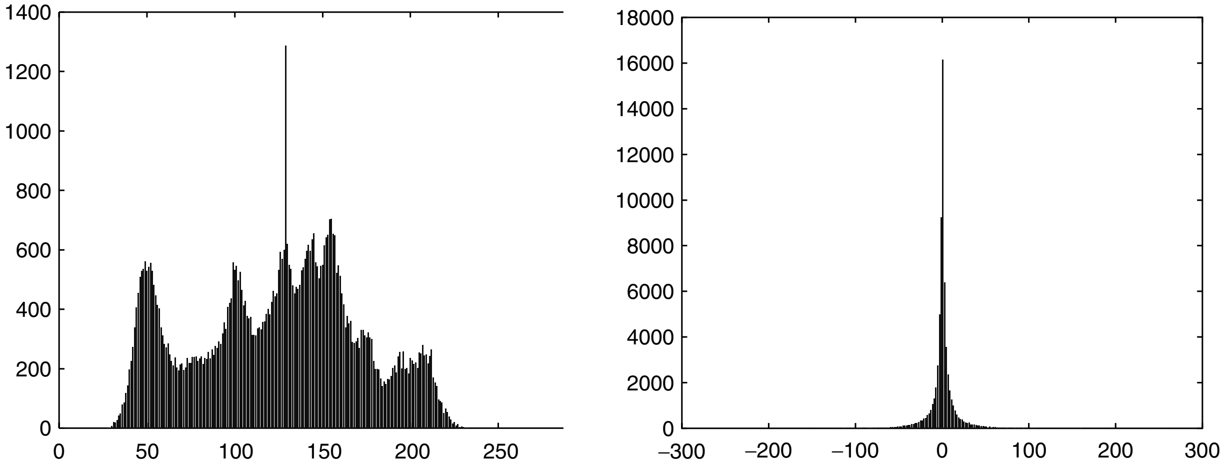

(A) Histogram of the Image LENA

(B) Histogram of the Coefficients $c\ (m, n)$ Generated According to Equation 4.36

FIGURE 4.18 Redundant Images with Small Coefficient Values

$$H(S) = -\sum_{i=1}^{L} p_i \log_2 p_i, \qquad (4.37)$$

where the source S consists of L symbols $\{s_1, \ldots, S_L\}$, with symbol s_i having probability of occurrence p_i. Examples of such codes are **Huffman codes** (Cover and Thomas, 1991) and **arithmetic codes** (Bell *et al.*, 1990). A discussion of them is beyond the scope of this article. For a thorough treatment of these codes, the reader is referred to Bell *et al.* (1990) and Cover and Thomas (1991).

For example, the image LENA has the histogram in Figure 4.18(A). It corresponds to an entropy of 7.40 bits/pixel, and thus, one needs at least 8 bits to represent each pixel of the image LENA. On the other hand, the entropy of the coefficients, whose histogram is in Figure 4.18(B), is 3.18 bits/coefficient. Therefore, one can find a Huffman code that just needs 4 bits to represent each of them. This is equivalent to a compression ratio of 2:1. This compression was achieved by the combination of the transformation (taking differences) and coding (Huffman codes) operation.

It is noteworthy that the compression obtained in the above example was achieved without any loss; that is, the input image could be recovered, without error, from its compressed version. This is referred to as **lossless compression**. In some circumstances, one is willing to give up the error-free recovery to obtain larger compression rates. This is referred to as **lossy compression**. In the case of images, lossy compression is used a great deal, especially when one can introduce distortions with just a low degree of visibility (Watson, 1993).

These higher compression rates can be obtained through quantization, as described in Section 4.2. In the example above, the differences $c(m, n)$ have a dynamic range from $0 - 255 = -255$ to $255 - 0 = 255$. Therefore, there are 512 such differences. By applying quantization as in Figure 4.9, the number of possible differences can be decreased at the expense of some distortion being introduced. Figure 4.19 describes a practical way of achieving a lossy compression using DPCM. Notice that, in this case, due to quantization, the decoder cannot recover the original pixels without loss. Therefore, instead of $c(m, n)$ being computed as in equation 4.36, with $x(m, n-1)$ being the prediction for the pixel $x(m, n)$, the prediction for $x(m, n)$ is the "recoverable" value of $x(m, n-1)$ at the decoder. Note that to achieve this, there must be a perfect copy of the decoder in the encoder. Details of this kind of coder/decoder can be found in Jayant and Noll (1984).

For the LENA image, if one uses a 16-level quantizer of the same type as the one in Figure 4.9, then the histogram of the quantized differences $Q[c(m, n)]$ is as in Figure 4.20(A). The bit rate necessary to represent them can be made arbitrarily close to the entropy by means of conveniently designed Huffman codes. In this case, the entropy is 1.12 bits/pixel. Therefore, the reconstructed image in Figure 4.20(B) is the result of a compression ratio of more than 7:1. As can be seen, despite the high compression ratio achieved, the quality of the reconstructed image is quite acceptable.

This example highlights the nature and effect of the three basic operations described in Figure 4.17: **transformation** for reducing the redundancy between the pixels; **quantization** for reducing the number of symbols to encode; and **coding** to associate to the generated symbols, the smallest average number of bits possible.

4.6.2 Transform Coding

In the DPCM encoder/decoder already discussed, the transformation consisted of taking the differences between a pixel

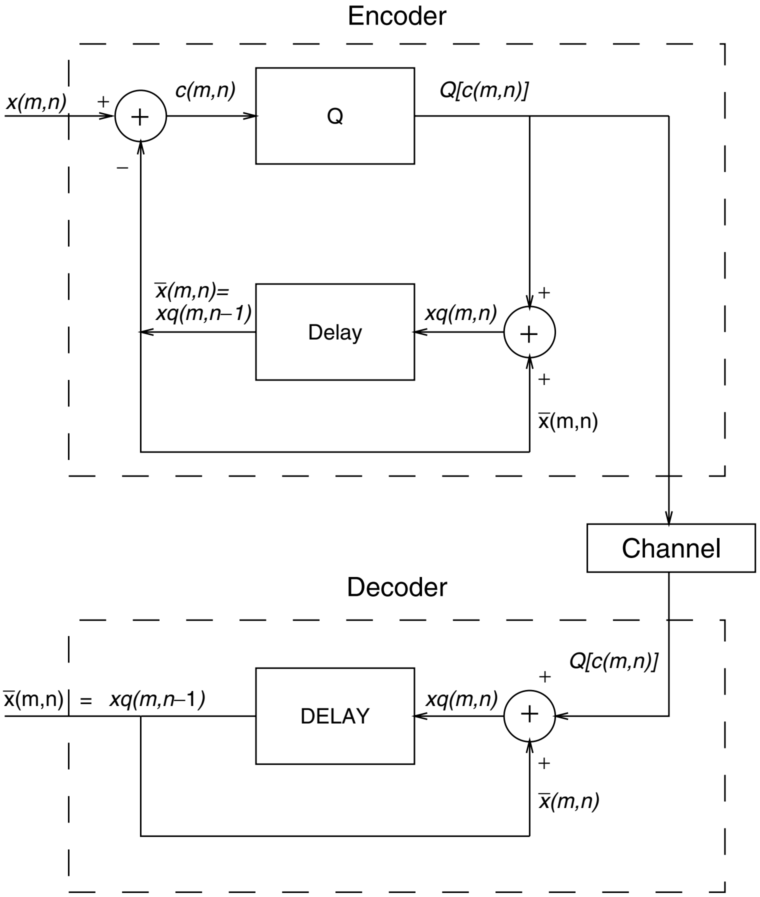

FIGURE 4.19 DPCM Encoder/Decoder

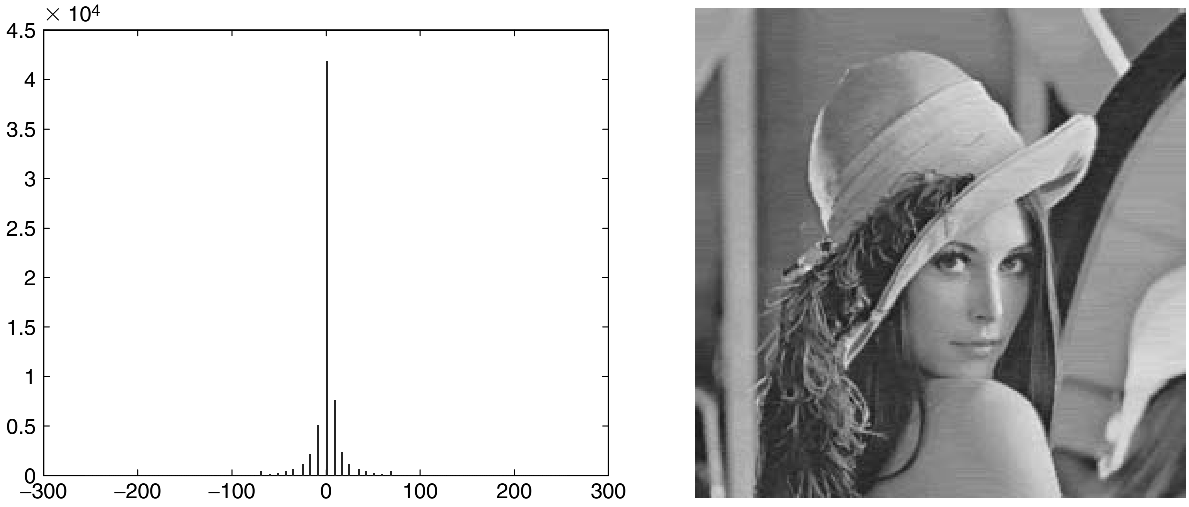

(A) Histogram of the Quantized Differences $Q[c(m, n)]$ in Figure 4.19 for the Case of the LENA Image

(B) Recovered Image $x(m,n)$

FIGURE 4.20

and the adjacent pixel to its left. It indeed reduced the redundancy existing in the image. However, only the redundancy between two adjacent pixels was exploited. By looking at images like the ones in Figures 4.16(A) through 4.16(B), we notice that a pixel has a high correlation with many pixels surrounding it. This implies that not only the redundancy between adjacent pixels but also the redundancy in an area of the image can be exploited. By exploiting this, one expects to obtain even higher compression ratios. **Transform coding** is the generic name given to compression methods in which this type of redundancy reduction is carried out by means of a linear transform (Clarke, 1985).

By far, the most widely used linear transform in compression schemes up to date is the **discrete cosine transform** (DCT). It is part of the old JPEG standard (Pennebaker and Mitchell, 1993) as well as most modern video compression standards, like H.261 (ITU-T, 1990), H.263 (ITU, 1996), MPEG-1 (ISO/IEC, 1994), MPEG-2 (ISO/IEC, 1994) and MPEG-4 (ISO/IEC, 1997). The DCT of a length N signal $x(n)$ consists of the coefficients $c(k)$ such that (Ahmed *et al.*, 1974):

$$c(k) = \alpha(k) \sum_{n=0}^{N-1} x(n) \cos\left[\frac{\pi(2n+1)k}{2N}\right], \tag{4.38}$$

where $\alpha(0) = \sqrt{\frac{1}{N}}$, $\alpha(k) = \sqrt{\frac{2}{N}}$, and $1 \leq k \leq N-1$.

Given the DCT coefficients, the original signal can be recovered using:

$$x(n) = \sum_{k=0}^{N-1} c(k)\alpha(k) \cos\left[\frac{\pi(2n+1)k}{2N}\right]. \tag{4.39}$$

For images, the DCT can be calculated by first computing the one-dimensional DCT of all the rows of the image and then computing the one-dimensional DCT of all the columns of the result.

The DCT is very effective in reducing the redundancy of real images. It tends to concentrate energy in very few transform coefficients. In other words, the coefficients with most of the energy are in general the ones with low values of k in equation 4.38. Since, in this equation, k is proportional to the frequency of the cosine function, usually one refers to them as low-frequency coefficients. To illustrate this, Figure 4.21 shows the 256 × 256 DCT of the image LENA 256 × 256. Actually, the logarithm of the absolute value of the coefficients has been plotted. Black corresponds to zero, and the whiter the pixel, the higher its value.

We can see clearly that the energy is highly concentrated in the low-frequency coefficients. Therefore, it is natural to think of a lossy image compression system in which only the coefficients having higher energies are encoded. To get a feeling of this, one can look at Figure 4.22. There, the LENA image has been divided into 8 × 8 blocks, and the DCT of each block was computed. In Figures 4.22(A) to 4.22(D), we can see the image recovered, respectively, using 1, 3, 15, and all 64 coefficients of each block. We note, for example, that the difference between the original image and the one recovered using 15 coefficients is almost imperceptible.

FIGURE 4.21 A 256 × 256 DCT of the 256 × 256 LENA Image

Because the DCT highly concentrates the energy in few coefficients, a large number of the DCT coefficients are zero after quantization. Therefore, a coding method that avoids explicitly encoding the zeros can be very efficient. In practice, this is achieved by scanning the quantized DCT coefficients as in Figure 4.23 prior to encoding. Then, instead of encoding each coefficient, one encodes the pairs (run, level); **level** indicates the quantized value of the nonzero coefficient, while **run** indicates the number of zeros that comes before them. The encoding is performed using an entropy coder, like a Huffman or arithmetic coder. High compression rates can be achieved using such schemes. For example, the JPEG standard (Pennebaker and Mitchell, 1993) is essentially based on the above scheme. The same applies to the H.261, H.263, MPEG-1, MPEG-2, and MPEG-4 standards. Figure 4.24 shows the LENA 256 × 256 image encoded using JPEG with 0.5 bits/pixel and a compression ratio of 16:1.

One of the main drawbacks of DCT-based image compression methods is the blocking effect that occurs at low rates (see Figure 4.22). One way to solve this is to use a **wavelet transform** in the transformation stage.

Essentially, a wavelet transform is an octave band decomposition in which each band is subsampled according to its bandwidth (Mallat, 1998; Vetterli and Kovačević, 1995). A way of achieving this is to first divide a signal into low- and high-pass bands, with each band being subsampled by two. Then, only the low-pass channel is again low- and high-pass filtered, and each band is subsampled by two. This process is recursively repeated until a predetermined number of stages is reached. For an image, the same process is performed for

both its rows and columns. Figure 4.25 shows an image and its wavelet transform. Figure 4.25(B) shows that the wavelet transform contains mostly coefficients with small magnitudes. In addition, the transform's bands are directional; that is, besides the low-frequency band, one can see horizontal, vertical, and diagonal bands. From an image compression point of view, it is important to notice that the coefficients with small value, which are put to zero after quantization, tend to be clustered. This facilitates their efficient coding, thereby producing high compression ratios. Image coding methods based on the wavelet transform have the advantage of the absence of blocking effects in low rates. Figure 4.24(B) shows a LENA 256 × 256 image compressed at a rate of 16:1 using a wavelet-based encoder. One can notice the superior image quality compared to the DCT-coded one in Figure 4.24(A). Indeed, the JPEG 2000 standard (ISO/IEC, 2000) is based on the wavelet transform. References to state-of-the-art wavelet image encoding methods can be found in works by Andrew (1997), Lan and Tewfik (1999), Said and Pearlman (1996), Shapiro (1993), and Taubman (1999).

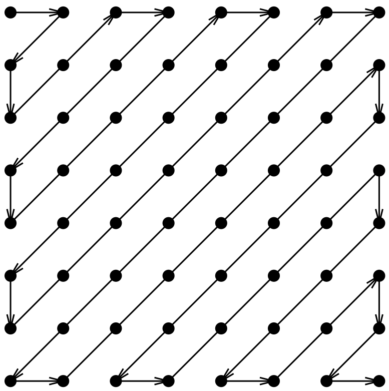

FIGURE 4.23 Scanning Order of the Quantized DCT Coefficients

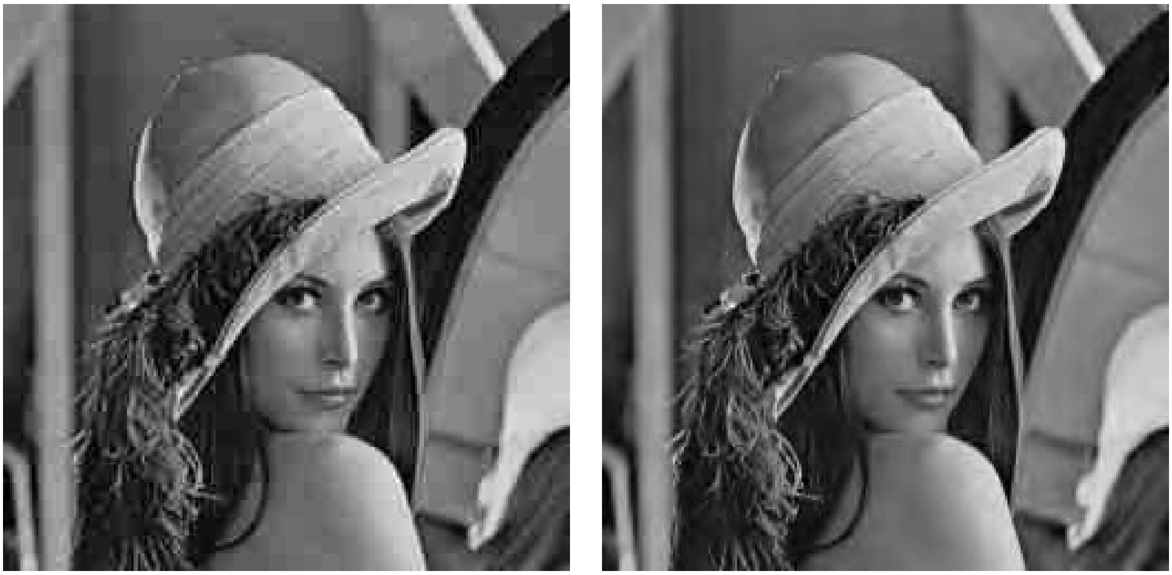
4.7 Image Analysis

The discipline of image analysis is a very vast one. It deals with the automatic extraction of information from an image or sequence of images. It is also an essential part of computer vision systems. In this section, we provide a brief overview of its main issues. For a more detailed treatment, the reader is referred to some excellent texts on image processing and computer vision, such as Castleman (1979), Faugeras (1993), Gonzales and Wintz (1977), Haralick and Shapiro (1992, 1993), Jain (1989), Law (1991), Pratt (1978), Rosenfeld and Kak (1982), and Russ (1995).

For an image to be analyzed, its main **features** have to be isolated. **Spatial features** like edges, central moments, and entropy are used a great deal. However, **frequency domain** features obtained in the Fourier transform domain may also be useful. Since, for analysis purposes, a scene must be segmented in objects, there must be ways of extracting the objects and representing them. Edge extraction systems are some of the first steps for isolating the different image objects. They are usually based on some form of gradient-based approach, where the edges are associated to large gray level variations. Once the edges are extracted, one can use contour following algorithms to identify the different objects. **Texture** is also a useful feature to be used.

Once the features are extracted, one uses image **segmentation algorithms** to separate the images into different regions. The simplest are the ones based on amplitude thresholding, in which the features used for region determination are the amplitudes of the pixels themselves; each region is defined by a range of amplitudes. If the features used are the edges, one can use **boundary representation** algorithms to define the regions in an image. One can also use **clustering algorithms** to define a region as the set of pixels having similar features. **Quad-trees** are a popular approach for defining regions. **Template** or **texture matching algorithms** can be used to determine which pixels represent a same shape or pattern, thereby defining regions based on them. These belong to the class of **pattern recognition** algorithms that have, by themselves, a large number of applications. In the case of image sequences **motion detection** can be used to define the regions as the pixels of the image having the same kind of movement. For each region, one can also perform **measurements**, such as **perimeter area** and **Euler number**. **Mathematical morphology** (Serra, 1982) is a discipline commonly employed for performing such measurements.



(A) Using the JPEG Standard

(B) Using Wavelet Transforms

(A) Octagon Image

(B) Wavelet Transform

FIGURE 4.25 An Image and Its Wavelet Transform. White corresponds to positive values, black to negative values, and gray to zero values.

Having the different image regions defined, one must group them into objects by labeling the regions so that all the regions belonging to an object have the same label and regions belonging to different objects have different labels. To achieve this, one can use some kind of clustering algorithm.

Once the objects are identified, they must be classified in different categories. The classification can be based, for example, on their shapes. Then, image understanding techniques can be used to identify high-level relations among the different objects.

The image analysis tools mentioned above can be exemplified by Figure 4.26. It shows one bolt and two nuts. The features to be extracted are, for example, the contours of the nuts and the bolt. The regions can be defined as the pixels inside the different contours; alternatively, they can be represented as the pixels having gray level within predetermined ranges. Depending on the application, we may know the shape of one object (e.g., the bolt) and perform pattern matching to determine the position of the bolt on the image. One could also use mathematical morphology to compute the Euler number to count the “number of holes” of each object and consider the nuts as the ones having just one hole. Then, the inner perimeter of the nuts can be determined to check whether they comply to manufacturing specifications. By closely observing the bolt, one can notice that it is composed of several different regions (e.g., its head clearly belongs to a region different from its body). Therefore, after the segmentation algorithm, one should perform region labeling to determine which regions should be united to compose the bolt. Once having established that the image is composed of three objects, image classification and understanding techniques should be used to figure out what kind of objects they are. In this case, one must determine that there are two nuts and one bolt from the data extracted in previous steps. Finally, a robot could use this information, extracted automatically, to screw the bolt into the round nut.

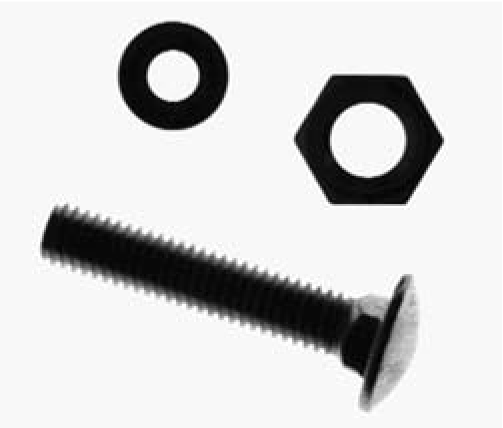

FIGURE 4.26 Hardware Image

As mentioned previously, this section provides only a very brief overview of this vast subject, but the open literature provides a vast treatment of it as first described in this section.

4.8 Summary

This chapter presented an introduction to image processing techniques. First, the issues of image sampling and quantization were dealt with. Then, image enhancement and restoration techniques were analyzed. Image compression methods were described, and the chapter finished with a very brief description of image analysis techniques.

Multimedia Systems and Signal Processing

John R. Smith
IBM, T. J. Watson Research Center,
Hawthorne, New York, USA

5.1 Introduction

With the growing ubiquity and portability of multimedia-enabled devices, **universal multimedia access** (UMA) is emerging as one of the important applications for the next generation of multimedia systems (Smith, 2000). The basic concept of UMA is the adaptation, summarization, and personalization of multimedia content according to usage environment. The different dimensions for adaptation include rate and quality reduction (Kuhn *et al.*, 2001), adaptive spatial and temporal sampling (Smith, 1999), and semantic summarization of the multimedia content (Tseng *et al.*, 2002). The different relevant dimensions of the user environment include device capabilities, bandwidth, user preferences, usage context, and spatial and temporal awareness.

UMA facilitates the scalable or adaptive delivery of multimedia to users and terminals regardless of bandwidth or capabilities of terminal devices and their support for media formats. In addition, UMA allows the content to be customized for users at a high-semantic level through summarization and personalization according to user preferences and usage context (Tseng *et al.*, 2002). UMA is relevant for emerging applications that involve delivery of multimedia for pervasive computing (e.g., handheld computers, palm devices, portable media players), consumer electronics (e.g., television set-top boxes, digital video recorders, television browsers, Internet appliances), and mobile applications (e.g., cell phones, wireless computers) (Bickmore and Schlit, 1997; Smith *et al.*, 1999, 1998b; Han and Smith, 2000). UMA is partially addressed by scalable or layered encoding, progressive data representation, and object- and scene-based encodings (such as MPEG-4) that inherently provide different embedded levels of content quality (Vetro *et al.*, 1999). From the network perspective, UMA involves important concepts related to the growing variety of communication channels, dynamic bandwidth variation, and perceptual quality of service (QoS) (Mohan and Smith, 1999, 1998). UMA involves different preferences of the user (recipients of the content) and the content publisher in choosing the form, quality, and personalization of the content. UMA promises to integrate these different perspectives into a new class of content-adaptive applications that allows users to access multimedia content without concern for specific encodings, terminal capabilities, or network conditions.

5.1.1 MPEG-7/-21 and UMA

The emerging MPEG-7 and MPEG-21 standards address UMA in a number of ways. The overall goal of MPEG-7 is to enable fast and efficient searching, filtering, and adaptation of multimedia content (Salembier and Smith, 2001; Smith, 2003). In MPEG-7, the application of UMA was conceived to allow the scalable or adaptive delivery of multimedia by providing tools for describing transcoding hints and content variations (van Beek *et al.*, 2003; Smith and Reddy, 2001). MPEG-21 addresses the description of user environment, which includes terminals and networks (Smith, 2002). Furthermore, in MPEG-21, digital item adaptation facilitates the adaptation of digital items and media resources for usage environment. The MPEG-21 digital item adaptation provides tools for describing user preferences and usage history in addition to tools for digital item and media resource adaptation (Salembier and Smith, 2001).

5.1.2 UMA Architecture

The basic problem of UMA concerns allowing users to access multimedia content anytime, anywhere, and without concern for particular formats, devices, networks, and so forth. Consider the server–proxy–client network architecture shown in Figure 5.1. UMA can be enabled in a number of ways. First, it is possible to store multiple variations of the content at the server and select the best variation for each particular request (Li *et al.*, 1998). Given multiple media resources in a presentation, it may be necessary to make the selection of multiple variants jointly to meet the overall delivery constraints (Smith *et al.*, 1999). As an alternative, it is possible to perform content adaptation at the server or in the network, such as at the proxy device. For example, considering a scenario in which a user allocates 10 min for receiving a video summary of a sports game, the server or proxy can manipulate the video content to produce a highlighted video that is personalized for the user's particular preference, such as a focus on a favorite team or player or preferred types of plays in the game (e.g., for a baseball game, this could be strikeouts, hits, homeruns, etc.).

5.1.3 Outline

This chapter describes UMA as one of the emerging applications of multimedia systems and signal processing. In particular, it describes how different multimedia systems and signal processing tools use MPEG-7 and MPEG-21 for enabling UMA. Section 5.2 describes the MPEG-7 support for UMA, which includes transcoding hints and variations descriptions. Section 5.3 describes the MPEG-21 support for UMA, which includes digital item adaptation. Section 5.4 describes how transcoding of images can be optimized using MPEG-7 transcoding hints. Section 5.5 describes a method for the optimized selection of media resources, which applies to MPEG-7 variations and MPEG-21 digital items.

5.2 MPEG-7 UMA

MPEG-7 addresses the requirements of UMA by providing a number of different tools for content adaptation (Smith and Reddy, 2001; Kuhn and Suzuki, 2001). For one, MPEG-7 defines **description schemes** that describe different abstraction

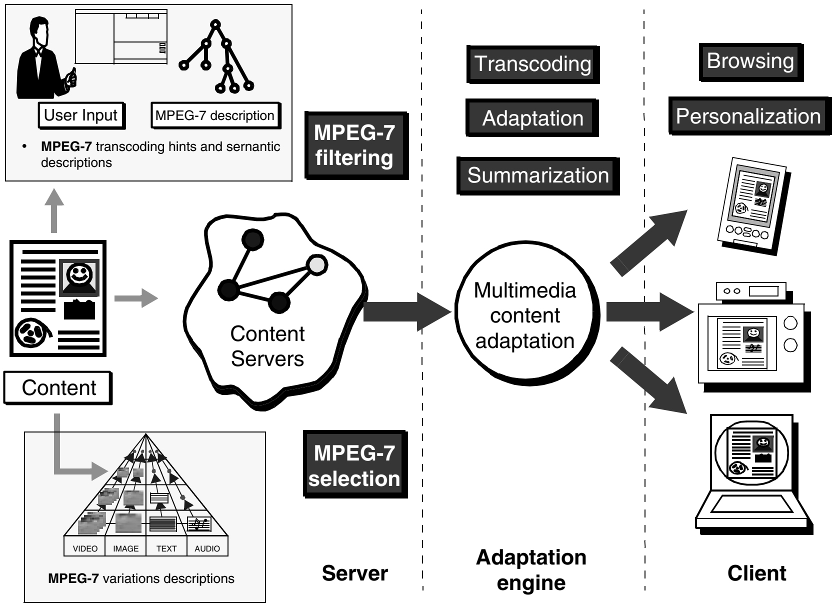

FIGURE 5.1 Universal Multimedia Access. UMA involves the adaptive delivery of multimedia content according to usage environment, which includes devices and networks, user preferences, and usage context.

levels and variations of multimedia content. For example, the different abstraction levels include the composition of objects from sub-objects, the extraction of plot structure of a video, summaries of multimedia programs, and different variations of the multimedia data with different resource requirements. In addition, MPEG-7 supports the transcoding, translation, summarization, and adaptation of multimedia material according to the capabilities of the client devices, network resources, and user and author preferences. For example, adaptation hints may be provided that indicate how a photograph should be compressed to adapt it for a handheld computer or how a video should be summarized to speed up browsing over a low-bandwidth network (Smith *et al.*, 1998a).

5.2.1 MPEG-7 Transcoding Hints

The MPEG-7 **Media Transcoding Hint Description Scheme** gives information that can be used to guide the transcoding of multimedia, including description of importance, priority, and content value and description of transcoding behavior based on transcoding utility functions and network scaling profile, as shown in Figure 5.1. In addition, media coding tools give information about multimedia data including the image and video frame size (width and height), frame rates of video, data sizes for image, video and audio download and storage, formats, and MIME-types.

The MPEG-7 media transcoding hints allow content servers, proxies, or gateways to adapt image, video, audio, and multimedia content to different network conditions, user and publisher preferences, and capabilities of terminal devices with limited communication, processing, storage, and display capabilities. MPEG-7 provides the following types of transcoding hint information as part of its Media Transcoding Hints:

- **Importance** MPEG-7 specifies the relative importance of resources, segments, regions, objects, or media resources. The importance takes values from 0.0 to 1.0, where 0.0 indicates the lowest importance and 1.0 indicates the highest importance.
- **Spatial resolution** MPEG-7 specifies the maximum allowable spatial resolution reduction factor for perceptability. This feature takes values from 0.0 to 1.0, where 0.5 indicates that the resolution can be reduced by half, and 1.0 indicates the resolution cannot be reduced

Importance Hints

The **Importance Hints** can be used to annotate different regions with information that denotes the importance segment hint type of each region. The Importance Hint descriptions can then be used to transcode the images for adaptive delivery according to constraints of client devices and bandwidth limitations. For example, text regions and face regions can be compressed with a lower compression factor than the factors for the remaining part of the image. The other parts of the image are blurred and compressed with a higher factor to greatly reduce the overall size of the compressed image. MPEG-7 UMA enables more intelligent transcoding capability using the MPEG-7 Importance Hint information than otherwise would be provided. The MPEG-7 Importance Hint information has advantages over methods for automatic extraction of regions from images in the transcoder in that the Importance Hints can be provided by the content authors or publishers directly. This allows greater control in the adaptation and delivery of content.

Spatial Resolution Hints

The **Spatial Resolution Hints** can be used to denote the minimum resolution with which a segment should be displayed. For example, if an image region contains a face or textual information, then it may be necessary to preserve a minimum resolution for the contents to be discernible.

Example Transcoding Hints Annotation

The following example shows an MPEG-7 description of transcoding hints for an image in which three regions have been annotated ($R1$, $R2$, and $R3$). Values are assigned for the importance of Spatial Resolution Hint attributes of each region.

5.2.2 MPEG-7 Variations

The **MPEG-7 Variation Description** addresses a general framework for managing and selecting multimedia content for adapting delivery. As depicted in Figure 5.2, the Variation DS describes different variations of media resources with different **modalities** (e.g., video, image, text, and audio) and **fidelities** (e.g., summarized, compressed, scaled, etc.) (Li *et al*., 1998).

The MPEG-7 Variation DS describes the relationships among the different variations of a media resource. For example, Figure 5.2 shows the variations of a video resource *A*. The variations differ in fidelity and modality. The vertical axis shows lower fidelity variations of each resource. The horizontal axis shows different modality variations (e.g., image, text, and audio) of each resource.

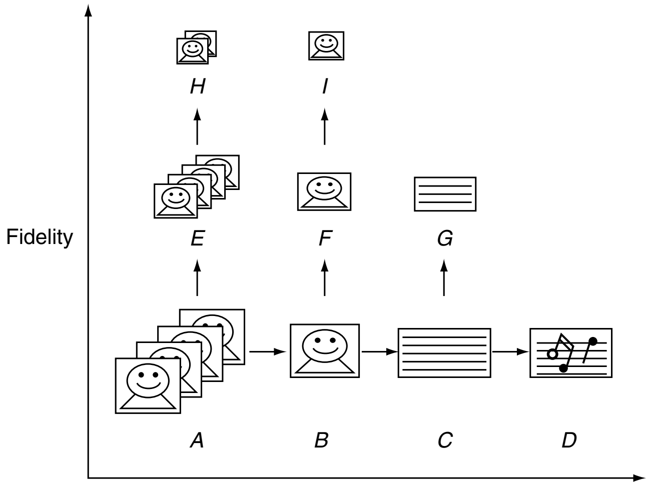

FIGURE 5.2 The MPEG-7 Variation DS. This feature allows the selection and adaptive delivery of different variations of multimedia content.

5.3 MPEG-21 Digital Item Adaptation

MPEG-21 specifies an XML Schema-based language for describing media resource adaptability, user environment, and other concepts related to adapting and configuring digital items and adapting media resources to user environments. While MPEG-7 has an important role in describing media resource adaptability, user preferences, and controlled terms, MPEG-21 further describes media resource adaptability, usage environment, and adaptation rights. MPEG-21 is also investigating a language for describing and manipulating bit streams (BSDL).

The Digital Item Declaration part of MPEG-21 specifies an XML Schema-based language for declaring digital items, which are packages of media resources and metadata. The following example shows a digital item that contains music plus images and gives its digital item declaration.

Digital Item Example (Music and Images)

Figure 5.3 shows an example digital item that contains two descriptors and three media resource items. One of the descriptors gives creation information about the digital item and defines a title. The other descriptor gives a purely text-based description of the digital item. The digital item contains one

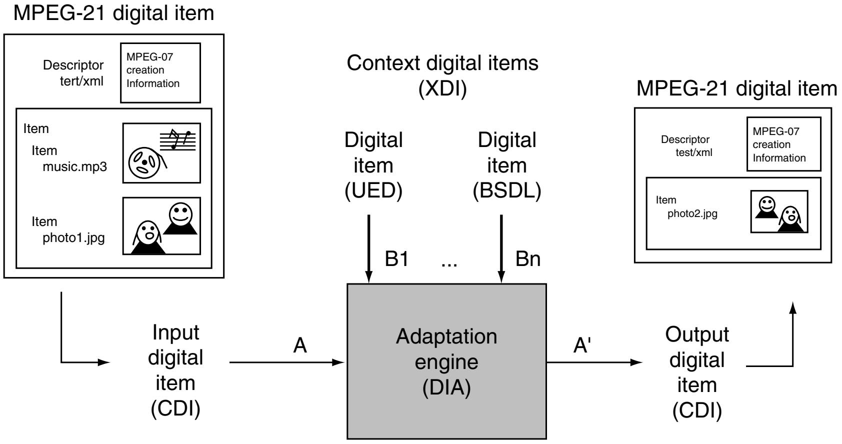

FIGURE 5.3 MPEG-21 Digital Item Adaptation. This feature addresses the configuration of digital items and adaptation of their media resources.

music file and two photos. The media resources are referenced by a locator.

The following MPEG-21 XML description gives the declaration for the digital item depicted in Figure 5.3. As shown next, the digital item declaration provides a container at the top level, which forms the logical package for the digital item. It contains a descriptor that holds the XML statement giving an MPEG-7 description and an item that contains further description and sub-item elements. The description contained by the item holds a plain text statement giving a textual description of the item. The three sub-items each contain one component that gives a media resource. The first one gives an audio resource (music.mp3); the latter two each give an image (photo1.jpg and photo2.jpg).

5.3.2 Digital Item Configuration

MPEG-21 accommodates digital item adaptation in a number of ways, such as through digital item configuration or media resource adaptation or transcoding as shown in Figure 5.3. **Digital item configuration** is the mechanism by which selections are made among the elements of the digital items. The digital item declaration includes a **choice** element that describes a set of related selections that configure an item. A **selection** describes a specific decision affecting the inclusion of conditional elements from the item. The result is the digital item declaration can specify that items with the package that are optional or subject to conditions. For example, the declaration can describe two video files and indicate that one is conditionally included subject to display on a high-resolution terminal, whereas the other is included subject to display on a low-resolution terminal.

5.3.3 Media Resource Adaptation

Alternatively, MPEG-21 supports digital item adaptation through **media resource adaptation**. In this case, the media resources themselves are adapted or transcoded. The media resources in the digital item declarations can be manipulated in an adaptation engine according to usage environment. The adaptation engine can take as input a user environment description that includes user preferences, usage context, device capabilities, and so forth.

5.4 Transcoding Optimization

Since media-rich content often contains multiple media resources, there is much opportunity for optimizing the adaptation of this content by trading off the different transcoding operation for each of the component media resources. This chapter now investigates how this transcoding optimization can be applied to images consisting of multiple annotated regions.

5.4.1 Image Transcoding

Given that multiple regions in the image can be annotated, the **transcoding of images** needs to consider the individual importance and spatial resolution hint for each region (Smith and Reddy, 2001). Overall, this can be approached as an optimization problem in which the image needs to be manipulated, such as through cropping and rescaling, to produce an output image that maximizes the overall content value given the constraints on its delivery. The optimization problem is expressed as follows: The device imposes a constraint on the size of the image (i.e., size of the screen). The transcoding engine seeks to maximize the benefit derived from the content value of the transcoded image. The problem, thus, is to maximize the total content value given the constraints.

Following the particular structure provided by the MPEG-7 transcoding hints, consider that each region R_i has an importance I_i and spatial resolution hint S_i. Consider also that each region has a content value score V_i after rescaling the image globally using rescaling factor L, which is a function of its importance I_i and spatial resolution hint S_i. Rescaling goes as follows:

- **Importance Hint** (I_i): Indicates relative importance of region R_i, where $0 \leq I_i \leq 1$
- **Spatial Resolution Hint** (S_i): Indicates the minimum resolution of region for preserving details, where
- **Rescaling factor** (L): Indicates the global rescaling of the image, where $0 \leq S_i \leq 1$
- **Content Value** (V_i): Indicates value of the transcoded region $V_i = f(I_i, S_i, L)$as follows:

$$V_i = \begin{cases} I_i & \text{if } 1 \leq L. \\ L\frac{I_i}{S_i} & \text{if } 0 \leq L < 1. \\ 0 & \text{otherwise.} \end{cases}$$

Then, the problem can be stated as $\max\left(\sum_i V_i\right)$ such that $F_x(R_i^*) \leq D_s$, where:

- D_s gives the size of the device screen:
- R_i^* gives a selected rescaled region; and
- $F_s(R_i^*)$ gives the spatial size of the minimum bounding rectangle that encapsulates the selected rescaled regions.

One way to solve this problem is by using an exhaustive search for all possible combinations of the rescaled regions. In this case, for each unique combination of regions, the image is cropped to include only those selected regions, and the cropped image is then rescaled to fit the device screen size. Then, the regions are evaluated in terms of the image's content value under the rescaling and selection, and the total content value is computed. Then, the combination of regions with maximum benefit is selected as the optimal transcoding of the image. The complexity of this search is not great considering that each image will typically only have a handful of annotated regions.

5.4.2 Image Transcoding Examples

The following examples illustrate the transcoding of an image (shown in Figure 5.4) both with and without the MPEG-7 transcoding hints for importance and spatial resolution. This example considers four different display devices: personal computer (PC), television (TV) browser, handheld computer, and personal digital assistant (PDA) or mobile phone.

Figure 5.5 shows the transcoding of the image without using transcoding hints. In this case, the original image is adapted to the screen sizes by globally rescaling the image to fit the screen. The drawback of this type of adaptation is that the image details are lost when the size of the output image is small. For example, it is difficult to discern any details from the image displayed on the PDA screen (far right). The result is an equal loss of detail for all regions including those important regions, which results in a *lower* overall content value of the image for a display size.

Figure 5.6 shows the transcoding of the image using transcoding hints. In this case, the original image is adapted to the screen sizes by using a combination of cropping and rescaling to fit a set of selected image regions on the screen. The advantage of this type of adaptation is that the important image details are preserved when the size of the output image is small. For example, it is possible to discern important details from

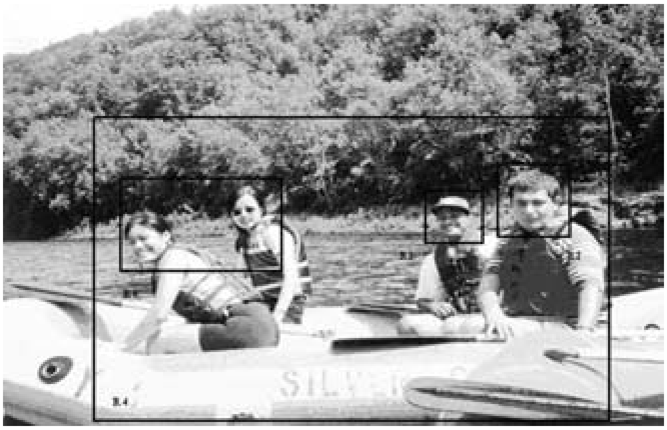

FIGURE 5.4 Image with Four Regions Annotated Using MPEG-7 Transcoding Hints

FIGURE 5.6 Example Transcoded Image Output Using the MPEG-7 Transcoding Hints. The hints are for image region importance and minimum allowable spatial resolution. The transcoding uses a combination of cropping and rescaling to maximize the overall content value.

the image displayed on the handheld and PDA screens. The result is an adaptive loss of detail for different regions by cropping those important regions, which results in a *higher* overall content value of the image for a display size.

5.5 Multimedia Content Selection

Considering that media-rich content is composed of multiple constituent media resources, this section investigates how different variations of the media resources can be selected based on the overall device and delivery constraints.

5.5.1 Resource Selection

A procedure is now described for optimizing the selection of the different variations of media resources in a multimedia document that maximizes the total **content value** given the constraints of the client devices (Smith *et al.*, 1999). A multimedia presentation $M = [D, L]$ can be defined as a tuple consisting of a multimedia document D and a document layout L. The multimedia document D is the set of media resources O_{ij}, written as follows:

$$D = \{(O_{ij})_n\} \text{ (multimedia document)},$$

where $(O_{ij})_n$ gives the nth media resource, which has modality i and fidelity j. The document layout L gives the relative spatial and temporal location and size of each media resource. The variation description V of a media resource describes the collection of the different variations of the media resource O_{ij}, as follows:

$$V = \{O_{ij}\} \text{ (variation description)}.$$

We then define a variation document VD as a multimedia document consisting of resources described by variation description $\{O_{ij}\}$, written as follows:

$$VD = \{V_n\} = \{\{O_{ij}\}_n\} \text{ (variation document)}.$$

Content Value Scores

To optimize the selection, the variation descriptions include content value scores $V((O_{ij}))$ for each of the media resources O_{ij}, as shown in Figure 5.7. The content value scores can be based on automatic measures, such as entropy, or on loss in fidelity that results from translating or summarizing the con-

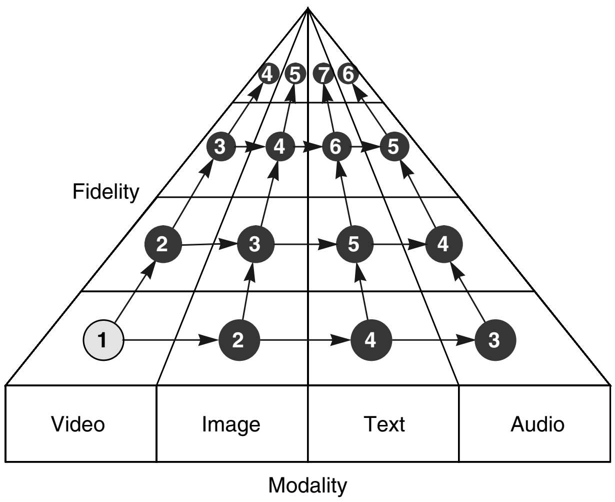

FIGURE 5.7 Example of the Reciprocal Content Value Scores. These scores are assigned for different video media resource variations.

tent. For example, the content value scores can be linked to the distortion introduced from compressing the images or audio. Otherwise, the content value scores can be tied directly to the methods that manipulate the content or be assigned manually.

Figure 5.7 illustrates examples of the relative reciprocal content value scores of different variations of a video media resource. In this example, the original video (lower left) has the highest content value. The manipulation of the video along the dimension of fidelity or modality reduces the content value. For example, converting the video to a sequence of images results in a small reduction in content value. Converting the video to a highly compressed audio track produces a higher reduction in the content value.

5.5.2 Variation Selection

Given a multimedia document with N media resources, let $\{O_{ij}\}_n$ give the variation description of the nth media resource. Let $V((O_{ij})_n)$ give the relative content value score of the variation of the nth media resource with modality i and fidelity j, and let $D((O_{ij})_n)$ give its data size.

Let D_T give the total maximum data size allocated for the multimedia document by the client device. The total maximum data size may, in practice, be derived from the user's specified maximum load time and the network conditions or from the device constraints in storage or processing.

Maximum Content Value

The content selection process selects media resource variations O^*_{ij} from each variation description to maximize the total content value for a target data size D_T as follows:

$$\sum_n V((O^*_{ij})_n) = \max\left(\sum_n V((O_{ij})_n)\right)$$

and

$$\sum_n D((O^*_{ij})_n) \leq D_T, \tag{5.1}$$

where $(O^*_{ij})_n$ gives for each n the optimal variation of the media resource, which has fidelity i and modality j.

Minimum Load Time

Alternatively, given a minimum acceptable total content value V_T, the content select process selects media resource variations O^*_{ij} from each variation description to minimize the total data size as follows:

$$\sum_n D((O^*_{ij})_n) = \min\left(\sum_n D((O_{ij})_n)\right),$$

and

$$\sum_n V((O^*_{ij})_n) \geq V_T, \tag{5.2}$$

where, as above, $(O^*_{ij})_n$ gives for each n the optimal variation of the media resource, which has fidelity i and modality j.

Device Constraints and Preferences

By extending the selection process, other constraints of client devices can be considered. For example, the content selection system can incorporate device screen size S_T as follows: let $S((O_{ij})_n)$ give the spatial size of the variation of the nth media resource with modality i and fidelity j. Then, we add the following constraint to the optimization process:

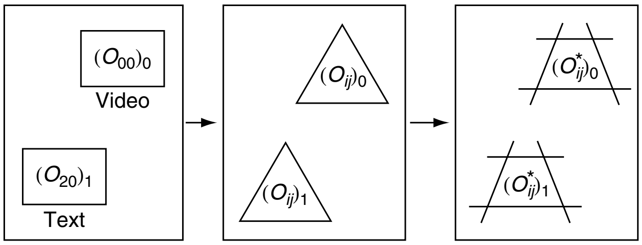
$$\sum_n S((O^*_{ij})_n) \leq S_T. \tag{5.3}$$

In the same way, we can include additional device constraints such as color depth, streaming bandwidth, and processing power.

5.5.3 Selection Optimization

Given the variation descriptions for describing different variations of the media resources, the overall number of different variations of each variation document is combinatorial in the number of media resources (N) and number of variations of each media resource (M) and is given by M^N. To solve the optimization problems of equations 5.1 and 5.2 convert the constrained optimization problems into the equivalent Lagrangian unconstrained problems, as described in Mohan *et al.* (1998).

The optimization solution is based on the resource allocation technique proposed in Shoham and Gersho (1990) for arbitrary discrete functions. This is illustrated by converting the problem in equation 5.1 to the following unconstrained problem:



(A) $(O_{00})_0$ Video and $(O_{20})_1$ Text

(B) Variation Document with $(O_{ij})_0$ and $(O_{ij})_1$

(C) Selected Variations of the Media Resources $(O^*_{ij})_0$ and $(O^*_{ij})_1$

FIGURE 5.8 Example Content Selection for a Multimedia Document **D** Consisting of Two Media Resources

$$\min\left\{\sum_n D((O_{ij})_n) - \lambda(V_T - V((O_{ij})_n))\right\}. \tag{5.4}$$

the optimal solution gives that for all n, the selected variations of the media resources $(O^*_{ij})_n$ operate at the same constant trade-off λ in content value $V((O_{ij})_n)$ versus data size $D((O_{ij})_n)$. To solve the optimization problem, it is only necessary to search over values of λ.

5.5.4 Example Selection

Illustrated here is the content selection in an example multimedia document, as shown in Figure 5.8. The multimedia document has two media resources: a video resource $= (O_{00})_0$ and a text resource $= (O_{20})_1$. For each media resource $(O_{ij})_n$, where $n \in \{0, 1\}$, a variation document $\{O_{ij}\}_n$ can be constructed, which gives the different variations of the media resource. The selection process selects the variations $(O^*_{ij})_0$ and $(O^*_{ij})_1$, respectively, to maximize the total content value.

Consider the four variations of each media resource with content values and data sizes given in Table 5.1. By iterating over values for the trade-off λ in content value and data size, the content selection table of Table 5.2 is obtained which shows the media resource variations that maximize the total content value $\max(\Sigma_n V((O_{ij})_n))$ for different total maximum data sizes D_T, as given in equation 5.1.

5.6 Summary

Universal Multimedia Access (UMA) is one of the important emerging applications for multimedia systems and signal processing. The basic idea of UMA is to adapt media-rich content according to usage environment. The emerging MPEG-7 and MPEG-21 standards address different aspects of UMA by standardizing metadata descriptions for adapting this content. In this chapter, we described how UMA is supported in multimedia systems through media resource transcoding and multimedia content selection.

TABLE 5.1 Summary of Different Variations of Two Media Resources: $(O_{ij})_0$ and $(O_{ij})_1$

$(O_{ij})_n$	$V((O_{ij})_n)$	$D((O_{ij})_n)$	Modality
$(O_{00})_0$	1.0	1.0	Video
$(O_{01})_0$	0.75	0.25	Video
$(O_{10})_0$	0.5	0.10	Image
$(O_{11})_0$	0.25	0.05	Image
$(O_{20})_1$	1.0	0.5	Text
$(O_{21})_1$	0.5	0.10	Text
$(O_{32})_1$	0.75	0.25	Audio
$(O_{33})_1$	0.25	0.05	Audio

TABLE 5.2 Summary of the Selected Variations of the Two Media Resources: $(O_{ij})_0$ and $(O_{ij})_1$*

D_T	$(O^*_{ij})_0$	$(O^*_{ij})_1$	$\Sigma_n V((O^*_{ij})_n)$	$\Sigma_n D((O^*_{ij})_n)$
1.5	$(O_{00})_0$	$(O_{20})_1$	2.0	1.5
1.25	$(O_{00})_0$	$(O_{32})_1$	1.75	1.25
1.0	$(O_{01})_0$	$(O_{20})_1$	1.75	0.75
0.6	$(O_{10})_0$	$(O_{20})_1$	1.5	0.6
0.35	$(O_{01})_0$	$(O_{21})_1$	1.25	0.35
0.35	$(O_{10})_0$	$(O_{32})_1$	1.25	0.35
0.2	$(O_{10})_0$	$(O_{21})_1$	1.0	0.2
0.1	$(O_{11})_0$	$(O_{33})_1$	0.5	0.1

*These resources are under different total maximum data size constraints D_T.

Notre Dame, Indiana, USA*

6.1 Introduction

Statistical signal processing is an important subject in signal processing that enjoys a wide range of applications, including communications, control systems, medical signal processing, and seismology. It plays an important role in the design, analysis, and implementation of adaptive filters, such as adaptive equalizers in digital communication systems. It is also the foundation of multiuser detection that is considered an effective means for mitigating multiple access interferences in spread-spectrum based wireless communications.

The fundamental problems of statistical signal processing are those of signal detection and estimation that aim to extract information from the received signals and help make decisions. The received signals (especially those in communication systems) are typically modeled as random processes due to the existence of uncertainties. The uncertainties usually arise in the process of signal propagation or due to noise in measurements. Since signals are considered random, statistical tools are needed. As such, techniques derived to solve those problems are derived from the principles of **mathematical statistics**, namely, hypothesis testing and estimation.

This chapter presents a brief introduction to some basic concepts critical to statistical signal processing. To begin with, the principles of Bayesian and Fisher statistics relevant to estimation are presented. In the discussion of Bayesian statistics, emphasis is placed on two types of estimators: the minimum mean-squared error (MMSE) estimator and the maximum a posteriori (MAP) estimator. An important class of linear estimators, namely the Wiener filter, is also presented as a linear MMSE estimator. In the discussion of Fisher statistics, emphasis will be placed on the maximum likelihood estimator (MLE), the concept of sufficient statistics, and information inequality that can be used to measure the quality of an estimator.

This chapter also includes a brief discussion of signal detection. The signal detection problem is presented as one of binary hypothesis testing. Both Bayesian and Neyman-Pearson optimum criteria are presented and shown to be implemented with likelihood ratio tests. The principles of hypothesis testing also find a wide range of applications that involve decision making.

6.2 Bayesian Estimation

Bayesian estimation methods are generally employed to estimate a random variable (or parameter) based on another random variable that is usually observable. Derivations of Bayesian estimation algorithms depend critically on the a posteriori distribution of the underlying signals (or signal parameters) to be estimated. Those a posteriori distributions are obtained by employing Bayes' rules, thus the name Bayesian estimation.

Consider a random variable X that is some function of another random variable S. In practice, X is what is observed and S is the **signal** (or signal parameter) that is to be estimated. Denote the estimate as $\hat{S}(X)$, and the error as $\varepsilon \overset{\Delta}{=} S - \hat{S}(X)$. Generally, the **cost** is defined as a function of the estimation error that clearly depends on both X and S, thus $J(\varepsilon) = J(S, X)$.

The objective of Bayesian estimation is to minimize the **Bayes' risk** $\mathcal{R}$, which is defined as the ensemble average (i.e., the expected value) of the cost. In particular, the Bayes' risk is defined by:

$$\begin{aligned}\mathcal{R} &\overset{\Delta}{=} E\{J(\varepsilon)\}\\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} J(s, x) f_{S,\, X}(s, x)\, dx ds,\end{aligned}$$

where $f_{S,\, X}(s, x)$ is the joint probability density function (pdf) of the random variables S and X. In practice, the joint pdf is not directly obtainable. However, by Bayes' rule:

$$f_{S,X}(s, x) = f_{S|X}(s|x) f_X(x), \tag{6.1}$$

the **a posteriori** pdf can be used to facilitate the derivation of Bayesian estimates. With the **a posteriori** pdf, the Bayes' risk can now be expressed as:

$$\mathcal{R} = \int_{-\infty}^{\infty} \left\{ \int_{-\infty}^{\infty} J(s, x) f_{S|X}(s|x) ds \right\} f_X(x) dx. \tag{6.2}$$

Because the cost function is, in general, non-negative and so are the pdfs, minimizing the Bayes' risk is equivalent to minimizing:

$$\int_{-\infty}^{\infty} J(s, x) f_{S|X}(s|x) ds. \tag{6.3}$$

Depending on how the cost function is defined, the Bayesian estimation principle leads to different kinds of estimation algorithms. Two of the most commonly used cost functions are the following:

$$J_{MS}(\varepsilon) = |\varepsilon|^2. \tag{6.4a}$$

$$J_{\mathrm{MAP}}(\varepsilon) = \begin{cases} 0 & \text{if } |\varepsilon| \leq \frac{\Delta}{2} \\ 1 & \text{if } |\varepsilon| > \frac{\Delta}{2} \quad \text{where} \quad \Delta \ll 1. \end{cases} \tag{6.4b}$$

These example cost functions result in two popular estimators, namely, the minimum mean-squared error (MMSE) estimator and the maximum a posteriori (MAP) estimator. These two estimators are discussed in more detail below.

6.2.1 Minimum Mean-Squared Error Estimation

When the cost function is defined to be the mean-squared error (MSE), as in equation 6.4a, the Bayesian estimate can be derived by substituting $J(\varepsilon) = |\varepsilon|^2 = (s - \hat{s}(x))^2$ into equation 6.2. Hence the following is true:

$$\mathcal{R}_{MS} = \int_{-\infty}^{\infty} \left\{ \int_{-\infty}^{\infty} (s - \hat{s}(x))^2 f_{S|X}(s|x) ds \right\} f_X(x) dx. \tag{6.5}$$

Denote the resulting estimate as $\hat{s}_{MS}(x)$, and use the same argument that leads to equation 6.3. A necessary condition for minimizing $\mathcal{R}_{MS}$ results as:

$$\frac{d}{d\hat{s}} \int_{-\infty}^{\infty} (s - \hat{s}(x))^2 f_{S|X}(s|x) ds = 0. \tag{6.6}$$

The differentiation in equation 6.6 is evaluated at $\hat{s} = \hat{s}_{MS}(x)$. Consequently:

$$\int_{-\infty}^{\infty} (s - \hat{s}_{MS}(x)) f_{S|X}(s|x) ds = 0;$$

and

$$\hat{s}_{MS}(x) = \int_{-\infty}^{\infty} s f_{S|X}(s|x) ds = E\{s|x\}. \tag{6.7}$$

In essence, the estimate that minimizes the MSE is the conditional-mean estimate. If the a posteriori distribution is Gaussian, then the conditional-mean estimator is a linear function of X, regardless of the functional relation between S and X. The following theorem summarizes a very familiar result.

Theorem

Let $\boldsymbol{X} = [X_1, X_2, \ldots, X_K]^T$ and S be jointly Gaussian with zero means. The MMSE estimate of S based on $\boldsymbol{X}$ is $E[S|\boldsymbol{X}]$ and $E[S|\boldsymbol{X}] = \sum_{i=1}^{K} a_i x_i$, where a_i is chosen such that $E[(S - \sum_{i=1}^{K} a_i X_i) X_j] = 0$ for any $j = 1, 2, \ldots, K$.

6.2.2 Maximum a Posteriori Estimation

If the cost function is defined as in equation 6.4b, the Bayes' risk is as follows:

$$\mathcal{R}_{\mathrm{MAP}} = \int_{-\infty}^{\infty} f_X(x)[1 - \int_{\hat{s}_{\mathrm{MAP}} - \frac{\Delta}{2}}^{\hat{s}_{\mathrm{MAP}} + \frac{\Delta}{2}} f_{S|X}(s|x) ds] dx.$$

To minimize $\mathcal{R}_{\mathrm{MAP}}$, we maximize $\int_{\hat{s}_{\mathrm{MAP}} - \frac{\Delta}{2}}^{\hat{s}_{\mathrm{MAP}} + \frac{\Delta}{2}} f_{S|X}(s|x) ds$. When Δ is extremely small (as is required), this is equivalent to maximizing $f_{S|X}(s|x)$. Thus, $\hat{s}_{\mathrm{MAP}}(x)$ is the value of s that maximizes $f_{S|X}(s|x)$.

Normally, it is often more convenient (for algebraic manipulation) to consider $\ln f_{S|X}(s|x)$, especially since $\ln(x)$ is a monotone nondecreasing function of x. A necessary condition for maximizing $\ln f_{S|X}(s|x)$ is as written here:

$$\frac{\partial}{\partial s}\ln f_{S|X}(s|x)\Big|_{s=\hat{s}_{\mathrm{MAP}}(x)}=0. \tag{6.8}$$

Equation 6.8 is often referred to as the **MAP equation**. Employing Bayes' rule, the MAP equation can also be written as:

$$\frac{\partial}{\partial s}\ln f_{X|S}(x|s)+\frac{\partial}{\partial s}\ln f_S(s)\Big|_{s=\hat{s}_{\mathrm{MAP}}(x)}=0. \tag{6.9}$$

Example (van Trees, 1968)

Let X_i, $i=1, 2, \ldots, K$ be a sequence of random variables modeled as follows:

$$X_i = S + N_i \quad i = 1; 2, \cdots, K,$$

where S is a zero-mean Gaussian random variable with variance σ_s^2 and $\{N_i\}$ is a sequence of independent and identically distributed (iid) zero-mean Gaussian random variables with variance σ_n^2. Denote $\boldsymbol{X}=[X_1X_2\ldots X_K]^T$.

$$f_{X|S}(x|s)=\prod_{i=1}^{K}\frac{1}{\sqrt{2\pi}\sigma_n}\exp\left[-\frac{(x_i-s)^2}{2\sigma_n^2}\right]$$

$$f_S(s)=\frac{1}{\sqrt{2\pi}\sigma_s}\exp\left[-\frac{1}{2}\frac{s^2}{\sigma_s^2}\right]$$

$$f_{S|X}(s|x)=\frac{f_{x|s}(x|s)f_S(s)}{f_x(x)}$$

$$=\frac{1}{f_X(x)}\frac{1}{\sqrt{2\pi}\sigma_s}\left[\prod_{i=1}^{K}\frac{1}{\sqrt{2\pi}\sigma_n}\right]\exp\left[-\frac{1}{2}\left(\frac{\sum_{i=1}^{K}(x_i-s)^2}{\sigma_n^2}+\frac{s^2}{\sigma_s^2}\right)\right]$$

$$f_{S|x}(s|x)=C(x)\exp\left[-\frac{1}{2\sigma_p^2}\left(s-\frac{\sigma_s^2}{\sigma_s^2+\sigma_n^2/K}\left(\frac{1}{K}\sum_{i=1}^{K}x_i)\right)^2\right], \tag{6.10}$$

where $\sigma_p^2 \triangleq \left(\frac{1}{\sigma_s^2}+\frac{K}{\sigma_n^2}\right)^{-1}=\frac{\sigma_s^2\sigma_n^2}{K\sigma_s^2+\sigma_n^2}$.

From equation 6.10, it can be seen clearly that the conditional mean estimate and the MAP estimate are equivalent. In particular:

$$\hat{s}_{ms}(x)=\hat{s}_{MAP}(x)=\frac{\sigma_s^2}{\sigma_s^2+\sigma_n^2/K}\left(\frac{1}{K}\sum_{i=1}^{K}x_i\right).$$

In this example, the MMSE estimate and the MAP estimate are equivalent because the a posteriori distribution is Gaussian. Some useful insights into Bayesian estimation can be gained through this example (van Trees, 1968).

Remarks

1. If $\sigma_s^2 \ll \frac{\sigma_n^2}{K}$, the a priori knowledge is more useful than the observed data, and the estimate is very close to the a priori mean (i.e., 0). In this case, the a posteriori distribution almost has no effect on the value of the estimate.
2. If $\sigma_s^2 \gg \frac{\sigma_n^2}{K}$, the estimate is directly related to the observed data as it is the sample mean, while the a priori knowledge is of little value.
3. The equivalence of $\hat{s}_{\mathrm{MAP}}$ to $\hat{s}_{ms}(x)$ is not restricted to the case of Gaussian a posteriori pdf. In fact, if the cost function is symmetric and nondecreasing and if the a posteriori pdf is symmetric and unimodal and satisfies $\lim_{s\to\infty} J(s, x)f_{S|X}(s|x)=0$, then the resulting Bayesian estimation (e.g., MAP estimate) is equivalent to $\hat{s}_{MS}(x)$.

6.3 Linear Estimation

Since the Bayesian estimators (MMSE and MAP estimates) presented in the previous section are usually not linear, it may be impractical to implement them. An alternative is to restrict the consideration to only the class of linear estimators and then find the **optimum estimatior** in that class. As such, the notion of optimality deviates from that of Bayesian estimation, which minimizes the Bayes' risk.

One of the most commonly used optimization criteria is the MSE (i.e., minimizing the error variance). This approach leads to the class of **Wiener filters** that includes the **Kalman filter** as a special case. In essence, the Kalman filter is a realizable Wiener filter as it is derived with a realizable (state-space) model. Those linear estimators are much more appealing in practice due to reduced implementational complexity and relative simplicity of performance analysis.

The problem can be described as follows. Given a set of zero-mean random variables, $X_1, X_2, \ldots, X_K$, it is desired to estimate a random variable S (also zero-mean). The objective here is to find an estimator $\hat{S}$ that is linear in X_i and that is optimum in some sense, like MMSE.

Clearly, if $\hat{S}$ is constrained to be linear in X_i, it can be expressed as $\hat{S}=\sum_{i=1}^{K} a_iX_i$. This expression can be used independently of the model that governs the relation between $\boldsymbol{X}$ and S. One can see that once the coefficients a_i, $i=1, 2, \ldots, K$ are determined for all i, $\hat{S}$ is unambiguously (uniquely) specified. As such, the problem of finding an optimum estimator becomes one of finding the optimum set of coefficients, and estimation of a random signal becomes estimation of a set of deterministic parameters.

If the objective is to minimize the MSE, namely:

$$E\{\|S-\hat{S}\|^2\} = E\left\{\|S-\sum_{i=1}^{K} a_i X_i\|^2\right\}, \tag{6.11}$$

a necessary condition is that:

$$\frac{\partial}{\partial a_i} E\{\|S-\hat{S}\|^2\} = 0 \quad \text{for all } i. \tag{6.12}$$

Equation 6.12 is equivalent to:

$$E\left\{\left(S-\sum_{j=1}^{K} a_j X_j\right) X_i^*\right\} = 0 \quad \text{for all } i. \tag{6.13}$$

In other words, a necessary condition for obtaining the linear MMSE estimate is the **uncorrelatedness** between the estimation error and the observed random variables. In the context of vector space, equation 6.13 is the well-known **orthogonality principle**. Intuitively, the equation states that the linear MMSE estimate of S is the projection of S onto the subspace spanned by the set of random variables $\{X_i\}$. In this framework, the norm of the vector space is the mean-square value while the inner product between two vectors is the correlation between two random variables.

Let the autocorrelation coefficients of x_i be $E\{X_j X_i^*\} = r_{ji}$ and the crosscorrelation coefficients of X_i and S be $E\{SX_i^*\} = \rho_i$. Then, equation 6.13 is simply:

$$\rho_i = \sum_{j=1}^{K} a_j r_{ji} \quad \text{for all } i, \tag{6.14}$$

which is essentially the celebrated **Wiener-Hopf** equation. Assume that r_{ij} and ρ_j are known for all i, j, then the coefficients $\{a_i\}$ can be solved by equation 6.14. In fact, this equation can be stacked up and put in the following matrix form:

$$\begin{bmatrix} r_{11} & r_{21} & \cdots & r_{K1} \\ r_{12} & r_{22} & \cdots & r_{K2} \\ \vdots & \vdots & \ddots & \vdots \\ r_{1K} & r_{2K} & \cdots & r_{KK} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_K \end{bmatrix} = \begin{bmatrix} \rho_1 \\ \rho_2 \\ \vdots \\ \rho_K \end{bmatrix} \tag{6.15}$$

or simply:

$$R\underline{a} = \underline{\rho}. \tag{6.16}$$

Thus, the coefficient vector can be solved by:

$$\underline{a} = R^{-1}\underline{\rho}, \tag{6.17}$$

which is sometimes termed the **normal equation**. The orthogonality principle of equation 6.13 and the normal equation 6.17 are the basis of Wiener filter, which is one of the most studied and commonly used linear adaptive filters with many applications (Haykin, 1996, 1991).

The matrix inversion in equation 6.17 could present a formidable numerical difficulty, especially when the vector dimension is high. In those cases, some computationally efficient algorithms, like Levinson recursion, can be employed to mitigate the impact of numerical difficulty.

6.4 Fisher Statistics

Generally speaking, there are two schools of thoughts in statistics: **Bayes** and **Fisher**. Bayesian statistics and estimation were presented in the previous section, where the emphasis was on estimation of random signals and parameters. This section is focused on estimation of a deterministic parameter (or signal). A natural question that one may ask is if the Bayesian approach presented in the previous section is applicable here or if the estimation of deterministic signals can be treated as a special case of estimating random signals. A closer examination shows that an alternative approach needs to be taken (van Trees, 1968) because the essential issues that govern the performance of estimators differ significantly.

The fundamental concept underlying the Fisher school of statistics is that of **likelihood function**. In contrast, Bayesian statistics is derived from conditional distributions, namely, the a posteriori distributions. This section begins with an introduction of the likelihood function and a derivation of the maximum likelihood estimation method. These are followed by the notion of sufficient statistics, which plays an important role in Fisherian statistics. Optimality properties of maximum likelihood estimates are then examined with the definition of Fisher information. Cramér-Rao lower bound and minimum variance unbiased estimators are then discussed.

6.4.1 Likelihood Functions

Fisher's approach to estimation centers around the concept of likelihood function (Fisher, 1992). Consider a random variable X that has a probability distribution $F_X(x)$ with probability density function (pdf) $f_X(x)$ parameterized by a parameter θ.

The likelihood function (with respect to the parameter θ) is defined as:

$$L(x;\, \theta) = f_X(x|\theta). \tag{6.18}$$

It may appear, at the first sight, that the likelihood function is nothing but the pdf. It is important, however, to note that the likelihood function is really a function of the parameter θ for a fixed value of x, whereas the pdf is a function of the realization of the random variable x for a fixed value of θ. Therefore, in a likelihood function, the variable is θ, while in a pdf the variable is x. The likelihood function is a quantitative indication of how *likely* that a particular realization (observation) of the random variable would have been produced from a particular distribution. The higher the value the likelihood function, the more likely the particular value of the parameter will have produced that realization of x. Hence, the cost function in the Fisherian estimation paradigm is the likelihood function, and the objective is to find a value of the parameter that maximizes the likelihood function, resulting in the **maximum likelihood estimate** (MLE).

The MLE can be derived as follows. Let there be a random variable whose pdf, $f_X(x)$, is parameterized by a parameter θ. Define the objective function:

$$L(x;\ \theta) = f_X(x|\theta), \tag{6.19}$$

where $f_X(x|\theta)$ is the pdf of X for a given θ. Then, the MLE is obtained by:

$$\hat{\theta}_{MLE}(x) = Arg\{\max_{\theta} L(x;\ \theta)\}. \tag{6.20}$$

Clearly, a necessary condition for $L(x;\ \theta)$ to be maximized is that:

$$\frac{\partial}{\partial\theta} L(x; \theta)\Big|_{\theta=\hat{\theta}_{MLE}} = 0. \tag{6.21}$$

This equation is sometimes referred to as the **likelihood equation**. In general, it is more convenient to consider the **log-likelihood function** defined as:

$$l(x;\ \theta) = \ln L(x;\ \theta) \tag{6.22}$$

and the **log-likelihood equation** as:

$$\frac{\partial}{\partial\theta} l(x; \theta)\Big|_{\theta=\hat{\theta}_{MLE}} = 0. \tag{6.23}$$

Example

Consider a sequence of random variables X_i, $i = 1, 2, \cdots, K$ modeled as:

$$X_i = \theta + N_i,$$

where N_i is a sequence of iid zero-mean Gaussian random variables with variance σ^2. In practice, this formulation can be considered as one of estimating a DC signal embedded in white Gaussian noise. The issue here is to estimate the strength, i.e., the magnitude, of the DC signal based on the a set of observations $\mathrm{x_i}$, $\mathrm{i} = 1, 2, \cdots, \mathrm{K}$. The log-likelihood function as defined in equation 6.22 is given by:

$$l(\underline{x}; \theta) = -K \ln(\sqrt{2\pi}\sigma) - \frac{1}{2\sigma^2}\sum_{i=1}^{K}(x_i - \theta)^2,$$

where $\underline{x} = [x_1, x_2, \ldots, x_k]^T$.

Solving the log-likelihood equation, 6.23, yields:

$$\hat{\theta}_{MLE}(x) = \frac{1}{K}\sum_{i=1}^{K} x_i.$$

Thus, the MLE for a DC signal embedded in additive zero mean white Gaussian noise is the **sample mean**. As it turns out, this sample mean is the **sufficient statistic** for estimating θ. The concept of the sufficient statistic is critical to the optimum properties of MLE and, in general, to Fisherian statistics. Generally speaking, the likelihood function is directly related to sufficient statistics, and the MLE is usually a function of sufficient statistics.

6.4.2 Sufficient Statistics

Sufficient statistics is a concept defined in reference to a particular parameter (or signal) to be estimated. Roughly speaking, a sufficient statistic is a function of the set of observations that contains all the information possibly obtainable for the estimation of a particular parameter. Given a parameter θ to be estimated, assume that $\underline{x}$ is the vector consisting of the observed variables. A statistic $T(\underline{x})$ is said to be a **sufficient statistic** if the probability distribution of $\underline{X}$ given $T(\underline{x}) = t$ is independent of θ. In essence, if $T(\underline{x})$ is a sufficient statistic, then all the information regarding estimation of θ that can be extracted from the observation is contained in $T(\underline{x})$. The Fisher factorization theorem stated below is sometimes used as a definition for the sufficient statistic.

Fisher Factorization Theorem

A function of the observation set $T(\underline{X})$ is a sufficient statistic if the likelihood function of $\underline{X}$ can be expressed as:

$$L(\underline{x}; \theta) = h(T(\underline{x}),\ \theta)g(\underline{x}). \tag{6.24}$$

In the example shown in Section 6.4.1, $\sum_{i=1}^{K} x_i$ is a sufficient statistic, and the sample mean $\frac{1}{K}\sum_{i=1}^{K} x_i$ is the MLE for θ. The fact that $\sum_{i=1}^{K} x_i$ is a sufficient statistic can be easily seen by using the Fisher factorization theorem. In particular:

$$L(\underline{x}; \theta) = \left(\frac{1}{\sqrt{2\pi}\sigma}\right)^K \exp\left[-\frac{1}{2\sigma^2}\sum_{i=1}^{K}(x_i - \theta)^2\right]. \tag{6.25}$$

The above equation can be expressed as:

$$L(\underline{x}; \theta) = \left\{\exp\left[\frac{\theta}{\sigma^2}\left(\sum_{i=1}^{K} x_i\right) - \frac{K\theta^2}{2\sigma^2}\right]\right\}\left(\frac{1}{\sqrt{2\pi}\sigma}\right)^K \exp\left[-\frac{1}{2\sigma^2}\sum_{i=1}^{K} x_i^2\right]. \tag{6.26}$$

Identifying equation 6.26 with 6.24, it can be easily seen that, if the following is defined:

$$h(T((x), \theta) = \exp\left[\frac{\theta}{\sigma^2}\left(\sum_{i=1}^{K} x_i\right) - \frac{K\theta^2}{2\sigma^2}\right]$$

and

$$g(x) = \left(\frac{1}{\sqrt{2\pi}\sigma}\right)^K \exp\left[-\frac{1}{2\sigma^2}\sum_{i=1}^{K} x_i^2\right],$$

then $T(x) = \sum_{i=1}^{K} x_i$ is clearly a sufficient statistic for estimating θ. It should be noted that the sufficient statistic may not be unique. In fact, it is always subject to a scaling factor.

In equation 6.26, it is seen that the pdf can be expressed as:

$$f_X(x|\theta) = \{\exp\left[c(\theta)T(x) + d(\theta) + S(x)\right]\}I(x), \qquad (6.27)$$

where $c(\theta) = \frac{\theta}{\sigma^2}$, $T(x) = \sum_{i=1}^{K} x_i$, $d(\theta) = -\frac{1}{2\sigma^2}\sum_{i=1}^{K} x_i^2$, $S(x) = -\frac{K}{2}\ln(2\pi\sigma^2) - \frac{1}{2\sigma^2}\sum_{i=1}^{K} x_i^2$, and $I(x)$ is an indicator function that is valued at 1 wherever the value of the pdf is nonzero and zero otherwise. A pdf that can be expressed in the form given in equation 6.27 is said to belong to the **exponential family of distributions** (EFOD).

It can be verified easily that Gaussian, Laplace (or two-sided exponential), binomial, and Poisson distributions all belong to the EFOD. When a pdf belongs to the EFOD, one can easily identify the sufficient statistic. In fact, the mean and variance of the sufficient statistic can be easily calculated (Bickel and Doksum, 1977).

As stated previously, the fact that the MLE is a function of the sufficient statistic helps to ensure its quality as an estimator. This will be discussed in more detail in the subsequent sections.

6.4.3 Information Inequality and Cramér-Rao Lower Bound

There are several criteria that can be used to measure the quality of an estimator. If $\theta(X)$ is an estimator for the parameter θ based on the observation X, three criteria are typically used to evaluate its quality:

1. **Bias**: If $E[\hat{\theta}(X)] = \theta, \theta(\hat{X})$ is said to be an **unbiased estimator**.
2. **Variance**: For estimation of deterministic parameters and signals, variance of the estimator is the same as variance of the estimation error. It is a commonly used performance measure, for it is practically easy to evaluate.
3. **Consistency**: This is an asymptotic property that is examined when the sample size (i.e., the dimension of the vector X) approaches infinity. If $\theta(\hat{X})$ converges with probability one to θ, then it is said to be **strong consistent**. If it converges in probability, it is **weak consistent**.

In this section, the discussion will be focused on the second criterion, namely the variance, which is one of the most commonly used performance measures in statistical signal processing. In the estimation of deterministic parameters, **Fisher's information** is imminently related to variance of the estimators.

The Fisher's information is defined as:

$$I(\theta) = E\left\{\left[\frac{\partial}{\partial\theta} l(x;\theta)\right]^2\right\}. \qquad (6.28)$$

Note that the Fisher's information is non-negative, and it is additive if the set of random variables is independent.

Theorem (Information Inequality)

Let $T(X)$ be a statistic such that its variance $V_\theta(T(X)) < \infty$, for all θ in the parameter space Θ. Define $\psi(\theta) = E_\theta\{T(X)\}$. Assume that the following regularity condition holds:

$$E\left\{\left[\frac{\partial}{\partial\theta} l(x;\,\theta)\right]\right\} = 0 \quad \text{for all} \quad \theta \in \Theta, \qquad (6.29)$$

where $l(x,\ \theta)$ has been defined in equation 6.22. Assume further that $\psi(\theta)$ is differentiable for all θ. Then:

$$V_\theta(T(X)) \leq \frac{[\psi'(\theta)]^2}{I(\theta)}. \qquad (6.30)$$

Remarks

1. The regularity condition defined in equation 6.29 is a restriction imposed on the likelihood function to guarantee that the order of expectation operation and differentiation is interchangeable.
2. If the regularity condition holds also for second order derivatives, $I(\theta)$ as defined in equation 6.28 can also be evaluated as:

$$I(\theta) = -E\left\{\frac{\partial^2}{\partial\theta^2} l(x;\theta)\right\}.$$

3. The subscript θ of the expectation (E_θ) and of the variance (V_θ) indicates the dependence of expectation and variance on θ.
4. The information inequality gives a lower bound on the variance that any estimate can achieve. It thus reveals the best that an estimator can do as measured by the error variance.
5. If $T(X)$ is an unbiased estimator for θ, (i.e., $E_\theta\{T(X)\} = \theta$), then the information inequality, equation 6.30, reduces to:

$$V_\theta(T(X)) \leq \frac{1}{I(\theta)}, \qquad (6.31)$$

which is the well-known **Cramér-Rao lower bound** (CRLB).

6. In statistical signal processing, closeness to the CRLB is often used as a measure of *efficiency* of an (unbiased) estimator. In particular, one may define the **Fisherian efficiency** of an unbiased estimator $\hat{\theta}(\boldsymbol{X})$ as:
$$\eta(\hat{\theta}(X)) = \frac{I^{-1}(\theta)}{V_\theta\{\hat{\theta}(X)\}}. \qquad (6.32)$$
Note that η is always less than one, and the larger η, the more efficient that estimator is. In fact, when $\eta = 1$, the estimator achieves the CRLB and is said to be an efficient estimator in the Fisherian sense.
7. If an unbiased estimator has a variance that achieves the CRLB for all $\theta \in \Theta$, it is called a **uniformly minimum variance unbiased estimator** (UMVUE). It can be shown easily that UMVUE is a consistent estimator and MLE is usually the UMVUE.

6.4.4 Properties of MLE

The MLE has many interesting properties, and it is the purpose of this section to enlist some of those properties.

1. It is easy to see that the MLE may be biased. This is because being unbiased was not part of the objective in seeking MLE. MLE, however, is always asymptotically unbiased.
2. As shown in the previous section, MLE is a function of the sufficient statistic. This can also be seen from the Fisher factorization theorem.
3. MLE is asymptotically a minimum variance unbiased estimator. In other words, its variance asymptotically achieves the CRLB.
4. MLE is consistent. In particular, it converges to the parameter with probability one (or in probability).
5. Under the **regularity condition** of equation 6.29, if there exists an unbiased estimator whose variance attains the CRLB, it is the MLE.
6. Generally speaking, the MLE of a transformation of a parameter (or signal) is the transformation of the MLE of that parameter (or signal). This is referred to as the **invariance properly** of the MLE.

The fact that MLE is a function of sufficient statistics means that it depends on **relevant information**. This does not necessarily mean that it will always be the *best* estimator (in the sense of, say, minimum variance), for it may not make the best use of the information. However, when the sample size is large, all the information relevant to the unknown parameter is essentially available to the MLE estimator. This explains why MLE is **asymptotically unbiased**, it is consistent, and its variance achieves asymptotically the CRLB.

Example (Kay, 1993)

Consider the problem of estimating the phase of a sinusoidal signal received with additive Gaussian noise. The problem is formulated as:

$$X_i = A\cos(\omega_o i + \phi) + N_i \quad i = 0, 1, \ldots, K-1$$

where $\{N_i\}$ is an iid sequence of zero-mean Gaussian random variables with variance σ^2. Employing equation 6.23, MLE can be obtained by minimizing:

$$J(\phi) = \sum_{i=1}^{K-1} (x_i - A\cos(\omega_o i + \phi))^2.$$

Differentiating $J(\theta)$ with respect to θ and setting it equal to zero yields:

$$\sum_{i=0}^{K-1} x_i \sin(\omega_o i + \hat{\phi}_{MLE}) = A\sum_{i=0}^{K-1} x_i \sin(\omega_o i + \hat{\phi}_{MLE})\cos(\omega_o i + \hat{\phi}_{MLE}).$$

Assume that:

$$\frac{1}{K}\sum_{i=0}^{K-1} \cos(2\omega_o i + 2\phi) = 0 \quad \text{for all } \phi.$$

Then the MLE for the phase can be approximated as:

$$\hat{\phi}_{MLE} \approx -\arctan\frac{\sum_{i=0}^{K-1} x_i \sin(\omega_o i)}{\sum_{i=0}^{K-1} x_i \cos(\omega_o i)}.$$

Perceptive readers may see that implementation of MLE can easily become complex and numerically difficult, especially when the underlying distribution is non-Gaussian. If the parameter to be estimated is a simple scalar, and its admissible values are limited to a finite interval, search algorithms can be employed to guarantee satisfactory results. If this is not the case, more sophisticated numerical optimization algorithms will be needed to render good estimation results. Among others, iterative algorithms such as the Newton-Raphson method and the expectation maximization method are often employed.

6.5 Signal Detection

The problem of signal detection can be formulated mathematically as one of binary hypothesis testing. Let X be the random variable that represents the observation, and let the observation space be denoted by Ω (i.e., $x \in \Omega$). There are basically two hypotheses:

$$\textbf{Null hypothesis } H_0 : X \sim F_0. \qquad (6.33a)$$
$$\textbf{Alternative } H_1 : X \sim F_1. \qquad (6.33b)$$

The F_0 is the probability distribution of X given that H_0 is true, and F_1 is the probability distribution of X given that H_1 is true. In some applications (e.g., a simple radar communication system), it may be desirable to detect a signal of constant amplitude, and then F_1 will simply be F_0 shifted by a mean value equal to the signal amplitude. In general, this formulation also assumes that, with probability one, either the null hypothesis or the alternative is true. Specifically, let π_0 and π_1 be the prior probabilities of H_0 and H_1 being true, respectively. Then:

$$\pi_0 + \pi_1 = 1. \tag{6.34}$$

The objective here is to decide whether H_0 or H_1 is true based on the observation of $X = x$. A decision rule, namely a detection scheme, $d(x)$ essentially partitions Ω into two subspaces Ω_0 and Ω_1. The subspace Ω_0 consists of all observations that lead to the decision that H_0 is true, while Ω_1 consists of all observations that lead to the decision that H_1 is true. For notational convenience, one may also define *d(x)* as follows:

$$d(x) = \begin{cases} 0 & \text{if } x \in \Omega_0 \\ 1 & \text{if } x \in \Omega_1 \end{cases}. \tag{6.35}$$

For any decision rule *d(x)*, there are clearly four possible outcomes:

1. Decide H_0 when H_0 is true
2. Decide H_0 when H_1 is true
3. Decide H_1 when H_0 is true
4. Decide H_1 when H_1 is true

Two types of error can occur:

1. **Type-I error** (**false alarm**) Decide H_1 when H_0 is true. The probability of type-I error is as follows:

$$\alpha = \int_{\Omega_1} f_0(x)dx. \tag{6.36}$$

2. **Type-II error** (**miss**): Decide H_0 when H_1 is true. The probability of type-II error is as follows:

$$P_m = \int_{\Omega_0} f_1(x)dx. \tag{6.37}$$

Another quantity of concern is the probability of detection, which is often termed the **power** in signal detection literature, defined by:

$$\beta = 1 - P_m = \int_{\Omega_1} f_1(x)dx. \tag{6.38}$$

Among the various decision criteria, Bayes and Neyman-Pearson are most popular. Detection schemes may also be classified into parametric and nonparametric detectors. The discussion here focuses on Bayes and Neyman-Pearson criteria that are considered parametric. Before any decision criteria can be derived, the following constraints need be stated first:

$$Prob\{d(x) = 0|H_0\} + Prob\{d(x) = 1|H_0\} = 1 \tag{6.39a}$$

$$Prob\{d(x) = 0|H_1\} + Prob\{d(x) = 1|H_1\} = 1. \tag{6.39b}$$

The above constraints of equations 6.39a and 6.39b are simply outcomes of the assumptions that $\Omega_0 \cup \Omega_1 = \Omega$ and $\Omega_0 \cap \Omega_1 = \emptyset$ (i.e., for every observation, an unambiguous decision must be made).

6.5.1 Bayesian Detection

The objective of a Bayes criterion is to minimize the so-called Bayes' risk which is, again, defined as the expected value of the cost. To derive a Bayes' detection rule, the costs of making decisions need to be defined first. Let the costs be denoted by C_{ij} being cost of choosing *i* when *j* is true. In particular:

$$\mathrm{C}_{01} = \text{cost of choosing } \mathrm{H}_0 \text{ when } \mathrm{H}_1 \text{ is true.}$$

$$\mathrm{C}_{10} = \text{cost of choosing } \mathrm{H}_1 \text{ when } \mathrm{H}_0 \text{ is true.}$$

In addition, assume that the prior probabilities π_0 and π_1 are known. The Bayes' risk is then evaluated as follows:

$$\begin{aligned} \mathcal{R} \triangleq E\{C\} = {}& \pi_0\{Prob\{d(x) = 0|H_0\}C_{00} + Prob\{d(x) = 1|H_0\}C_{10}\} \\ & + \pi_1\{Prob(d(x) = 0|H_1)C_{10} + Prob(d(x) = 1|H_1)C_{11}\}. \end{aligned} \tag{6.40}$$

Substituting equations 6.34, 6.39a and 6.39b into equation 6.40 yields:

$$\begin{aligned} \mathcal{R} = {}& \pi_0 C_{00}\int_{\Omega_0} f_0(x)dx + \pi_0 C_{10}\int_{\Omega_1} f_0(x)dx \\ & + \pi_1 C_{01}\int_{\Omega_0} f_1(x)dx + \pi_1 C_{11}\int_{\Omega_1} f_1(x)dx \\ = {}& \pi_0 C_{10} + (1-\pi_0)C_{11} + \int_{\Omega_0}\{(1-\pi_0)(C_{01}-C_{11})f_1(x) \\ & - \pi_0(C_{10}-C_{00})f_0(x)\}dx. \end{aligned}$$

Note that the sum of the first two terms is a constant. In general, it is reasonable to assume that:

$$C_{01} - C_{11} > 0 \quad \text{and} \quad C_{10} - C_{00} > 0.$$

In other words, the costs of making correct decisions are less than those of making incorrect decisions:

$$I_1(\mathrm{x}) \triangleq (1-\pi_0)(C_{01}-C_{11})f_1(x).$$

$$I_2(\mathrm{x}) \triangleq \pi_0(C_{10}-C_{00})f_0(x).$$

It can be seen easily that $I_1(x) \geq 0$ and $I_2(x) \geq 0$. Thus, $\mathcal{R}$ can be rewritten as:

$$\mathcal{R} = \text{constant} + \int_{\Omega_0} [I_1(x) - I_2(x)]dx.$$

To minimize $\mathcal{R}$, the observation space Ω need be partitioned such that $x \in \Omega_1$ whenever:

$$I_1(x) \geq I_2(x).$$

In other words, decide H_1 if:

$$(1 - \pi_0)(C_{01} - C_{11})f_1(x) \geq \pi_0(C_{10} - C_{00})f_0(x). \quad (6.41)$$

So, the Bayes' detection rule is essentially evaluating the likelihood ratio defined by:

$$L(x) \triangleq \frac{f_1(x)}{f_0(x)}. \quad (6.42)$$

Comparing it to the threshold yields:

$$\lambda \triangleq \frac{\pi_0}{1 - \pi_0}\frac{C_{10} - C_{00}}{C_{01} - C_{11}}. \quad (6.43)$$

In particular:

$$L(x) = \frac{f_1(x)}{f_0(x)}\begin{cases} \geq \lambda \Rightarrow H_1 \\ < \lambda \Rightarrow H_0 \end{cases}. \quad (6.44)$$

A decision rule characterized by the likelihood ratio and a threshold as in equation 6.44 is referred to as a likelihood ratio test (LRT). A Bayes' detection scheme is always an LRT.

Depending on how the a posteriori probabilities of the two hypotheses are defined, the Bayes' detector can be realized in different ways. One typical example is the so-called MAP detector that renders the minimum probability of error by choosing the hypothesis with the maximum a posteriori probability. Another class of detectors is the minimax detectors, which can be considered an extension of Bayes' detectors. The minimax detector is also an LRT. It assumes no knowledge of the prior probabilities (i.e., π_0 and π_1) and selects the threshold by choosing the prior probability that renders the maximum Bayes' risk. The minimax detector is a *robust* detector because its performance does not vary with the prior probabilities.

6.5.2 Neyman-Pearson Detection

The principle of the Neyman-Pearson criterion is founded on the **Neyman-Pearson Lemma** stated below:

Neyman-Pearson Lemma

Let $d_{\lambda^*}(x)$ be a likelihood ratio test with a threshold λ^* as defined in equation 6.44. Let α^* and β^* be the false-alarm rate and power, respectively, of the test $d_\lambda * (x)$. Let $d_\lambda(x)$ be another arbitrary likelihood ratio test with threshold λ and false-alarm rate and power as, respectively, α and β. If $\alpha \leq \alpha^*$, then $\beta \leq \beta^*$.

The Neyman-Pearson Lemma showed that if one desires to increase the power of an LRT, one must also accept the consequence of an increased false-alarm rate. As such, the Neyman-Pearson detection criterion is aimed to maximize the power under the constraint that the false-alarm rate be upper bounded by, say, α_0. The Neyman-Pearson detector can be derived by first defining a cost function:

$$J = (1 - \beta) + \lambda(\alpha - \alpha_0). \quad (6.45)$$

It can be shown that:

$$J = \lambda(1 - \alpha_0) + \int_{\Omega_0} [f_1(x)dx - \lambda f_0(x)]dx, \quad (6.46)$$

and an LRT will minimize J for any positive λ. In particular:

$$L(x) \triangleq \frac{f_1(x)}{f_0(x)}\begin{cases} \geq \lambda \Rightarrow H_1 \\ < \lambda \Rightarrow H_0 \end{cases}.$$

To satisfy the constraint and to maximize the power, choose λ so that $\alpha = \alpha_0$, namely:

$$\alpha = \int_\lambda^\infty f_{L|H_0}(l|H_0)dl = \alpha_0,$$

where $f_{L|H_0}(l|H_0)$ is the pdf of the likelihood ratio. The threshold is determined by solving the above equation.

The Neyman-Pearson detector is known to be the most powerful detector for the problem of detecting a constant signal in noise. One advantage of the Neyman-Pearson detector is that its implementation does not require explicit knowledge of the prior probabilities and costs of decisions. However, as is the case for Bayes' detector, evaluation of the likelihood ratio still requires exact knowledge of the pdf of X under both hypotheses.

6.5.3 Detection of a Known Signal in Gaussian Noise

Consider a signal detection problem formulated as follows:

$$\begin{aligned} H_0 &: X_i = N_i \\ H_1 &: X_i = N_i + S, \end{aligned} \quad (6.47)$$

$i = 1, 2, \ldots, K$. Assume that S is a deterministic constant and that X_i, $i = 1, 2, \ldots, K$ are iid zero-mean Gaussian random variables with a known variance^2. The likelihood ratio is then as written here:

$$L(x) = \frac{f_1(x_1, x_2, \ldots, x_K)}{f_0(x_1, x_2, \ldots, x_K)} = \prod_{i=1}^{K}\frac{f_1(x_i)}{f_0(x_i)}.$$

Taking the logarithm of $L(x)$ yields the log-likelihood ratio of:

$$lnL(x) = \sum_{i=1}^{K} \frac{(2x_i S - S^2)}{2\sigma^2}. \qquad (6.48)$$

Straightforward algebraic manipulations show that the LRT is characterized by comparing a test statistic:

$$T(x) \triangleq \sum_{i=1}^{K} x_i \qquad (6.49)$$

with the threshold λ. If $T(x) \geq \lambda$, then H_1 is said to be true; otherwise, H_0 is said to be true.

It is interesting to note that $T(x) = \sum_{i=1}^{K} x_i$ turns out to be the sufficient statistic for estimating S, as shown in Section 6.4.2. This should not be surprising as detection of a constant signal in noise is a dual problem of estimating the mean of the observations.

Under the iid Gaussian assumption, the test statistic is clearly a Gaussian random variable. Furthermore, $E\{T(X)|H_0\} = 0$, $E\{T(X)|H_1\} = KS$, and $Var\{T(X)|H_0\} = Var\{T(X)|H_1\} = K\sigma^2$. The pdf of $T(x)$ plotted in Figure 6.1, can be written as:

$$f_{T|H_0}(t|H_0) = \frac{1}{\sqrt{2\pi K\sigma^2}} e^{-\frac{t^2}{2K\sigma^2}}$$

$$f_{T|H_1}(t|H_1) = \frac{1}{\sqrt{2\pi K\sigma^2}} e^{\frac{-(t-KS)^2}{2K\sigma^2}}.$$

The false alarm rate and power are given by:

$$\alpha = \int_{\lambda_0}^{\infty} f_{T|H_0}(t|H_0)dt.$$

$$\beta = \int_{\lambda_0}^{\infty} f_{T|H_1}(t|H_1)dt.$$

The above two equations can be further specified as:

$$\alpha = \int_{\lambda 0}^{\infty} \frac{1}{\sqrt{2\pi K\sigma^2}} e^{-t^2/2K\sigma^2} \mathrm{dt} = 1 - \Phi\left(\frac{\lambda_0}{\sigma\sqrt{K}}\right). \qquad (6.50)$$

$$\beta = \int_{\lambda 0}^{\infty} \frac{1}{\sqrt{2\pi K\sigma^2}} e^{-(t-Ks)^2/2K\sigma^2} \mathrm{dt} = 1 - \Phi\left(\frac{\lambda 0 - KS}{\sigma\sqrt{K}}\right). \qquad (6.51)$$

In equations 6.50 and 6.51, this is true:

$$\Phi(x) \triangleq \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} e^{-t^2/2} dt.$$

For the Neyman-Pearson detector, the threshold λ_0 is determined by the constraint on the false alarm rate:

$$\lambda_0 = \sigma\sqrt{K}\Phi^{-1}(1-\alpha).$$

Combining equations 6.50 and 6.51 yields a relation between the false alarm rate and power, namely:

$$\beta = 1 - \Phi\left(\Phi^{-1}(1-\alpha) - \sqrt{K}\frac{S}{\sigma}\right). \qquad (6.52)$$

Figure 6.1 is a good illustration of the Neyman-Pearson Lemma. The shaded area under $f_{T|H_1}(t|H_1)$ is the value of power, and the shaded area under $f_{T|H_0}(t|H_0)$ is the false alarm rate. It is seen that if the threshold is moved to the left, both the power and the false alarm rate increase.

Remarks

1. It can be seen from equation 6.51 that as the sample size K increases, α decreases and β increases. In fact, $\lim_{K-\infty} \beta = 1$.
2. Define $d^2 \triangleq \frac{s^2}{\sigma^2}$, which can be taken as the signal-to-noise ratio (SNR). From equation 6.52, one can see that $\lim_{d\rightarrow\infty} \beta = 1$.
3. If the test statistic is defined with a scaling factor, namely $T(x) = \sum_{i=1}^{K} \frac{S}{\sigma^2} X_i$, the detector remains unchanged as long as the threshold is also scaled accordingly. Let $h_i \triangleq \frac{s}{\sigma^2}$, and then $T(x) = \sum_{i=1}^{K} h_i x_i$. The detector is essentially a discrete-time **matched filter**. This detector is also known as the correlation detector as it correlates signal with the observation. When the output of the detector is of a large numerical value, the correlation between the observation and the signal is high, and H_1 is (likely to be) true.

The Neyman-Pearson detector can be further characterized by the receiver–operation curve (ROC) shown in Figure 6.2, which is a plot of equation 6.52, parameterized by d, the SNR.

It should be noted that all continuous LRTs have ROCs that are above the line of $\alpha = \beta$ and are concave downward. In addition, the slope of a curve in a ROC curve at a particular point is the value of the threshold λ required to achieve the prescribed value of α and β.

6.6 Suggested Readings

There is a rich body of literature on the subjects of statistical signal processing and mathematical statistics. A classic textbook on detection and estimation is by van Trees (1968). This book provides a good basic treatment of the subject, and it is easy to read. Since then, many books have been written. Textbooks written by Poor (1988) and Kay (1993, 1998) are the more popular ones. Poor's book provides a fairly complete coverage of the subject of signal detection and estimation. Its presentation is built on the principles of mathematical statistics and includes some brief discussions of nonparametric and robust detection theory. Kay's books are more relevant to signal processing applications though they also include a good deal of theoretical treatment in statistics. In addition, Kassam (1988)

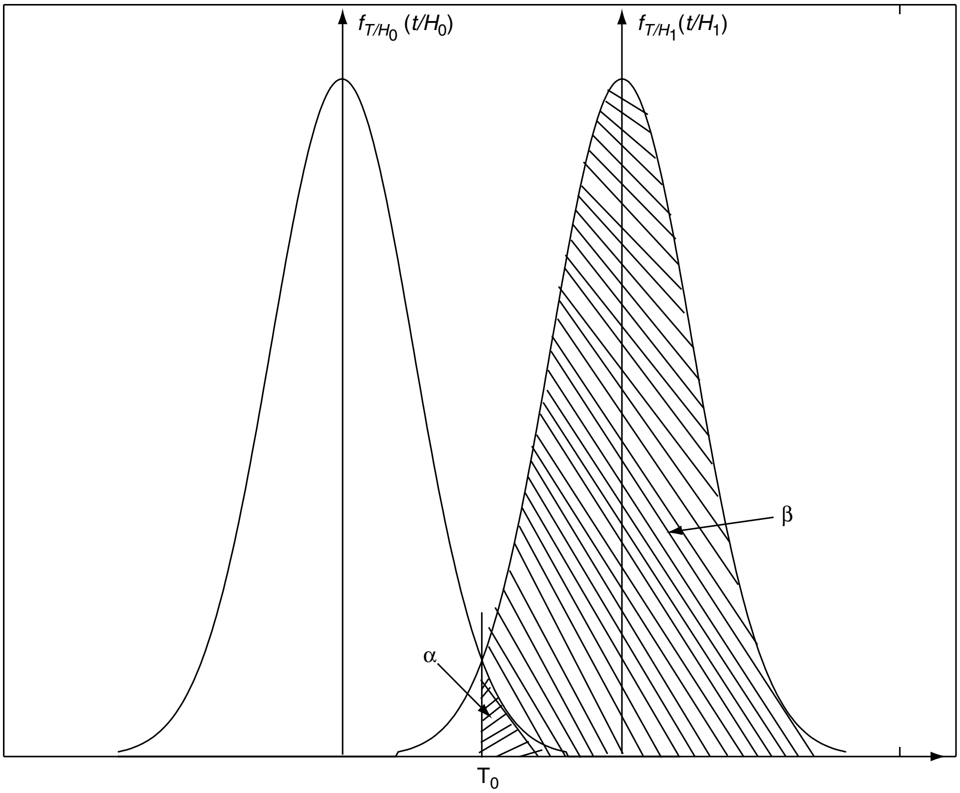

FIGURE 6.1 Probability Density Function of the Test Statistic

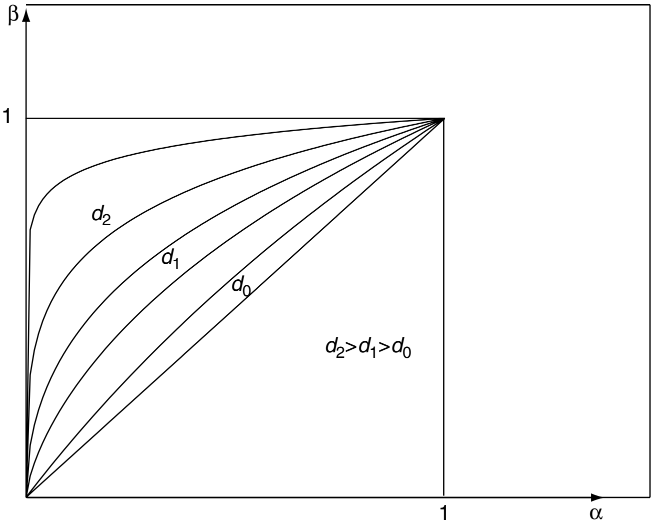

FIGURE 6.2 An Example of Receiver Operation Curves

offers a good understanding of the subject of signal detection in non-Gaussian noise, and Weber (1987) offers useful insights into signal design for both coherent and incoherent digital communication systems. If any reader is interested in learning more about mathematical statistics, Bickel and Doksum (1977) would be a good reference. It contains in-depth coverage of the subject. For quick references to the subject, however, a book by Silvey (1975) is a very useful one.

It should be noted that studies of statistical signal processing cannot be effective without proper background in probability theory and random processes. Many reference books on that subject, such as Billingsley (1979), Kendall and Stuart (1977), Papoulis and Pillai (2002), and Stark and Woods (2002), are available.

VLSI Signal Processing

Surin Kittitornkun
King Mongkut's Institute of Technology Ladkrabang, Bangkok, Thailand

Yu-Hen Hu
Department of Electrical and Computer Engineering, University of Wisconsin-Madison, Madison, Wisconsin, USA

7.1 Introduction

The field of very large scale integrated (VLSI) signal processing concerns the design and implementation of signal processing algorithms using application-specific VLSI architecture, including programmable digital signal processors and dedicated signal processors implemented with VLSI technology. In this chapter, we survey important developments in this field, including algorithm design, architecture development, and design methodology.

An implementation of a digital signal processing (DSP) algorithm consists of the computer program of that algorithm and the hardware on which the program is executed. In many signal processing applications, real-time processing is an essential requirement. Real-time implies that the results of a signal processing algorithm must be computed by a predefined deadline after the inputs are sampled. For example, in a cellular phone, the speech coding signal processing algorithm must be executed to match the speed of normal conversation. An implementation of a real-time signal processing application has three special characteristics:

(1) Input signal samples are made available while the program is being executed. The computation cannot be started early until the input signal samples are received.

(2) Results must be computed before the prespecified deadline. When real-time constraint is not met, the quality of services will be dramatically compromised.

(3) Vast amount of operations must be computed. The data rate of a single Moving Picture Experts Group MPEG-II encoded video signal stream can easily exceed 20 million samples per second. On average, each sample will require tens or even hundreds of fixed-point or floating point arithmetic operations to process. Multiple streams of video and audio signals often need to be processed simultaneously. Hence, signal processing algorithms are always computation-intensive.

An efficient implementation of a real-time signal processing algorithm must be able to perform an extremely large amount of arithmetic operations within a short duration. In other words, it must sustain high throughput rate.

Signal processing is often found in embedded systems such as electrical appliances where the user interacts with the system's main function instead of specific signal processing algorithms. For example, speech coding is regularly performed in cellular phones while users may never be aware of its existence.

A signal processing algorithm can be implemented on a general purpose computer, a special purpose programmable digital signal processor, or even dedicated hardware. The tasks of implementation involve algorithm design, code generation (programming), and architecture synthesis. With the same integrated circuit technology, a specialized hardware platform may offer better performance than general-purpose hardware by eliminating redundant operations and components. However, the design and manufacturing cost will be higher.

7.1.1 VLSI Application Specific Processors

In the early 1960s, most DSP algorithms, such as the fast Fourier transform (FFT), were implemented in Fortran programs running on a general-purpose mainframe computer. It could take hours to process a short 30-second speech. Obviously, general purpose computing systems were insufficient to meet the high throughput rate demanded by a real-time signal processing algorithm. Dedicated application-specific computing systems, however, were too expensive to be a realistic solution for most commercial signal processing applications.

This situation changed in mid-1970s. Quantum leaps in integrated circuit manufacturing technology led to the era of VLSI systems. By 1980, hundreds of thousands transistors could be reliably and economically fabricated on a single silicon chip. With the transistor count per chip growing exponentially, it became quite clear that to manage the design complexity of VLSI circuits, IC design methodologies must be revolutionized. In 1980, Mead and Conway championed the notion of structured VLSI design. In Mead and Conway's (1980) seminal book Introduction to VLSI Systems, the authors argued that a hierarchical design style exhibiting regularity and locality must be adopted to design millions of transistors on a single chip. A novel architecture called **systolic array** was used as an example that satisfies all these requirements.

This idea of structured VLSI design further inspired the concept of a silicon compiler, which, in analogy with the software compiler, would automatically generate a silicon implementation starting from a high-level description. These pioneering ideas stimulated many important developments in the IC industry, such as the proliferation of electronic design automation (EDA) tools, the popularity of semi-custom design styles (e.g., gate array and standard cell layout), and the availability of silicon foundry services. By the time of mid-1980s, a new industry known as application specific IC (ASIC) design started to thrive. Numerous chip sets for video coding, three-dimensional (3-D) audio processing, and graphic rendering have been available on the market at appealing costs.

7.1.2 VLSI and Signal Processing

The VLSI revolution impacted on signal processing system architecture in a number of important ways:

- **High speed**: As the IC manufacturing technology evolves, the feature dimensions of transistors continue to shrink. Smaller transistors means faster switching speed and, hence, higher clock rate. Faster processing speed means more demanding signal processing algorithms can now be implemented for real-time processing.
- **Parallelism**: Higher device density and larger chip area promise to pack millions of transistors on a single chip. This makes it feasible to exploit parallel processing to achieve an even higher throughput rate by processing multiple data streams concurrently. To fully exploit the benefit of parallel processing, however, the formulation of signal processing algorithms must be reexamined. Algorithm transformation techniques are also developed to exploit maximum parallelism from a given DSP algorithm formulation.
- **Local communication**: As device dimensions continue to decrease and chip area continues to increase, the cost of intercommunication becomes significant in terms of both chip real estate and transmission delay. Hence, pipelined operation with a local bus is preferred to broadcasting using global interconnection links. Compiler and code generation methods need to be updated to maximize the efficiency of pipelining.
- **Low-power architecture**: Smaller transistor feature size makes it possible to reduce the operating voltage and, thereby, significantly reduces the power consumption of an IC chip. This trend makes it possible to develop digital signal processing systems on portable or handheld mobile computers.

On the other hand, the stringent performance requirement and regular deterministic formulation of signal processing applications also profoundly influenced the VLSI design methodology.

- **High-level synthesis design methodology**: The quest to streamline the process of translating a complex algorithm into a functional piece of silicon that meets the stringent performance and costs constraints has led to significant progress in the area of high-level synthesis, system compilation, and optimal code generation. Ideas such as dataflow modeling, loop unrolling, software pipelining, which were originally developed for general purpose computing systems, have enjoyed great success when applied to aiding the synthesis of an application-specific signal processing system from a high-level behavioral description.
- **Multimedia processing architecture**: With the maturity and popularity of multimedia signal processing applications, general purpose microprocessors have incorporated special-purpose architecture, such as the multimedia extension instruction set (e.g., MMX). Signal processors also led the wave of a novel architectural concept such as very long instruction word (VLIW) architecture. In fact, it is argued that incorporating multimedia features is the only way to sustain the exponential growth in performance through the next decade.

7.1.3 Chapter Overview

This chapter puts more emphasis on DSP algorithm to hardware synthesis and its hardware implementation. First, a DSP algorithm can be expressed as an *n*-level nested Do-loop, a recurrent equation, and a data flow graph (DFG). Next, one of these representations gets synthesized to its hardware counterpart. The hardware architecture is not only driven by the algorithm representation but also the sampling rate of input/output signals. Due to limited hardware resources, operations and data of a particular algorithm can be scheduled at the right time and assigned at the right execution unit basis provided that the precedence and semantics are preserved. For a high-throughput application such as image/video processing, synthesis of a regular network of processing elements (PEs) is discussed in detail. Eventually, implementation technology and tools of a particular architecture are surveyed.

7.2 Algorithm to Hardware Synthesis

Other than a mathematical equation, a DSP algorithm has a variety of different representations including a nested Do-loop algorithm, recurrent algorithm, and data/signal flow graph. The DSP algorithm can also be classified as a terminating and a nonterminating program. Unlike the terminating program, a nonterminating one is specified to execute for an infinite amount of time.

7.2.1 DSP Common Characteristics

DSP systems implemented in either hardware or software-programmable DSP processors are characterized by the following common characteristics. First, data flow/real-time computing corresponds to its analog counterpart in that an output signal is a convolution of an input signal and the impulse response of a given analog linear time-invariant (LTI) system. The convolution is assumed to take infinitesimal time to compute. In a practical DSP system, a stream of output data is a discrete convolution sum of another stream of sampled/discretized input data and the impulse response of a discrete LTI system. Furthermore, the discrete convolution sum takes a finite amount of time to compute a useful datum (sampling time period). Hence, the notion of real-time computing is imposed. Such DSP systems may involve human interface, such as speech recognition for voice dialing or audio and video signal processing in Dolby Digital/DVD home theaters. Second, some DSP systems have an infinite run time. For instance, a particular communication system on either the transmitting or receiving end must process the transmitted/received signal to maintain the continuous data/audio/video stream such as the backbone network of the Internet. Third, some DSP algorithms can be described in a nested Do-loop construct. This includes any vector/matrix multiplication (inner/outer product), correlation, and the like. A number of DSP algorithms can be written in a recursive equation: infinite impulse response (IIR) filter, least mean square/recursive least square (LMS/RLS) adaptive filter, and so on. Finally, DSP is applied in a variety of applications ranging from seismogram to the communication system in the space shuttle/station. As a result, a variety of data types and sampling rates must be taken into consideration.

Because of these DSP common characteristics, many DSP algorithms can be conveniently formulated into the form of nested Do-loops perhaps with an infinite loop bound.

7.2.2 Nested Do-Loop Algorithm

The regular structure of **nested Do-loop algorithms** has been explored extensively for a compiler of general-purpose parallel computing (Banerjee, 1993; Wolfe, 1996). With the help of the compiler, the algorithms can be executed according to particular scheduling and assignment to match the underlying architecture such as SIMD, MIMD, and many others. In general, without the regular structure of loop indices, such scheduling and assignment are NP-hard.

Similarly, the implementation of a nested Do-loop formulation of DSP algorithms is actually a "mapping" process consisting of task scheduling and assignment from abstract operations to a piece of hardware. In contrast to general-purpose computing, the underlying hardware is of the form programmable digital signal processor or ASIC in array-like structure.

Since the introduction of the temporal hyperplane by Lamport (1974), the scheduling and assignment problem of nested Do-loop algorithms has been explored and developed to the so-called **systolic array** (Kung, 1982), exploiting regular array structure, temporal pipelining, and local communication. Along with the advance of VLSI technology, certain nested Do-loop algorithms can be scaled down and realizable in a single chip. Thus, the nested Do-loop scheduling and assignment problem can be formulated as an algebraic projection. Each loop index in the index space will be projected onto the index of a regular array of processing elements (PEs), and their execution time is determined by a family of equitemporal hyperplanes, where all indices on the same hyperplane are executed simultaneously.

Two different but closely related methodologies to processor array design are the **dependence method** (Moldovan, 1982; Rao and Kailath, 1988; Kurg, 1988) and the **parameter method** (Li and Wah, 1985). Both the dependence method and parameter method are based on the assumption that an algorithm is written in a uniform recurrence nested Do-loop, which can be depicted as a shift-invariant dependence graph (DG).

In this section, we mainly focus on the dependence method design methodology because it is easy to visualize in multidimensional representation. Despite the fact that the parameter method establishes the relationship between velocity, distance, and period of each variable throughout the course of parallel execution, it is not as popular as the dependence method. Nonetheless, the relationship between these two design methodologies has been elaborated by O'Keefe *et al.* (1992).

Space-Time Mapping

The dependence method can be illustrated by the notion of space-time mapping of this matrix–matrix multiplication. Multiplication of two 3×3 matrices, a and b, results in a 3×3 matrix c.

Example 1: Matrix–Matrix Multiplication

$$c = a \times b \tag{7.1}$$

First, the multiplication is formulated as a three-level nested Do-loop as follows:

```
Do $i = 1$ to 3.
  Do $j = 1$ to 3.
    $c[i, j] = 0.$
    Do $k = 1$ to 3.
      $c[i, j] = c[i, j] + a[i, k] \times b[k, j].$
    EndDo $k$
  EndDo $j$
EndDo $i$
```

It can then be reformulated in single assignment format (Kung, 1982) as the following:

```
Do $i = 1$ to 3.
  Do $j = 1$ to 3.
    Do $k = 1$ to 3.
      $a_3[i, j, k] = \begin{cases} a[i, k], & j = 0. \\ a_3[i, j-1, k], & j > 0. \end{cases}$
      $b_3[i, j, k] = \begin{cases} b[j, k], & i = 0. \\ b_3[i-1, j, k], & i > 0. \end{cases}$
      $c_3[i, j, k] = \begin{cases} 0, & k = 0. \\ c_3[i, j, k-1] + a_3[i, j, k] \times b_3[i, j, k], & k > 0. \end{cases}$
        $c[i, j] = \{c_3[i, j, k], k = 3.$
    EndDo $k$
  EndDo $j$
EndDo $i$
```

The a_3, b_3, and c_3 are the 3-D version a, b, and c, respectively. □

From this example, a three-level nested Do-loop algorithm can be written in a single assignment format and a perfect loop nest. The innermost loop body is composed of a set of input/propagation, computing/initialization, and output statements as shown in Figure 7.1. We denote $\boldsymbol{J}^n$ as the computing index space.

```
**Do** $i_1 = l_1$ to $u_1$
  ....
  **Do** $i_n = l_n$ to $u_n$
    Input/Propagation Statements
    $v_j^n[\vec{I}] = \begin{cases} v_j[\mathcal{G}_{v_j}(\vec{I})] & , \vec{I} \in \mathbf{I}_{v_j}^I \\ v_j^n[\vec{I} - \vec{d}_{v_j^n}] & , \vec{\mathrm{I}} \in \mathbf{I}_{v_j}^P \end{cases}$
    ....
    Computation/Initialization and Statements
    $v_k^n[\vec{I}] = \begin{cases} v_{k,\ Init}^n & , \vec{I} \in \mathbf{I}_{v_k}^N \\ \mathcal{F}_{v_k}(v_k^n[\vec{I} - \vec{d}_{v_k^n}], v_j^n[\vec{I}], \ldots & , \vec{I} \in \boldsymbol{I}_{v_k}^C \end{cases}$
    ....
    Output Statements
    $v_k[\mathcal{G}_{v_k}(\vec{I})] = v_k^n[\vec{I}]$ , $\vec{I} \in \mathbf{I}_{v_k}^O$
    ....
  **EndDo** $i_n$
  ....
**EndDo** $i_1$
```

FIGURE 7.1 *n*-Level Nested Do-Loop Algorithm.

Definition 1 Computing Index Space. $\boldsymbol{J}^n$

The computing index space is a set of *n*-dimensional integer-valued vectors such that $\boldsymbol{J}^n = \{\vec{I} = (i_1, i_2, \ldots, i_n)^i | i_1, i_2, \ldots, i_n \in \boldsymbol{Z}.l_1 \leq i_1 \leq u_1, l_2 \leq i_2 \leq u_2, \ldots ln \leq i_n \leq u_n\}$, where $\vec{a}^t$ denotes the transpose of $\vec{a}$. In other words, $\boldsymbol{J}^n \subset \boldsymbol{Z}^n$ is an *n-D* polyhedron with integer-valued vertices.

$\boldsymbol{J}^3 = \{(i, j, k)^t | 1 \leq i, j, k \leq 3\}$ in the matrix–matrix multiplication example.

Definition 2 Generic n-Level Nested Do-Loop

An *n*-level nested Do-loop model is shown in Figure 7.1. Each iteration is indexed by a computing index (vector) $\vec{I} = (i_1, i_2, \ldots i_n)^t$. The loop body consists of three different kinds of statements:

- Input/Propagation
  Let v_j be an input variable where v_j^n is its corresponding $n - D$ variable. At a particular input, index $\vec{I} \in \boldsymbol{I}_{v_i}^I$, $v_j[\mathcal{G}_{v_j}(\vec{I})]$ is assigned to v_j^n by the index transformation function $\mathcal{G}_{v_j}$. Other than for this exception, v_j^n is propagated along the direction of the propagation dependence vector $(DV)d_{v_j}^n$ at any index $\vec{I} \in \boldsymbol{I}_{v_j}^P$.
- Computation/Initialization
  The v_k^n an *n-D* version of variable v_k, is computed as a recurrent function $\mathcal{F}_{v_k}$ of itself and other input variables (e.g., v_j^n and so on). The vector $\vec{d}_{v_k^n}$ represents the operation dependence of current of v_k^n. Most of the time, the computation is carried on at index $\vec{I} \in \boldsymbol{I}_{v_k}^C \subseteq \boldsymbol{J}^n$. During the initialization phase, v_k^n is assigned to $v_{k,\ Unit}^n$ at index $I \in \boldsymbol{I}_{v_k}^v$

- Output v_k^n is output as v_k by the index transformation function $\mathcal{G}_{v_k}$ at index $\vec{I} \in \boldsymbol{I}_{v_k}^{O}$.

Note that each variable in the loop body follows the single assignment format. □

Based on the definition of an *n*-level nested Do-loop, there are three different kinds of variables: **input**, **output**, and **intermediate**.

Definition 3 Input Variable, v

For each input variable v_j its *n-D* correspondence is v_j^n. It is inputted at $\vec{I} \in \boldsymbol{I}_{v_j}^{I}$ and propagated at $\vec{I} \in \boldsymbol{I}_{v_j}^{P}$, where $\boldsymbol{I}_{v_j}^{l} \cap \boldsymbol{I}_{v_j}^{P} = \phi$ and ϕ is the empty setted.

Definition 4 Output Variable, v_k

For each output variable v_k, its *n-D* correspondence is v_k^n. It is initialized at $\vec{I} \in \boldsymbol{I}_{v_k}^{N}$ and computed at $\vec{I} \in \boldsymbol{I}_{v_k}^{C}$, where $\boldsymbol{I}_{v_k}^{C} \cap \boldsymbol{I}_{v_k}^{N} = \phi$. Its output value is defined at $\vec{I} \in \boldsymbol{I}_{u_k}^{U}$. □

Definition 5 Intermediate Variable v_k

For each intermediate variable v_k, its $n - D$ correspondence is v_k^n. It is intialized at $\vec{I} \in \boldsymbol{I}_{v_k}^{I}$ and computed at $\vec{I} \in I_{v_k}^{C}$, where $I_{v_k}^{C} \cap I_{v_k}^{N} = \phi$. Its output value is consumed only at $\vec{I} \in I_{v-k}^{U}$ □

In matrix–matrix multiplication, *a* and *b* are input variables, while *c* is the output variable. The propagation dependence vectors of *a* and *b* are $\vec{d}_{a_3} = (0, 1, 0)^t$ and $\vec{d}_{b_3} = (1, 0, 0)^t$, respectively. On the other hand, the true dependence vector of *c* is $(0, 0.1)^t$. If all dependence vectors are plotted in the index space $\boldsymbol{J}^3$, a 3-D DG is yielded in Figure 7.2(A). Each node represents a data flow graph (DFG) of multiplication and addition as shown in Figure 7.2(B), respectively.

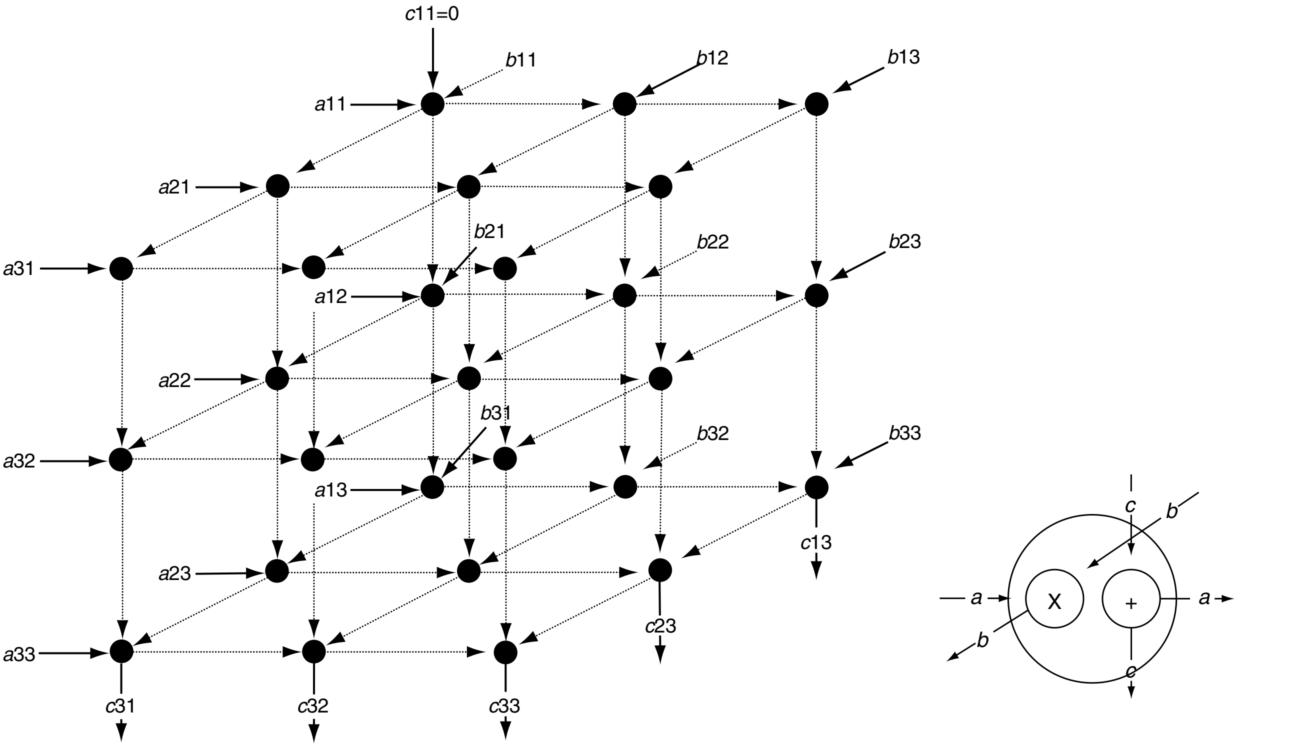
Definition 6 Dependence Graph

A dependence graph (DG) (Kung, 1988) is a directed graph $G_{DG} = (\Omega_{DG}, L_{DG})$, where Ω_{DG} is a set of nodes in index space $\boldsymbol{J}^n$ and where L_{DG} is a set of edges connecting a pair of nodes, *i* and *j* and $i, j \in \Omega_{DG}$ if and only if computing of node *j* depends on the result from node *i*. Note that these edges are also called dependence vectors either due to propagation or computation. In other words, a DG is a graphical representation of an *n*-level nested Do-loop defined in definition 2. Furthermore, any *DG* is computable if and only if it contains no loops or cycles. □

A DG with its detailed DFG in each node is considered a data flow graph as it is defined here.

Definition 7 Data Flow Graph

A data flow graph is a directed graph $G_{DFG} = (\Omega_{DFG}, L_{DFG})$, where Ω_{DFG} is a set of nodes representing operations or functions and where L_{DFG} is a set of edges connecting a pair of nodes,



(A) A 3 x 3 Matrix-Matrix Multiplication in a 3-D Dependence Graph

(B) Node (Loop Body) as a Data Flow Graph

FIGURE 7.2

i and j and $i, j \in \Omega_{DFG}$. This indicates the flow of data with or without delay element(s) as an output from node i to node j. □

The notion of linear space-time mapping is a transformation of index space $\boldsymbol{J}^n$ onto an (n-1)-D space and 1-D time index spaces. The space-time mapping matrix T consists of **scheduling vector** $s \in \boldsymbol{Z}^n$ and **processor allocation matrix** $P \in \boldsymbol{Z}^{n \times n-1}$, where $\boldsymbol{Z}$ is the integer number space. In other words, an algorithm described as a multiple perfect loop nest can be projected onto an (n-1)-D array of PEs and a scalar valued execution schedule with respect to the dependencies. The computing takes place in parallel at the allocated PEs according to the time (clock) schedule.

Definition 8 Space-Time Mapping

The space-time mapping matrix $T \in \boldsymbol{Z}^{n \times n}$ is given by:

$$T = \begin{bmatrix} s^{-t} \\ P^t \end{bmatrix}, \tag{7.2}$$

where $\vec{s}$ and P are linearly independent. In other words, Rank $(T) = n$.

The **schedule-allocation matrix** is another representation of the original index space in the computing schedule (time) and processor allocation (space) domains. The computing schedule $t(\boldsymbol{J}^n) \subset \boldsymbol{Z}^n$ and processor allocation $\boldsymbol{J}^1 \subset \boldsymbol{Z}$ can be obtained by:

$$\begin{bmatrix} t(\boldsymbol{J}^n) \\ \boldsymbol{J}^{n-1} \end{bmatrix} = \begin{bmatrix} \vec{s}^t \boldsymbol{J}^n \\ P^t \boldsymbol{J}^n \end{bmatrix} = T\boldsymbol{J}^n, \tag{7.3}$$

where $\boldsymbol{J}^{n-1}$ is the $(n-1) - D$ index spaces, respectively. In other words, the matrix T maps the execution index $\vec{q} \in \boldsymbol{J}^n$ to processor $P^t\vec{q}$ at time step (clock) $t(\vec{q})$.

Due to the shift-invariant DG_j all dependence vectors associated with any DG node can be represented in a **dependence matrix**, D_V:

$$D_V = [D_{v_1} \quad D_{v_2} \quad \dots\ ], \tag{7.4}$$

where variables $v_i \in V$ and V represent a set of all variables in the algorithm. The D_{v_i} is recursively defined as a set of dependence vectors associated with variable v_i:

$$D_{v_i} = \begin{bmatrix} \vec{d}_{i1} & \vec{d}_{i2} & \dots \end{bmatrix}, \tag{7.5}$$

where $\vec{d}_{ij} \in \boldsymbol{Z}^n$ is a dependence vector j of variable v_i. It is obvious that all the dependencies in every node in Figure 7.2(A) are captured by this dependence matrix:

$$D_V = \begin{bmatrix} \vec{d}_{b3} & \vec{d}_{a3} & \vec{d}_{c3} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{7.6}$$

Similarly, the mapping can be applied to the dependence matrix to obtain the **delay-edge matrix**. The D_V is transformed via space–time mapping to interprocessor links or edges and registers or delays, respectively. Interprocessor communication is carried out via an $\vec{e}_{v_i}$ edge that is pipelined with a number of delay elements or shift registers, $r(\vec{e}_{v_i})$:

$$\begin{bmatrix} r(e_V) \\ e_V \end{bmatrix} = \begin{bmatrix} \vec{s}^t D_V \\ P^t D_V \end{bmatrix} = TD_V. \tag{7.7}$$

In equation 7.7, the **delay vector** is as follows:

$$r(e_V) = [r(\vec{e}_{v_1}) \quad r(\vec{e}_{v_2}) \quad \dots\ ]. \tag{7.8}$$

The **edge matrix** is as follows:

$$e_V = [\vec{e}_{v_1} \quad \vec{e}_{v_2} \quad \dots\ ]. \tag{7.9}$$

The delay-edge matrix describes the global structure of the resulting PE array regardless of the functionality inside each PE. This structure is called a **signal flow graph** and is mainly used to explain algorithms in DSP.

Definition 9 Signal Flow Graph

A signal flow graph (SFG) (Kung, 1988) shown by $G = (\Omega, L)$ is a directed graph consisting of a set of vertices, (PEs) Ω and a set of edges (links) L. Each variable $v \in V$ has its own set of edges L_v such that an edge $l_v \in L_v$ associated with $r(e_v)$ delay elements of direction e_v connect two PEs ω_i and ω_j, where $\omega_i, \omega_j \in \Omega$. Based on shift-invariant DG, the resulting SFG after space–time mapping is considered structurally time-invariant in which only edge structures remain invariant. □

Partitioning

If the number of processors is limited and much less than the number of PEs required for a particular algorithm, the DG must be partitioned and mapped to fit that fixed size array. Hwang and Hu (1992) have proposed a two-level locally sequential globally parallel (LSGP) scheduling to reduce the overall computing time. The DG is first partitioned into a set of disjoint blocks. Those blocks will be allocated to available processors and scheduled with a two-level schedule. The first-level sequential schedule is obtained from applying permissible loop transformations. The second-level parallel schedule is formulated as an integer programming problem subject to the total computation latency. An interblock schedule is applied to determine the relative timing of each block's computation and satisfy the precedence constraints imposed by dependence vectors across the block boundaries.

Partitioning the same DG to several blocks is considered a special case of multistage systolic mapping MSSM (Hwang and Hu, 1992), where each stage is characterized by a different DG of a different nested Do-loop algorithm. It can be viewed as an locally parallel globally parallel (LPGP). Scheduling problem for parallel processing of a complex operation chain. After mapping consecutive stages, it may result in mismatched I/O operations.

Therefore, a systematic approach is proposed to reduce data communication overhead and overlap part of the computation in successive stages to minimize performance degradation.

Lower-*D* Mapping

In this section, the dependence method or space–time mapping will be extended to map an *n-D* DG to the final 1-D or 2-D SFG. The earliest attempt to map an *n-D* DG to an $(n-2)$-*D* clock schedule and a 2-D PE array using only a single space–time mapping matrix was proposed by Wong and Delosme (1985). The resulting multidimensional clock must be linearized to a scalar value to reduce implementation cost. This idea of mapping to a lower dimension is similar to **multiprojection** (Kung, 1988), which is equivalent to a sequence of consecutive space–time mappings. Later efforts to extend space–time mapping to *k-D* array, where $1 \leq k < n$, are reported by Lee and Kedem (1988, 1990), Shang and Fortes (1992), and Zimmerman (1996). Similarly, the generalization of the parameter method, called the **general parameter method** (Ganapathy and Wah, 1992), is formulated for a lower-*D* array as well.

Definition 10 One-Dimensional Space–Time Mapping

Contrary to the traditional space–time mapping, the transformation matrix consists of a scheduling vector $\vec{s}$ and a linear allocation vector P_1 as follows:

$$T_1 = \begin{bmatrix} \vec{s}^t \\ P_1^t \end{bmatrix} = \begin{bmatrix} s_1 & s_2 & \cdots & s_n \\ p_1 & p_2 & \cdots & p_n \end{bmatrix}, \qquad (7.10)$$

where $T_1 \in Z^{2\times n}$ and s_i, $p_i \in Z$ are relatively prime. Furthermore, $\vec{s}$ and P_1 must be linearly independent so that $Rank\,(T_1) = 2$. □

Similar to traditional mapping, the schedule–allocation matrix can also be obtained from low-*D* space–time mapping matrix T_1. The computation schedule, $t(\boldsymbol{J}^n) \subset \boldsymbol{Z}$ and processor allocation $\boldsymbol{J}^1 \subset \boldsymbol{Z}$ are as follows:

$$\begin{bmatrix} t(\boldsymbol{J}^n) \\ \boldsymbol{J}^1 \end{bmatrix} = \begin{bmatrix} \vec{s}^t \boldsymbol{J}^n \\ P_1^t \boldsymbol{J}^n \end{bmatrix} = T_1 \boldsymbol{J}^n. \qquad (7.11)$$

In other words, the matrix T_1 maps the execution of index $\vec{q} \in \boldsymbol{J}^n$ at processor $P_1^t \vec{q}$ at time step (clock tick) $t(\vec{q})$. This 1-D array mapping can be applied to obtain the delay-edge matrix as shown earlier in equation 7.7.

Design Objectives

Unlike the parameter method and the general parameter method, the space–time mapping has close form relationships of design objective functions. For instance, the total execution time, τ_e, can be obtained from:

$$\tau_e = t_{\text{cycle}} \times N_{\text{cycle}}, \qquad (7.12)$$

where t_{cycle} is the propagation delay of the critical path in each SFG node and where N_{cycle} is the number of clock cycles. The N_{cycle} is the number of steps between the first and the last computation indices (Kung, 1988) which is given by:

$$N_{\text{cycle}} = \max_{\vec{p},\, \vec{q} \in \mathbf{J}^n} \{\vec{s}(\vec{p} - \vec{q})\} + 1. \qquad (7.13)$$

In other words, N_{cycle} is the number of cuts by the temporal hyperplane. In addition, to minimizing only, the N_{cycle}. Wong and Delosme (1992) has proposed to minimize both t_{cycle} and N_{cycle}.

Although N_{cycle} seems to depend on the scheduling vector $\vec{s}$ only, the question on how many PEs are used and how the data are delivered to the right PE still remain. In the 1-D or linear array mapping, the number of PEs, N_{PE}, can be obtained explicitly as follows:

$$PE_{\max} = \max\{P_1^t q \mid \vec{q} \in \boldsymbol{J}^n\} \qquad (7.14)$$

$$PE_{\min} = \min\{P_1^t q \mid \vec{q} \in \boldsymbol{J}^n\}. \qquad (7.15)$$

As a result, the number of PEs, N_{PE}, is expressed as:

$$N_{PE} = PE_{\max} - PE_{\min} + 1. \qquad (7.16)$$

In other words, N_{PE} is the number of distinct projections of the index space $\boldsymbol{J}^n$ on the vector P_1.

Example 2 4 × 4 Matrix–Matrix Multiplication

A 4 × 4 matrix–matrix multiplication (Pee and Kedem, 1988) DG is scheduled and allocated to a linear or 1-D array of PEs by this 1-D space–time mapping matrix:

$$T_1 = \begin{bmatrix} \vec{s}^t \\ P_1^t \end{bmatrix} = \begin{bmatrix} 2 & 1 & 3 \\ 1 & 1 & -1 \end{bmatrix}. \qquad (7.17)$$

As a result, the array is shown in Figure 7.3. It takes 10 cycles for the data to fill in the pipeline and $N_{\text{cycle}} = 19$ cycles to finish the execution. The maximum PE utilization is 60%. This is due to the constraint that I/O is allowed on either end of the array. □

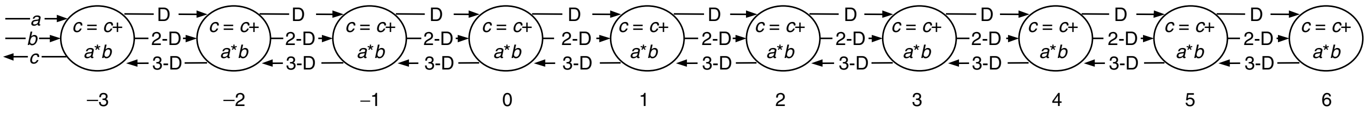


FIGURE 7.3 Signal Flow Graph of 4 × 4 Matrix–Matrix Multiplication. PE number ranges are from −3 to 6 (Lee and Kedem, 1988).

7.2.3 Recurrent Algorithm

In the previous section, an n-level nested Do-loop can be regarded as a terminating program. In this section, a nonterminating recurrent program is taken into consideration. Examples of this kind of algorithm include IIR and adaptive filters. These algorithms are characterized by a current output that is defined by a given function of the previous outputs and the current input. As such, the validity of the output depends on how often its computation is initiated, called the **initiation period**. Two optimization techniques **loop unfolding** and **look-ahead transformation** are discussed next.

Loop Unfolding

Loop unfolding exploits the interiteration precedence or the so-called **loop-carried dependence**. After the loop is unfolded, the new initiation period may be reduced. For example, a nonterminating program is shown in algorithm 1.

Algorithm 1 A Nonterminating Recurrent Program

```
Do $n = 1$ to $\infty$.
    $aa(n) = f_{aa}[aa(n-1), ca(n-1), ba(n)]$.
    $ab(n) = f_{ab}[aa(n-1), ca(n-1), ba(n)]$.
    $ba(n) = f_{ba}[ab(n-1)]$.
    $bc(n) = f_{bc}[ab(n-1)]$.
    $ca(n) = f_{ca}[bc(n)]$.
EndDo $n$
```

The $xy(n)$ denotes an arc (data) flowing from node x to node y at the iteration n, and f_{xy} denotes a definition of $xy(n)$. Its corresponding DFG is illustrated in Figure 7.4. After the loop body is unfolded by a factor of two, the resulting program is listed here:

```
Do $n = 1$ to $\infty$.
    $aa(2n+1) = f_{aa}[aa(2n), ca(2n), ba(2n+1)]$.
    $ab(2n+1) = f_{ab}[aa(2n), ca(2n), ba(2n+1)]$.
    $ba(2n+1) = f_{ba}[ab(2n)]$.
    $bc(2n+1) = f_{bc}[ab(2n)]$.
    $ca(2n+1) = f_{ca}[bc(2n+1)]$.
    $aa(2n+2) = f_{aa}[aa(2n+1), ca(2n+1), ba(2n+2)]$.
    $ab(2n+2) = f_{ab}[aa(2n+1), ca(2n+1), ba(2n+2)]$.
    $ba(2n+2) = f_{ba}[ab(2n+1)]$.
    $bc(2n+2) = f_{bc}[ab(2n+1)]$.
    $ca(2n+2) = f_{ca}[bc(2n+2)]$.
EndDo $n$
```

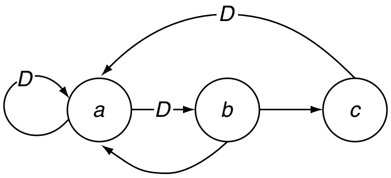

FIGURE 7.4 A Data Flow Graph of Algorithm 1.

As discussed by Parhi (Parhi, 1989), loop unfolding can reduce the iteration period in a multiprocessor implementation. For a perfect-rate DFG, however, its iteration period is bounded and cannot be reduced further. The schedule associated with a perfect-rate DFG is called a rate-optimal schedule.

Look-Ahead Transformation

Loop unfolding can only improve the iteration period but cannot achieve an iteration period less than the iteration bound of the algorithm. To lower the iteration bound, the look-ahead transformation is devised such that the nth iteration's output can be expressed as a function of previous $n-k$ iteration outputs and the necessary inputs. The program shown here is a terminating first-order recurrent program.

```
Do $n = 0$ to 7
    $y(n+1) = a(n)y(n) + x(n)$
EndDo $n$
```

The **look-ahead transformation** can be illustrated by a back substitution as follows:

$$\begin{aligned} y(8) &= a(7)y(7) + x(7). \\ &= a(7)[a(6)y(6) + x(6)] + x(7). \\ &= y(6)a(7)a(6) + x(6)a(7) + x(7). \end{aligned} \tag{7.18}$$

For example, the last element $y(8)$ can be obtained directly from $y(6)$, $x(6)$, and $x(7)$. The term $y(6)a(7)a(6) + x(6)a(7)$ is called the *overhead* of this transformation. As we keep substituting, the final result becomes:

$$\begin{aligned} y(8) &= y(0)\prod_{i=0}^{8} a(8-i) + x(0)\prod_{i=0}^{6} a(8-i) \\ &+ x(5)\prod_{i=0}^{1} a(8-i) + \ldots + x(6)a(8) + x(7). \end{aligned} \tag{7.19}$$

After the look-ahead transformation, a new DFG of this algorithm is obtained. The iteration period of the new DFG may be less than that of the one that is not look-ahead.

7.2.4 SFG/DFG Optimization

In this subsection, the relationship between multiprocessor implementation of a recurrent algorithm and VLSI implementation of the space–time mapping is established. After the SFG/DFG is obtained, some optimization techniques such as cut-set/retiming and geometric transformation can be applied.

DG/SFG Versus DFG

As definition 6, the DG with its functional DFG in each DG node can be perceived as a complete DG (Kung, 1988) or a DFG of a nested Do-loop algorithm. On the other hand, each DFG node describing a recurrent algorithm in Section 7.2.3 corresponds to a set of operations or functions in a processor.

During the space–time mapping, each DG node or computation index is allocated and scheduled to execute at a specific SFG node. In parallel, multiprocessor implementation of recurrent DFG can be obtained by scheduling and assignment strategies, such as the one proposed by Wang and Hu (1995). As a result, several DG nodes correspond to an SFG node (PE), while several DFG nodes can be assigned to the same processor.

In a fully systolic SFG, each edge is associated with register(s). The clock cycle time of each SFG node is determined by its critical path. The delay of the critical path is determined by the maximum computation delay on a zero-register path. On the other hand, a recurrent algorithm is constrained by its iteration period analogous to a clock period. Other than minimizing the iteration period or cycle time, both space–time mapping and multiprocessor implementation try to minimize the number of PEs/processors, respectively.

Due to some undesirable properties of SFG (e.g., long zero-delay link, broadcasting link, dimensionality or geometry) the following strategies have been exploited to reorganize the SFG in such a way that the result is more suitable for VLSI implementation.

Cut-Set and Retiming

The primary methods of SFG optimization employed are cut-set and retiming (Kung, 1988). The objective is to convert an SFG into a fully pipelined form so that all the edges between modular sections have at least one delay element. A cut-set is a minimal set of edges including the target edge, non-zero-delay edges going in either direction, and zero-delay edges going in the same direction as the target edge. The procedure consists of these three steps:

- Partitioning cuts the DFG/SFG nodes to two sets to achieve a cut-set.
- Delay elements associated with a cut-set are all scaled by a positive integer.
- A number of delay elements are transferred between inbound and outbound edges with respect to the partition in such a way that there remains at least one delay element.

The retiming was first proposed by Leiserson *et al.* (1983). It is equivalent to moving around the delays in the DFG such that the total number of delays in any loop remains unaltered. The retiming can be applied to a single-rate DFG to reduce the iteration period in a programmable multiprocessor implementation. A rate-optimal schedule cannot be guaranteed, however, and cannot reduce the iteration period in perfect-rate DFG (Parhi *et al.*, 1989). Very similar to the retiming, delay distribution methodology is presented for the FIR and IIR digital filter (Chen and Moricz, 1991). The optimization is performed on an DFG/SFG, which represents a 1-D algorithm and then is generalized to *n-D* one. The strategies consist of balancing, rescaling, distribution, factorization, and inversion.

Geometric Transformation

The recent effort to transform a 1-D SFG to 2-D SFG was exhibited in Yeo and Hu (1995) and Kittitornkum and Hu (2001) by making use of a spiral and long interconnect. Both arrays were proposed for full-search block matching motion estimation, which is one of the most computation-intensive tasks in real-time digital video coding.

7.2.5 Bit-Level Algorithm

In digital communication, a huge amount of information is transformed into a series of data bits by source coding (e.g., audio and video coding) and various forms of channel coding (e.g., error correction) prior to the transmission. Therefore, every bit of received data is so important that many algorithms have been proposed and developed to save the communication bandwidth and error resilience. Such algorithms include **variable length coding** at the source coding level and **Viterbi decoding** at the channel coding level.

Variable Length Coding

The most well-known and widely used **variable-length coding** (VLC) is the Huffman code. The coding part can be easily implemented as a look-up table to achieve a high output rate. On the other hand, its decoding end can be implemented in a number of VLSI architectures to satisfy different input/output data rates as surveyed by Chang and Messerchmitt (1992). The VLSI architecture can be classified as tree-based and programmable logic array-based (PLA-based). The tree-based architecture is a direct map of the Huffman binary tree. The average decoding throughput of the pipelined version is in the range of $[L_{\min}, L_{\max}]$ bits/cycle, where $L_{\min}$ and $L_{\max}$ are minimum and maximum code lengths, respectively. This rate is apparently higher than a 1 bit/cycle of the sequential tree-based architecture.

A PLA in the PLA-based architecture is functioning as a look-up table storing the states of an finite state machine (FSM). Each state corresponds to either an internal node of the Huffman tree or a decoded output symbol. The design can be constrained to the following conditions.

- Constant input rate at N bits/cycle:

  An $N < L_{\max}$-bit input is buffered and used to look up the next state, the decoded symbol, as well as the shift amount if it is found from a PLA.

- Constant output rate of one symbol per clock cycle:

  The architecture resembles a constant input rate. A longer bit string $N \geq L_{\max}$, however, is used to look up a decoded symbol and its shift amount. The bit string will be shifted by a barrel shifter at the corresponding shift amount.

Viterbi Algorithm

The convolutional coding has been one of the most widely used error corrections in digital wireless communication. Therefore, the **Viterbi decoding algorithm** must be implemented efficiently in a pipelined/systolic fashion. A (K, R) convolutional coding scheme can be described by an FSM, where K is the constraint length and R is the code rate. Similar to a mealy FSM, there are a total of 2^K coding states where output bits and the next state depend on the current state and an input bit.

Among many VLSI implementations, a modified trace-back Viterbi algorithm (Truong, 1992) has been proposed to save register storage. The survivor path is traced back through the trellis diagram and used to determine the decoded information bit in the window of length $5K$. Besides, a 1-Gb/s $K = 2$ convolutional code sliding block Viterbi decoder has been recently reported (Black and Menge, 1997). It is designed for a high throughput magnetic and optical storage channel. Both backward and forward processing exist, with total window length of $M = 2L$ where $L = 5K$. However, $L = 3$ is chosen for performance/complexity trade-off. Thus, each processing unit uses an L-stage trace-back decoding unit. Its fully systolic architecture results in a very high throughput of $2Lf_{clk} = 2 \times 6 \times 83 \simeq 1$ Gb/s, where $f_{clk} = 83$ MHz. Each pipeline stage is an add-compare-select (ACS) unit. The fabricated chip size is $9.21 \times 8.77\,\text{nm}^2$ with a 1.2-μm double-metal CMOS technology.

7.3 Hardware Implementation

DSP application-specific integrated circuits (ASICs) are mostly implemented in digital CMOS circuit technology due to several advantages and maturity of fabrication technology. Other than an ASIC design in a large volume, field-programmable gate array (FPGA) and reconfigurable computing (RC) have been invented to amortize the cost in a low to medium volume. As the application advances toward multiprotocol mobile/wireless computing/communication. RC may emerge as an alternative to hard-wired ASIC. In this section, we put the emphasis on current state-of-the-art FPGA and RC implementation technology and tools.

7.3.1 Implementation Technology

FPGA

A custom computing system (CCS) is an array of interconnected FPGA chips hosted by a general purpose computer. CCS can be perceived as a dynamically reconfigurable data path for special-purpose tasks that cannot be efficiently implemented by software. There have been several examples of CCSs, including CHAMP (Patriguin and Gurevich, 1995), national adaptive processing architecture (NAPA) (Rupp *et al.*, 1998), and Splash-2 (Buell *et al.*, 1996).

- CHAMP is a system of 8 PEs interconnected in a 32-bit ring topology. Each PE consists of two Xilinx XC4013 FPGAs, which is a dual-port memory system.
- NAPA's aim is to develop a teraoperations/second-class computing system. Its emphasis is on algorithmic data path and function generation.
- Splash-2 is a large system of up to 16 array boards each containing 17 Xilinx XC4010 FPGA chips. Splash-2 is hosted by SPARCstation 2 and connected through an SBus interface board.

Besides custom computing systems, the following are some DSP algorithms implemented in FPGA:

- A 1-D discrete fourier transform (DFT) (Dick, 1996) systolic array of PE with coordinate rotation digital computer (CORDIC) arithmetic is reported. Each PE consumes about 44 configurable logic blocks (CLBs) of the Xilinx XC4010PG191-4. As a result, each FPGA chip can accommodate 10 PEs. With the operating 15.3-MHz clock frequency, 1000-point 1-D DFT only takes 51.45 ms to compute.
- A CORDIC arithmetic processor performing polar to Cartesian coordinate transformation is reported by Andraka (1998). The 52-MHz CORDIC processor features pipelined 14-bit 5 iterations per transformation and occupies only 50% of a Xilinx XC4013E-2 FPGA.
- An 8×8-pixel 2-D discrete cosine transform (DCT) implementation is reported (Woods *et al.*, 1996). The 2-D DCT is separated into two passes of 1-D DCT, each consisting of bit-serial arithmetic 12 multipliers and 32 adders/subtractors. The 2-D DCT consumes about 70% of a Xilinx XC6216 FPGA. At maximum clock frequency of 38 MHz, it can achieve 30 frames/second at 720 × 480 pixels.
- Direct sequence spread spectrum (DSSS) RAKE Receiver (Shankiti and Leeser, 2000) has been attempted on a Xilinx XC4028EX–3HQ240 FPGA chip. Each finger occupies 1000 CLBs, which is approximately one FPGA chip. With a 1-MHz clock, the system throughput can reach up to 4000 symbols/sec.
- A 1-D discrete wavelet transform (DWT) realization on FPGA is presented in (Stone and Manalokos, 1998). Both high-pass and low-pass filters are a six-tap bi-orthogonal binary filter. The system consumes 90% of an Altera EPF10K100GC503 whose capacity is equivalent to 100.000 gates. The operating clock frequency is 20 MHz.

TABLE 7.1 Summary of DSP Algorithms on FPGA Implementation

Design	f_{clk} (MHz)	Space Util. (%)	Device
CORDIC	52.0	50	Xilinx XC4013
1-D DFT	15.3	10	Xilinx XC4010
2-D 8 × 8 DCT	38.0	70	Xilinx XC6216
1-D six-tap DWT	20.0	90	Altera EPF10K100
RAKE Receiver	1.0	90	Xilinx XC4028

In addition to these examples summarized in Table 7.1, several efficient formats of finite impulse response (FIR) filter implementation using distributed arithmetic (White, 1989) were reported by Goslin (1995). As discussed earlier, LUTs are one of the fundamental constructs in FPGA. There are a few more advantages of implementing DSP algorithms on FPGA:

- Efficient bit-level logic operations
- Pipelining using flip/flops and shift registers
- ROM- or LUT-based algorithms, such as the Huffman code or Viterbi decoder
- Bit-parallel arithmetic support and dedicated multiplier unit in Xilinx Virtex II FGPA (Xilinx, 2000)

Reconfigurable Computing

Reconfigurable computing (RC) has a variety of hardware architecture as well as applications. In the next two sections, existing RC architecture and its algorithm to hardware mapping are surveyed.

Inspired by the 90/10 locality rule, in which a program executes about 90% of its instructions in 10% of its code, HW/SW partitioning is influenced by the following facts:

1. The higher percentage of run time of specialized computation, the more improvement of cost/performance if it is implemented in hardware.
2. The more specialized computation dominates the application, the more closely the specialized processor should be coupled with the host processor.

This rules of thumb have been successfully applied to the floating-point unit as well as RC.

The basic principle is that the hardware programmability of RC is combined with a general-purpose processing capability of the RISC microprocessor. The interface between these two can be either closely or loosely coupled depending on its applications. How frequently an RC's functionality should be reconfigured must be determined based on the performance criteria of particular HW/SW architecture. Unlike the long configuration latency of the FPGA, RC is attributed by its low-latency dynamic configurability.

Existing RC architecture models are mostly of the form 1-D or 2-D array of configurable logic cells interconnected by programmable links and switches. The array communicates with the outside world through peripheral I/O cells. The architecture can be classified by its processing capacity of each logic cell at different granularity levels.

TABLE 7.2 Granularity Versus Architecture of Reconfigurable Computing

Granularity	Reference
Fine-grained	DRLE
Multigrain	Pleiades
Coarse-grained	Garp, MATRIX, PipeRench, MorphoSys, REMARC

The architecture of a configurable cell, either fine-grained or coarse-grained, is mainly driven by either general-purpose or signal/image processing computing. Its configuration or *context* can be stored locally like SRAM-based FPGA. Instead of being off-chip and loosely coupled to the host processor, RC is going toward an on-chip coprocessor as the technology advances to SOC.

The following are some of the exiting RC systems as they are classified according to their granularity and application in Table 7.2.

- A **fine-grained configurable cell** performs simple logic functions with more complex function (e.g., fast carry look-ahead adder). A perfect example of this architecture is the dynamically reconfigurable logic engine (DRLE) (Nishitani, 1999). It is capable of real-time reconfiguration with several layers of configuration tables. An experimental chip is composed of a 4 × 12 array of configurable cells. Each cell can realize two different logic operations equivalent to 4-bit input to 1-bit output or 3-bit input to 2-bit output. Up to eight different configurations can be locally stored in each memory cell. With 0.25-micron CMOS technology, the chip contains 5.1 million transistors in a 10 × 10-mm^2 die area and consumes 500 mW at 70 MHz.
- A **multigrain configurable cell**, such as Pleiades (Zhang *et al.*, 2000; Rabaey *et al.*, 1997; Abnovs and Rabaey, 1996; Wan *et al.*, 1999), is a multigrain heterogeneous system partitioned by control-flow computing on microprocessor and data flow computing on RC for future wireless embedded devices. An RC array is composed of satellite (configurable) processors and a programmable interconnection to the main microprocessor. Data-flow computing is implemented using global asynchronous and local synchronous clocking to reduce overhead. Therefore, operation starts only when all input data are ready.
- A **coarse-grained configurable cell** performs more complex word parallel arithmetic functions such as, addition and multiplication, with simple bit-level logic functions. Mostly, this RC architecture is organized in a 2-D array of nanoprocessors with an arithmetic and logic unit (ALU), a multiplier, an instruction RAM, a data RAM, data registers, input registers, and an operand register. Reported architecture examples include Garp (Callahan

et al., 2000), PipeRench (Goldstein *et al.*, 1999), REMARC Reconfigurable Multimedia Array Coprocessor (REMARC) (Miyamori and Olukotun, 1998) MATRIX (Mirsky and Detton, 1996) and MorphoSys (Lu *et al.*, 1999).

7.3.2 Implementation Tools

In this subsection, we are focused more on an architecture-driven synthesis, in particular the regular array synthesis. Such array architecture is suitable to both FPGA and reconfigurable computing platforms.

Architecture-Driven Synthesis

One of the well-known DSP synthesis tools is the Cathedral I/II/III (De Man *et al.*, 1990, 1988; Note *et al.*, 1991). A DSP algorithm is described as a graph with operators as vertices and with arcs representing the flow of data in a language called SILAGE. The bit-true specification of all signal formats is specified up to bit-level including quantization and overflow characteristics. Since Cathedral is characterized as an architecture-driven synthesis tool, it supports the following architectural styles. Each architecture style is categorized by sample rate.

1. **Hard-wired bit serial architecture** supported in Cathedral I is suitable to a low-sample rate filter in audio, speech, and telecommunication applications. Because signals are processed bit by bit, least significant bit (LSB) first, the amount of logic is independent of the word length.
2. **Microcoded processors architecture** supported by Cathedral II is appropriate for low- to medium-rate algorithms with heavy decision making and intensive computations. Each processor is a dedicated interconnection of bit-parallel execution units controlled by branch controllers (e.g., highly complex, block-oriented DSP algorithms in the audio- to near-video-frequency range).
3. **Bit-sliced multiplexed data paths** supported in Cathedral III are suitable to a medium-level image, video, and radar processing ranging 1–10 MHz data rates with irregular and recursive high-speed algorithms. The data path consists of interconnected dedicated application-specific units such as registers, adders, multipliers, and so on.
4. **Regular array architecture**, which would be supported in Cathedral IV, is suited for front-end modules of image, video, and radar processing. A regular network of PEs features mostly localized communication and distributed storage. If it is fully pipelined and modular, the array corresponds to the so-called systolic architecture.

In the next subsection, the focus is shifted to a more specific architecture (i.e., the regular array architecture or systolic array mapped from *n*-level nested Do-loop).

Regular Array Architecture Synthesis

The design flow of traditional systolic synthesis is constituted of the following steps as illustrated in Figure 7.5.

1. **DG Capturing**: A DG is captured by means of either description language or graphical input. It is composed of nodes representing computation and edges representing dependencies between connected nodes. Nodes are organized in such a way that they are located on integer grids. In addition, information such as bit width and variable type can be associated with the graph.
2. **Space–time mapping**: It is a process of allocating and scheduling a number of DG nodes to a (usually smaller) number of PEs with respect to their dependencies. The allocation and scheduling can be either a linear or a nonlinear function of node indices. The result of space–time mapping is an SFG with desired objective cost function subject to design criteria.
3. **SFG optimization**: SFG is composed of nodes representing PEs and edges representing wires or busses associated with delay elements or shift registers. SFG optimization includes cut-set and retiming (Kung, 1988) according to additional design criteria and better VLSI realization.
4. **Intermediate representation generation (IR)**: An IR is generated from a given SFG with the help of a predesigned component library. The bit width of each variable is used to determine the size of register and bus. The final result is usually in HDL behavioral description for further behavioral-to-register transfer HDL synthesis.

As summarized in Table 7.3, these synthesis tools are discussed in alphabetical order:

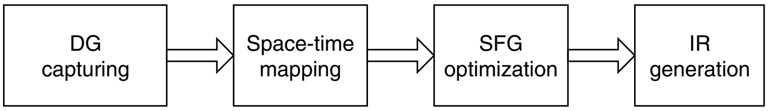

FIGURE 7.5 Systolic Space–Time Mapping Design Flow.

TABLE 7.3 Summary of Systolic Synthesis Tools

	DG capturing	Space–time lapping	SFG optimization	IR generation
ARREST	√	√	√	√
DG2VHDL	√	√	√	√
IRIS[1]			√	√
Khoros[2]	√	√	√	√
VACS	√	√	√	√
VASS	√	√	√	√

[1] Woods *et al.* (1997).

[2] Moorman and Crates (1999).

- ARREST (Burleson and Jung, 1992) extracts dependency vectors from an affine recurrence equation (ARE) description and generates the corresponding DG. Users are allowed to explore design space using a number of provided DG transformations. An SFG is obtained from affine transformation according to user-specified scheduling and projection vectors (Kung, 1988). ARREST permits the user to verify the functionality via a Verilog simulator and cost/performance tradeoff of different design decisions.
- The DG2VHDL (Stone and Manalokos, 2000, 1998) is proposed for general systolic mapping from a net list of DG to a synthesizable behavioral VHDL description of the input DSP algorithm. In addition, a corresponding test bench is generated for design validation.
- The VLSI array compiler system (VACS) (Kung and Jean, 1988) is developed for systolic and wave front array design. DG is captured and displayed in graphical format. Other than scheduling and projection vectors required in the space–time mapping process, processor axes and local memory size in each processor are optional inputs from the user. The optimal SFG is obtained by enumerating different criteria over a bounded search space.
- VASS captures DG in graphical format. It features multiprojection and the two-level pipeline technique for space–time mapping. An approach to transport all interior I/O ports to the array boundary is implemented. The output is the register transfer (RT) level data path synthesis of PE and associated control signals in net list format.

Even though systolic array design methodology was explored in the early 1980s, a deficit of automatic systolic design tools have inhibited traditional systolic design methodology to become useful for RC. To the best of both authors' knowledge, no such automatic design tool yet, exists which may be due to the following reasons.

- Design space of systolic arrays must be explored with human interaction (Kung and Jean, 1988; Burleson and Jung, 1992; Stone and Manalokos, 2000) to achieve an optimal trade-off between different design objectives and to satisfy design constraints.
- The exploration of the final design space is limited because the array dimension is decreased by one after each projection according to the multiprojection procedure.
- I/O port allocation is cumbersome because it is allocated to only array boundaries.
- The resultant array may not be applicable due to its large number of I/O ports and a massive amount of memory bandwidth required.

Regular Array to FPGA/RC Synthesis

RC emerges to exploit inherent and distributed storage, regularity and local communication of VLSI layout, dynamic reconfiguration, and spatial parallelism. As a consequence, more computational power as well as data flow computing with high-throughput demand for multimedia and communication applications can be realized at low-power consumption (Zhang *et al.*, 2000). Meanwhile, advances in semiconductor technology allow faster and larger FPGA/RC to become common practice. This leads to demand of efficient and automatic algorithm mapping tools.

Prior to algorithm-to-hardware synthesis, a system specification undergoes HW/SW partitioning. The success of FPGA/RC lies in how effective the algorithm is mapped to its hardware counterpart and how both hardware and software interact with one another. The latter part, however, is beyond the scope of this chapter.

Despite different levels of granularity of logic cells, the algorithm-to-hardware mapping procedures are performed similarly. Started from algorithm compilation as shown in Figure 7.6, an algorithm mapping methodology of FPGA/RC can be decomposed into the following phases.

1. **Algorithm compilation**: Compilation takes one of several forms of high-level languages (HLLs) to graph representation and then converts it suitable for algorithm transformation and optimization. Such, HLLs include C/C + +. NAPA C (Rupp, 1998), single assignment (SA)-C (Moorman and Cates, 1999), and Matlab. The tool to accomplish the task above is in various forms of compiler such as GNU C/C + + (Isshiki

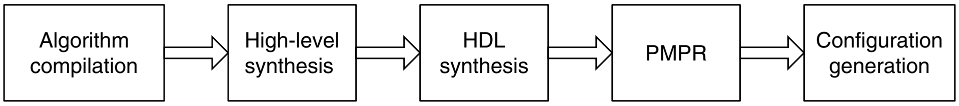

FIGURE 7.6 Algorithm-to-Hardware Mapping of Reconfigurable Computing

and Dai, 1996), NAPA C (Rupp, 1988). SUIF (Callahan *et al.*, 2000), and Cameron (Hammes *et al.*, 1999; Moorman and Cates, 1999). The most recent one is the System Generator from Xilinx and Mathworks (Xilinx, 2000). The suite of tools for algorithm development to hardware prototyping consists of an algorithm mapper, a net lister, a test bench generator, a synthesizer, a control designer a core generator an FPGA placer and router, and a logic simulator.

2. **High-level synthesis**: Synthesis converts the graph representation from the algorithm compilation phase into a behavioral description of hardware description language (HDL), such as VHDL. Verilog HDL, and Lola (Woods *et al.*, 1997). The available tools include ARREST (Burleson and Jung, 1992). DG2VHDL (Stone and Manalokos, 2000). IRIS (Woods *et al.*, 1997), Khoros (Moorman and Cates, 1999), VACS (Kung and Jean, 1988), and VASS (Yen *et al.*, 1996).
3. **HDL synthesis**: This synthesis is responsible for synthesizing a behavioral description of a given algorithm to its corresponding structural or RT level representation using, for example, the Synopsys Behavioral Compiler, Design Compiler, and other such compilers.
4. **Partitioning, mapping, placing, and routing** (PMPR): Partitioning is required for multichip design if it is also necessary for multichip implementation. After design is partitioned for an individual FPGA chip, logic formulation is mapped to underlying logic cells and placed according to the desired floor plan. Logic cells are interconnected by an automatic routing tool. A mapping, placing, and routing tool is provided by the manufacturer or locally implemented and integrated to the design flow such as IRIS (Woods *et al.*, 1997) for faster execution time.
5. **Configuration generation**. A configuration word (bit stream) is generated according to both the logic cell formulation and the routing information.

Table 7.4 summarizes some existing tools/methodologies and their corresponding design phases.

TABLE 7.4 Summary of Algorithm Mapping Methodologies

	Algorithm compilation	High-level synthesis	HDL synthesis	PMPR	Configuration generation

7.4 Conclusion

DSP is attributed by its data flow and real-time computing nature. This dictates the implementation of a high-throughput DSP application as a dedicated chip called ASIC. A broad range of DSP applications include seismic/radar/sonar/radio signal processing, human/computer/machine interface, storage and communication, and security/military operations. As such, a variety of data types, algorithm constructs, and sampling rates are involved. Data type can be either bit-level or bit-parallel (fixed-point/floating-point number). The algorithm can be described as a nonterminating/terminating nested Do-loop or recurrent equation. The sampling rate of the input signals influences the architectural style of algorithm-to-hardware synthesis. As the sampling rate increases, more parallellism/computation power is demanded from the hardware architecture. Consequently, processing power can be obtained from an implementation in either a network of interconnected execution units or a regular array of PEs.

Other than CMOS ASIC realization that needs high product volume to amortize the prototyping cost, FPGA is one of the alternatives provided that allows the timing requirement to be satisfied. In addition, reconfigurable computing has emerged with similar architecture to FPGA where a 2-D array of reconfigurable logic cells are interconnected by a programmable interconnect and surrounded by input/output cells. To satisfy dynamic reconfigurability on the same platform, the context or configuration is stored locally in each cell. This emergence of the dynamically configurable hardware may soon influence algorithm-to-hardware synthesis. Hence, the time to market can be shortened.

DIGITAL COMMUNICATION AND COMMUNICATION NETWORKS

Vijay K. Garg
Department of Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, Illinois, USA

Yih-Chen Wang
Lucent Technologies, Naperville, Illinois, USA

This section is concerned with *digital communication* and *data communication networks*. In the first part of the section we focus on the essentials of digital communication and in the second part we discuss important aspects of data communication networks.

In a digital communication system, the information is processed so that it can be represented by a sequence of discrete messages. The digital source may be the result of sampling and quantizing an analog source, or it may represent a digital source such as the contents of a computer memory. When the source is a binary source, the two possible values 0 and 1 are called bits for binary source.

A digital signal can be processed independently of whether it represents a discrete data source or a digitized analog source. This implies that an essentially unlimited range of signal conditioning and processing options is available to the designer. Depending on the origination and destination of the information being conveyed, it may include *source coding, encryption, pulse shaping* for spectral control, *forward error correction (FEC) coding*, *special modulation* to spread the signal spectrum, and *equalization* to compensate for channel distortion.

In most communication system designs, a general objective is to use as efficiently as possible the resources of bandwidth and transmitted power. Thus, we are interested in both *bandwidth efficiency*, defined as the ratio of data rate to signal bandwidth, and *power efficiency*, characterized by the probability of making a reception error as a function of signal-to-noise ratio (SNR).

Modulation produces a continuous-time waveform suitable for transmission through the communication channel, whereas *demodulation* is to extract the data from the received signal. We discuss various modulation schemes.

Spread spectrum refers to any modulation scheme that produces a spectrum for the transmitted signal much wider than bandwidth of the information to be transmitted independently of the bandwidth of the information-bearing signal. We discuss the *code division multiple access (CDMA)* spread spectrum scheme.

In the second part of the section, our focus is on data communications network usually involving a collection of computers and other devices operating autonomously and interconnected to provide computing or data services. The interconnection of computers and devices can be established with either wired or wireless transmission media. This part starts with an introduction to fundamental concepts of data communications and network architecture. These concepts would help readers to understand how different pieces of system components are working together to build a data communication network. Many data communication and networking terminologies are explained so that they would also help readers to understand advanced networking technologies. Two important network architectures are described. They are Open System Interconnection (OSI) and TCP/IP architecture. OSI is a network reference model that is referenced by all types of networks while the TCP/IP architecture provides a framework where the Internet has been built upon. The network evolution cannot be so successful without the widespread use of local networking. The local network technology including the wireless Local Area Network (WLAN) was then introduced followed by various wireless network access technologies, like FDMA, TDMA, CDMA, and WCDMA. The convergence of varieties of networks under the Internet has begun. One important driver has been the introduction of Session Initiation Protocol (SIP) that could provide a framework for Integrated Multimedia Network Service (IMS). The convergence won't be possible without extensive use of a Softswitch, the creation of ALL-IP architecture and providing broadband access utilizing optical networking technologies.

1

Signal Types, Properties, and Processes

Vijay K. Garg
Department of Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, Illinois, USA

Yih-Chen Wang
Lucent Technologies, Naperville, Illinois, USA

1.1 Signal Types

A **signal** is a function that carries some information. Mathematically, a signal can be classified as deterministic or random. For a **deterministic** signal, there is no uncertainty with respect to its value at any time. Deterministic signals are modeled by explicit mathematical expressions. For a **random** signal, there is some degree of uncertainty before the signal occurs. A probabilistic model is used to characterize a random signal. Noise in a communication system is an example of the random signal.

A signal $x(t)$ is **periodic** in time if there exists a constant $T_0 > 0$, such that:

$$x(t) = x(t + T_0) \text{ for } -\infty < t < \infty, \qquad (1.1)$$

where t is the time.

The smallest value of T_0 that satisfies equation 1.1 is called the **period of $\boldsymbol{x(t)}$**. The period T_0 defines the duration of one complete cycle of $x(t)$. A signal for which there is no such value of T_0 that satisfies equation 1.1 is referred to as a **nonperiodic signal**.

1.2 Energy and Power of a Signal

Instantaneous power of an electrical signal is given as:

$$p(t) = x^2(t), \qquad (1.2)$$

where $x(t)$ is either a voltage or current of the signal.

The energy dissipated during the time interval $(-T/2, T/2)$ by a real signal with instantaneous power given by equation 1.2 is written as:

$$E_x^T = \int_{-T/2}^{T/2} x^2(t)dt. \qquad (1.3)$$

The average power dissipated by the signal during interval T will be as follows:

$$P_x^T = \frac{1}{T} \cdot \int_{-T/2}^{T/2} x^2(t)dt. \qquad (1.4)$$

In analyzing communication signals, it is often desirable to deal with **waveform energy**. We refer to $x(t)$ as an energy signal only if it has nonzero but finite energy $0 < E_x < \infty$ for all time, where:

$$E_x = \lim_{T\to\infty} \int_{-T/2}^{T/2} x^2(t)dt = \int_{-\infty}^{\infty} x^2(t)dt. \qquad (1.5)$$

A signal is defined to be a power signal only if it has finite but nonzero power $0 < P_x < \infty$ for all time, where:

$$P_x = \lim_{T\to\infty} \frac{1}{T} \int_{-T/2}^{T/2} x^2(t)dt. \tag{1.6}$$

1.3 Random Processes

A **random process** $X(t, s)$ can be viewed as a function of two variables: **sample space** s, and **time** t. We show N sample functions of time, $\{X_k(t)\}$ (see Figure 1.1). Each of the sample functions can be considered as the output of a different noise generator. For a fixed sample point s_k, the graph of the function $X(t, s_k)$ versus time t is called a **realization** or **sample function** of the random process. To simplify the notation, we denote this sample function as:

$$X_k(t) = X(t,\ s_k). \tag{1.7}$$

We have an indexed ensemble (family) of random variables $\{X(t, s)\}$, which is called a random process. To simplify the notation, we suppress the s and use $X(t)$ to denote a random process.

A **random process** $X(t)$ is an ensemble of time functions together with a probability rule that assigns a probability to any meaningful event associated with an observation of one sample function of the random process.

1.3.1 Statistical Average of a Random Process

A random process whose distribution functions are continuous can be described statistically with a **probability density function** (pdf). We define the mean of the random process $X(t)$ as:

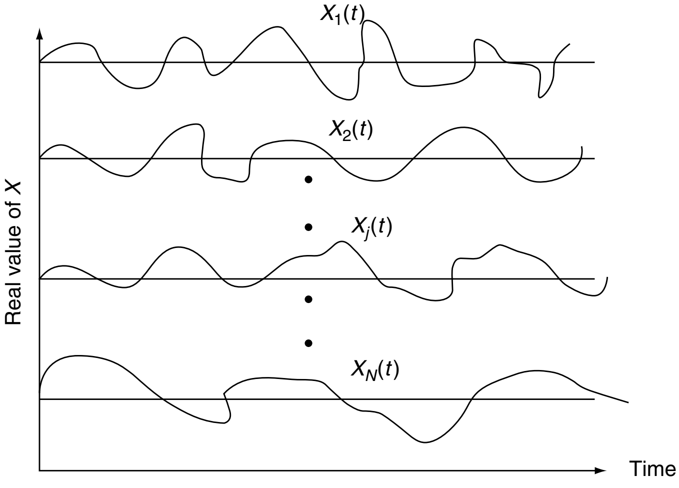

FIGURE 1.1 Random Noise Process

$$E\{X(t_k)\} = \int_{-\infty}^{\infty} (x \cdot px_k)dx = \mu_x(t_k), \tag{1.8}$$

where $X(t_k)$ is the random variable and $px_k(x)$ is the pdf of $X(t_k)$ at time t_k.

We define the autocorrelation function of the random process $X(t)$ to be a function of two variables, t_1 and t_2, as:

$$R_x(t_1,\ t_2) = E\{X(t_1)X(t_2)\}, \tag{1.9}$$

where $X(t_1)$ and $X(t_2)$ are random variables obtained by observing $X(t)$ at times t_1 and t_2, respectively.

The **autocorrelation function** is a measure of the degree to which two time samples of the same random process are related.

1.3.2 Stationary Process

A random process $X(t)$ is said to be **stationary** in the strict sense if none of its statistics is affected by a shift in time origin. A random process is said to be **wide-sense stationary** (WSS) if two of its statistics (mean and autocorrelation function) do not vary with shift in time origin. Therefore, a random process is WSS if:

$$E\{X(t)\} = \mu_x = \text{constant}, \tag{1.10}$$

and

$$R_x(t_1,\ t_2) = R_x(t_1 - t_2) = R_x(\tau), \tag{1.11}$$

where $\tau = t_1 - t_2$.

In a strict sense, *stationary* implies WSS, but WSS does *not* imply stationary.

1.3.3 Properties of an Autocorrelation Function

An **auto correlation function** reads as:

$$R_x(\tau) = E[X(t+\tau)X(t)] \text{ for all } t. \tag{1.12}$$

- The mean square value of a random process can be obtained from $R_x(\tau)$ by substituting $\tau = 0$ in equation 1.12:

$$R_x(0) = E[X^2(t)]. \tag{1.13}$$

- The autocorrelation function $R_x(\tau)$ is an even function of τ; that is:

$$R_x(\tau) = R_x(-\tau). \tag{1.14}$$

- The autocorrelation function $R_x(\tau)$ has its maximum magnitude at $\tau = 0$; that is:

$$|R_x(\tau)| \le R_x(0). \tag{1.15}$$

To prove this property, we consider the non-negative quantity:

$$E[\{X(t+\tau) \pm X(t)\}^2] \geq 0. \tag{1.16}$$

Or we can consider the following:

$$E[X^2(t+\tau)] \pm 2E[X(t+\tau)X(t)] + E[X^2(t)] \geq 0. \tag{1.17}$$

$$2R_x(0) \pm 2R_x(\tau) \geq 0. \tag{1.18}$$

$$-R_x(0) \leq R_x(\tau) \leq R_x(0). \tag{1.19}$$

$$|R_x(\tau)| \leq R_x(0). \tag{1.20}$$

1.3.4 Crosscorrelation Functions

We consider two random processes $X(t)$ and $Y(t)$ with autocorrelation function $R_X(t, u)$ and $R_Y(t, u)$, respectively. The two **crosscorrelation functions** of $X(t)$ and $Y(t)$ are defined as:

$$R_{XY}(t, u) = E[X(t)Y(u)], \tag{1.21}$$

and

$$R_{YX}(t, u) = E[Y(t)X(u)]. \tag{1.22}$$

$$R(t, u) = \begin{bmatrix} R_X(t, u) & R_{XY}(t, u) \\ R_{YX}(t, u) & R_Y(t, u) \end{bmatrix}, \tag{1.23}$$

or

$$R(\tau) = \begin{bmatrix} R_X(\tau) & R_{XY}(\tau) \\ R_{YX}(\tau) & R_Y(\tau) \end{bmatrix}. \tag{1.24}$$

where $\tau = t - u$.

The crosscorrelation function is not generally an even function of τ, and it does not have a maximum value at the origin. However, it obeys a symmetry relationship:

$$R_{XY}(\tau) = R_{YX}(-\tau). \tag{1.25}$$

1.3.5 Ergodic Processes

We consider the sample function $x(t)$ of a stationary process $X(t)$, with observation interval $-T/2 \leq t \leq T/2$. The time average will be as written here:

$$\mu_x(T) = \frac{1}{T}\int_{-T/2}^{T/2} x(t)dt. \tag{1.26}$$

The time average $\mu_x(T)$ is a random variable, and its value depends on the observation interval and which particular sample function of the random process $X(t)$ is selected for use in equation 1.26. Since $X(t)$ is assumed to be stationary, the mean of the time average $\mu_x(T)$ is given as:

$$E[\mu_x(T)] = \frac{1}{T}\int_{-T/2}^{T/2} E[x(t)]dt = \frac{1}{T}\int_{-T/2}^{T/2} \mu_x dt = \mu_x, \tag{1.27}$$

where μ_x is the mean of process $X(t)$.

We say that the process $X(t)$ is **ergodic** in mean if two conditions are satisfied:

(1) The time average $\mu_x(T)$ approaches the ensemble average μ_x in limit as the observation time T goes to infinity:

$$\lim_{T\to\infty} \mu_x(T) = \mu_x. \tag{1.28}$$

(2) The variance of $\mu_x(T)$, treated as a random variable, approaches zero in limit as the observation interval T goes to infinity.

$$\lim_{T\to\infty} var[\mu_x(T)] = 0. \tag{1.29}$$

Likewise, the process $X(t)$ is ergodic in the autocorrelation function if the following two limiting conditions are fulfilled:

$$(1)\ \lim_{T\to\infty} R_x(\tau, T) = R_x(\tau). \tag{1.30}$$

$$(2)\ \lim_{T\to\infty} var[R_x(\tau, T)] = 0. \tag{1.31}$$

Example 1

A random process is described by $x(t) = A\cos(2\pi ft + \phi)$, where ϕ is a random variable uniformly distributed on $(0, 2\pi)$. Find the autocorrelation function and mean square value.

Solutions:

$$\begin{aligned} R_x(t_1, t_2) &= E[A\cos(2\pi ft_1 + \phi)A\cos(2\pi ft_2 + \phi)] \\ &= A^2E\left\{\frac{1}{2}\cos 2\pi f(t_1 - t_2) + \frac{1}{2}\cos[2\pi f(t_1 - t_2) + 2\phi]\right\} \\ &= \frac{A^2}{2}\cos 2\pi f(t_1 - t_2). \end{aligned}$$

$$R_x(\tau) = \frac{A^2}{2}\cos 2\pi f(t_1 - t_2) = \frac{A^2}{2}\cos 2\pi f\tau.$$

$$R_x(0) = \frac{A^2}{2}.$$

1.4 Transmission of a Random Signal Through a Linear Time-Invariant Filter

Figure 1.2 shows a random input signal $X(t)$ passing through a linear time-invariant filter. The output signal $Y(t)$ can be

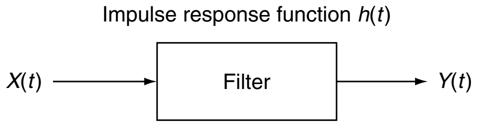

FIGURE 1.2 Random Signal Through a Linear Time-invariant Filter

related to the input through an impulse response function $h(\tau_1)$ as:

$$Y(t) = \int_{-\infty}^{\infty} h(\tau_1)X(t - \tau_1)d\tau_1. \tag{1.32}$$

The mean of $Y(t)$ is as follows:

$$\mu_Y(t) = E[Y(t)] = E\left[\int_{-\infty}^{\infty} h(\tau_1)X(t - \tau_1)d\tau_1\right]. \tag{1.33}$$

The system is stable provided that the expectation $E[X(t)]$ is finite for all t. We may interchange the order of expectation and integration in equation 1.33, and the following results:

$$\mu_Y(t) = \int_{-\infty}^{\infty} h(\tau_1)E[X(t - \tau_1)]d\tau_1 = \int_{-\infty}^{\infty} h(\tau_1)\mu_X(t - \tau_1)d\tau_1. \tag{1.34}$$

For a stationary process $X(t)$, the mean $\mu_X(t)$ is constant μ_X, so we may simplify equation 1.34 as:

$$\mu_Y = \mu_X \cdot \int_{-\infty}^{\infty} h(\tau_1)d\tau_1 = \mu_X \cdot H(0), \tag{1.35}$$

where $H(0)$ is the zero-frequency (dc) response of the system.

Equation 1.35 states that the mean of the random process $Y(t)$ produced at the output of a linear time-invariant system in response to $X(t)$ acting as the input process is equal to the mean of $X(t)$ multiplied by the dc response of the system, which is intuitively satisfying.

The autocorrelation function of the output random process $Y(t)$ is as follows:

$$R_Y(t, u) = E\left\{\left[\int_{-\infty}^{\infty} h(\tau_1)X(t - \tau_1)d\tau_1\right] \cdot \left[\int_{-\infty}^{\infty} h(\tau_2)X(u - \tau_2)d\tau_2\right]\right\}. \tag{1.36}$$

Assuming that mean square $E[X^2(t)]$ is finite for all t and the system is stable, then:

$$R_Y(t, u) = \int_{-\infty}^{\infty} h(\tau_1)d\tau_1 \int_{-\infty}^{\infty} h(\tau_2)d\tau_2 E[X(t - \tau_1) \cdot X(u - \tau_2)].$$
$$R_Y(t, u) = \int_{-\infty}^{\infty} h(\tau_1)d\tau_1 \int_{-\infty}^{\infty} h(\tau_2)d\tau_2 R_X(t - \tau_1, u - \tau_2). \tag{1.37}$$

When the input $X(t)$ is a stationary process, the autocorrelation function of $X(t)$ is only a function of difference between the observation time $t - \tau_1$ and $u - \tau_2$. Thus, with $\tau = t - u$, we have:

$$R_Y(\tau) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} [h(\tau_1)h(\tau_2) \cdot R_X(\tau - \tau_1 + \tau_2)](d\tau_1)(d\tau_2) \tag{1.38}$$

$$R_Y(0) = E[Y^2(t)] = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(\tau_1)h(\tau_2)R_X(\tau_2 - \tau_1)(d\tau_1)(d\tau_2) \tag{1.39}$$

$R_Y(0)$ is a constant.

1.5 Power Spectral Density

Let $H(f)$ denote the frequency response of the system; then:

$$h(\tau_1) = \int_{-\infty}^{\infty} [H(f) \cdot e^{j2\pi f\tau_1}]df. \tag{1.40}$$

The following also applies:

$$\begin{aligned} E[Y^2(t)] &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\left(\left[\int_{-\infty}^{\infty} [H(f) \cdot e^{j2\pi f\tau_1}]df\right] \cdot h(\tau_2)R_X(\tau_2 - \tau_1)\right)(d\tau_1)(d\tau_2) \\ &= \int_{-\infty}^{\infty} H(f)df \int_{-\infty}^{\infty} h(\tau_2)d\tau_2 \int_{-\infty}^{\infty} [R_X(\tau_2 - \tau_1)e^{j2\pi f\tau_1}]d\tau_1. \end{aligned} \tag{1.41}$$

Let $\tau = \tau_2 - \tau_1$, and the following results:

$$\begin{aligned} E[Y^2(t)] &= \int_{-\infty}^{\infty} H(f)df \cdot \int_{-\infty}^{\infty} [h(\tau_2)d\tau_2 e^{j2\pi f\tau_2}]d\tau_2 \cdot \int_{-\infty}^{\infty} [R_X(\tau)e^{-j2\pi f\tau}]d\tau \\ &= \int_{-\infty}^{\infty} |H(f)|^2 df \cdot \int_{-\infty}^{\infty} [R_X(\tau)e^{-j2\pi f\tau}]d\tau, \end{aligned} \tag{1.42}$$

where $|H(f)|$ is the magnitude response of the filter.

We define:

$$S_X(f) = \int_{-\infty}^{\infty} [R_X(\tau)e^{-j2\pi f\tau}]d\tau.$$

$S_X(f)$ is called the **power spectral density** or **power spectrum** of the stationary process $X(t)$,

Now, we can rewrite equation 1.42 as:

$$E[Y^2(t)] = \int_{-\infty}^{\infty} [|H(f)|^2 \cdot S_X(f)]df. \qquad (1.43)$$

The mean square value of a stable linear time-invariant filter is output in response to a stationary process is equal to the integral over all frequencies of the **power spectral density** of the input process multiplied by the squared magnitude response of the filter.

1.5.1 Properties of psd

We use the following definitions:

$$S_X(f) = \int_{-\infty}^{\infty} [R_X(\tau)e^{-j2\pi f\tau}]d\tau,$$

and

$$R_X(\tau) = \int_{-\infty}^{\infty} [S_X(f)e^{j2\pi f\tau}]df.$$

Using above expressions, we derive the following properties:

- **Property 1**
  For $f = 0$, we get:
  $$S_X(0) = \int_{-\infty}^{\infty} R_X(\tau)d\tau. \qquad (1.44)$$
- **Property 2**
  The mean square value of a stationary process equals the total area under the graph of psd:
  $$R_X(0) = E[X^2(t)] = \int_{-\infty}^{\infty} S_X(f)df. \qquad (1.45)$$
- **Property 3**
  The psd of a stationary process is always non-negative:
  $$S_X(f) \geq 0 \text{ for all } f. \qquad (1.46)$$
- **Property 4**
  The psd of a real-valued random process is an even function of frequency:
  $$S_X(-f) = S_X(f). \qquad (1.47)$$
  $$S_X(-f) = \int_{-\infty}^{\infty} [R_X(\tau)e^{j2\pi f\tau}]d\tau.$$
  Because $R_X(\tau)$ is equal to $R_X(-\tau)$, we can write:
  $$S_X(-f) = \int_{-\infty}^{\infty} [R_X(\tau)e^{j2\pi f\tau}]d\tau = S_X(f).$$
- **Property 5**
  The psd, appropriately normalized, has the properties usually associated with a probability density function:
  $$p_x(f) = \frac{S_X(f)}{\int_{-\infty}^{\infty} S_X(f)df} \geq 0 \text{ for all } f. \qquad (1.48)$$

1.6 Relation Between the psd of Input Versus the psd of Output

$$S_Y(f) = \int_{-\infty}^{\infty} [R_Y(\tau)e^{-j2\pi f\tau}]d\tau.$$

$$S_Y(f) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} [h(\tau_1)h(\tau_2)R_X(\tau - \tau_1 + \tau_2)e^{-2j\pi f\tau}](d\tau_1)(d\tau_2)d\tau.$$

Let $\tau_0 = \tau + \tau_1 - \tau_2$:

$$S_Y(f) = H(f)H^*(f)S_X(f) = |H(f)|^2 \cdot S_X(f). \qquad (1.49)$$

The psd of the output process *Y(t)* equals the power spectral density of the input *X(t)* multiplied by the squared magnitude response of the filter.

Example 2

Numbers 1 and 0 are represented by pulse of amplitude A and $-A$ volts, respectively, and duration T sec. The pulses are not synchronized, so the starting time t_d of the first complete pulse for positive time is equally likely to lie anywhere between 0 and T sec (see Figures 1.3 and 1.4). That is, t_d is the sample value of a uniformly distributed random variable T_d with its probability density function defined by:

$$f_{T_d}(t_d) = \begin{cases} \frac{1}{T} & 0 \leq t_d \leq T. \\ 0 & \text{elsewhere.} \end{cases}$$

$$R_X(\tau_1) = \frac{A^2}{T}\int_{-T/2}^{T/2} X(t)X(t - \tau_1)d\tau.$$

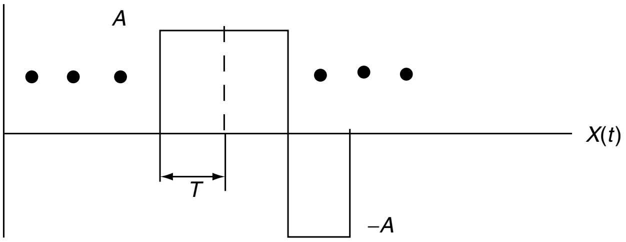

FIGURE 1.3 Pulse of Amplitude *A*

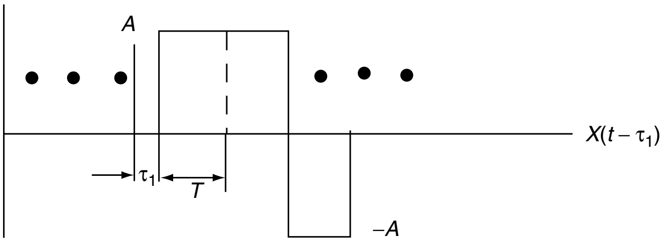

FIGURE 1.4 Shifted Pulse of Amplitude *A*

$$R_X(0) = \text{Total average power.}$$

$$R_X(\tau) = A^2\left(1 - \frac{|\tau|}{T}\right) \quad |\tau| < T$$

$$= 0 \quad |\tau| \geq T.$$

$$S_X(f) = A^2 \cdot T\left(\frac{sin\, \pi f T}{\pi f T}\right)^2.$$

$$\int_{-\infty}^{\infty} S_X(f)df = \text{Total average power}$$

$$S_X(f) = \int_{-T}^{T} A^2\left(1 - \frac{|\tau|}{T}\right)e^{-j2\pi f\tau}d\tau = A^2T\left(\frac{\sin \pi fT}{\pi fT}\right)^2$$

$$= \frac{A^2T^2}{T}\text{sin}c^2(fT) = \frac{\xi_g(f)}{T}.$$

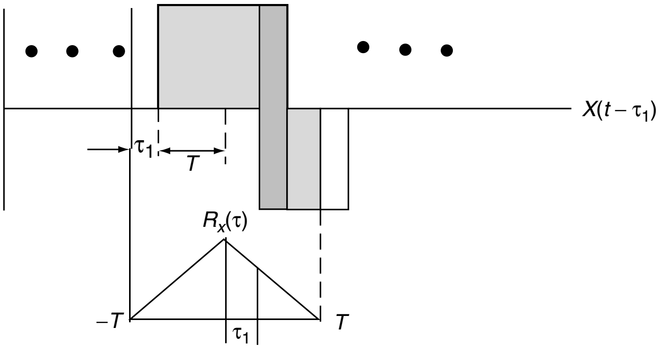

FIGURE 1.5 Autocorrelation Function

These example equations show that for a random binary wave in which binary numbers 1 and 0 are represented by pulse *g(t)* and $-g(t)$, respectively, the psd $S_X(f)$ is equal to the energy spectral density $\xi_g(f)$ of the symbol shaping pulse *g(t)*, divided by the symbol duration *T*. Note the autocorrelation function is shown in Figure 1.5.

Digital Communication System Concepts

Vijay K. Garg
Department of Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, Illinois, USA

Yih-Chen Wang
Lucent Technologies, Naperville, Illinois, USA

2.1 Digital Communication System

Figure 2.1 shows a block diagram of a typical **digital communication system**. We focus primarily on formatting and transmission of baseband signal. Data already in a digital format would bypass the formatting procedure. Textual information is transformed into binary digits by use of a coder. Analog information is formatted using three separate processes:

- Sampling
- Quantization
- Encoding

In all cases, the formatting steps result in a sequence of **binary digits.** These digits are transmitted through a baseband channel, such as a pair of wires or a coaxial cable. However, before we transmit the digits, we must transform the digits into **waveforms** that are compatible with the channel. For baseband channels, compatible waveforms are pulses. The conversion from binary digits to pulse waveform takes place in a **wave encoder** also called a **baseband modulator.** The output of the waveform encoder is typically a sequence of pulses with characteristics that correspond to the binary digits being sent. After transmission through the channel, the received waveforms are detected to produce an estimate of the transmitted digits, and then the final step is (reverse) formatting to recover an estimate of the source information.

2.2 Messages, Characters, and Symbols

When digitally transmitted, the characters are first encoded into a sequence of bits, called a **bit stream** or **baseband signal**. Groups of n bits can be combined to form a finite symbol set or **word** of $M = 2^n$ for such **symbols**. A system using a symbol set size of M is called an ***M*-ary system.** The value of n or M represents an important initial choice in the design of any digital communication system. For $n = 1$, the system is referred to as **binary**, the size of symbol set is $M = 2$, and the modulator uses two different waveforms to represent the binary 1 and the binary 0. In this case, the symbol rate and the bit rate are the same. For $n = 2$, the system is called **quaternary** or **4-ary** ($M = 4$). At each symbol time, the modulator uses one of the four different waveforms to represent the symbol (see Figure 2.2).

2.3 Sampling Process

Analog information must be transformed into a digital format. The process starts with **sampling** the waveform to produce a **discrete pulse-amplitude-modulated waveform** (see Figure 2.3). The **sampling process** is usually described in a time domain. This is an operation that is basic to digital signal processing and digital communication. Using the sampling

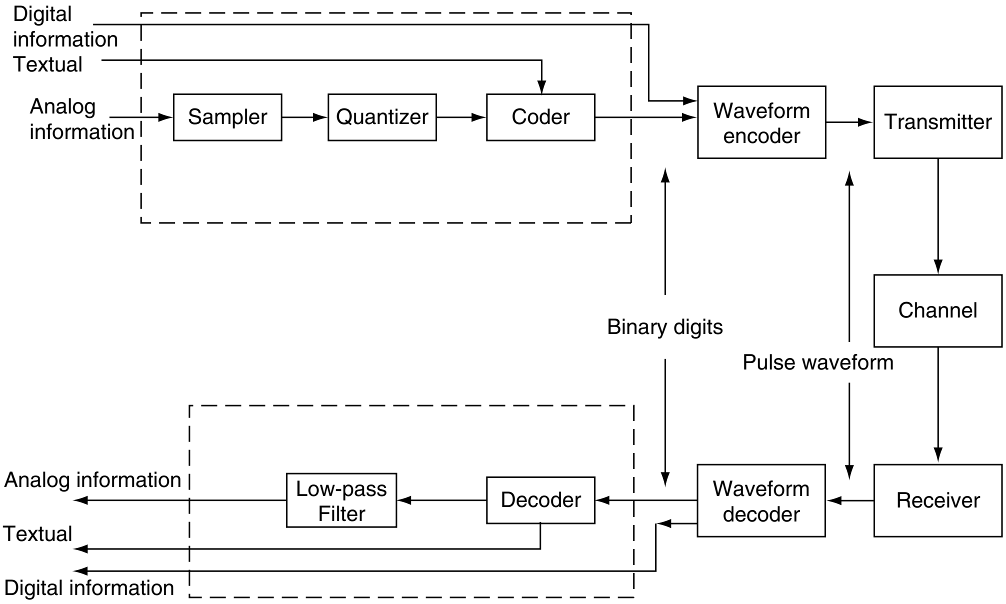

FIGURE 2.1 Block Diagram of a Typical Digital Communication System

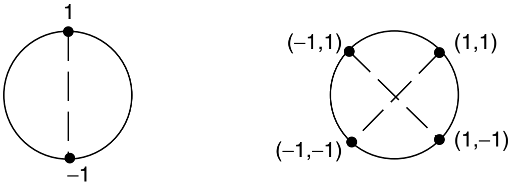

FIGURE 2.2 Binary and Quaternary Systems

process, we convert the analog signal in a corresponding sequence of samples that are usually spaced uniformly in time. The sampling process can be implemented in several ways, the most popular being the **sample-and-hold operation.** In this operation, a switch and storage mechanism (such as a transistor and a capacitor, or shutter and a film strip) form a sequence of samples of the continuous input waveform. The output of the sampling process is called **pulse amplitude modulation (PAM)** because the successive output intervals can be described as a sequence of pulses with amplitudes derived from the input waveform samples. The analog waveform can be approximately retrieved from a PAM waveform by simple low-pass filtering, provided we choose the sampling rate properly. The ideal form of sampling is called **instantaneous sampling.**

We sample the signal *g(t)* instantaneously at a uniform rate of f_s once every T_s sec. Thus, we can write:

$$g_\delta(t) = \sum_{n=-\infty}^{\infty} g(nT_s)\delta(t - nT_s), \qquad (2.1)$$

where $g_\delta(t)$ is the ideal sampled signal and where $\delta(t - nT_s)$ is the delta function positioned at time $t = nT_s$.

A delta function is closely approximated by a rectangular pulse of duration Δt and amplitude $g(nT_s)/\Delta t$; the smaller we make Δt, the better will be the approximation:

$$g_\delta(t) = f_s \sum_{m=-\infty}^{\infty} G(f - mf_s), \qquad (2.2)$$

where $G(f)$ is the Fourier transform of the original signal $g(t)$ and f_s is sampling rate.

Equation 2.2 states that the process of uniformly sampling a continuous-time signal of finite energy results in a periodic spectrum with a period equal to the sampling rate.

Taking the Fourier transform of both side, of Equation 2.1 and noting that the Fourier transform of the delta function $\delta(t - nT_s)$ is equal to $e^{-j2\pi nfT_s}$:

$$G_\delta(f) = \sum_{n=-\infty}^{\infty} g(nT_s)e^{-j2\pi nfT_s}. \qquad (2.3)$$

Equation 2.3 is called the **discrete-time Fourier transform.** It is the complex Fourier series representation of the periodic frequency function $G_\delta(t)$, with the sequence of samples $g(nT_s)$ defining the coefficients of the expansion.

We consider any continuous-time signal $g(t)$ of finite energy and infinite duration. The signal is strictly band-limited with no frequency component higher than W Hz. This implies that the Fourier transform $G(f)$ of the signal $g(t)$ has the property that $G(f)$ is zero for $|f| \geq W$. If we choose the

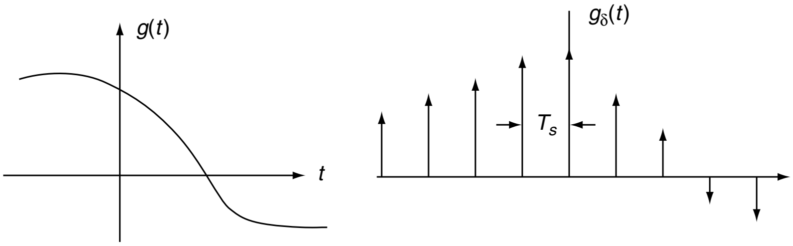

FIGURE 2.3 Sampling Process

sampling period $T_s = 1/2W$, then the corresponding spectrum is given as:

$$G_\delta(f) = \sum_{n=-\infty}^{\infty} g\left(\frac{n}{2W}\right) e^{-\frac{j\pi nf}{W}} = f_s G(f) + f_s \sum_{m=-\infty,\ m\neq 0}^{\infty} G(f - mf_s) \tag{2.4}$$

Consider the following two conditions:

(**1**) $G(f) = 0$ for $|f| \geq W$.
(**2**) $f_s = 2W$.

We find from equation 2.4 by applying these conditions,

$$\begin{aligned} G(f) &= \frac{1}{2W} G_\delta(f) \quad - W < f < W. \\ \therefore G(f) &= \frac{1}{2W} \sum_{n=-\infty}^{\infty} g\left(\frac{n}{2W}\right) e^{-\left(\frac{j\pi nf}{W}\right)} \quad - W < f < W. \end{aligned} \tag{2.5}$$

Thus, if the sample value $g(n/2W)$ of a signal $g(t)$ is specified for all n, then the Fourier transform $G(f)$ of the signal is uniquely determined by using the discrete-time Fourier transform of equation 2.5. Because $g(t)$ is related to $G(f)$ by the inverse Fourier transform, it follows that the signal $g(t)$ is itself uniquely determined by the sample values $g(n/2W)$ for $-\infty < n < \infty$. In other words, the sequence $\{g(n/2W)\}$ has all the information contained in $g(t)$.

We state the sampling theorem for band-limited signals of finite energy in two parts that apply to the transmitter and receiver of a pulse modulation system, respectively.

(**1**) A band-limited signal of finite energy with no frequency components higher than W Hz is completely described by specifying the values of signals at instants of time separated by $1/2\ W$ sec.

(**2**) A band-limited signal of finite energy with no frequency components higher than W Hz may be completely recovered from a knowledge of its samples taken at the rate of $2\ W$ samples/sec.

This is also known as the **uniform sampling theorem**. The sampling rate of $2\ W$ samples per second for a signal bandwidth W Hz is called the **Nyquist rate** and $1/2\ W$ sec is called the **Nyquist interval**.

We discuss the sampling theorem by assuming that signal $g(t)$ is strictly band-limited. In practice, however, an information-bearing signal is not strictly band-limited, with the result that some degree of under sampling is encountered. Consequently, some aliasing is produced by the sampling process. Aliasing refers to the phenomenon of a high-frequency component in the spectrum of the signal seemingly taking on the identity of a lower frequency in the spectrum of its sampled version.

2.4 Aliasing

Figure 2.4 shows the part of the spectrum that is aliased due to **under sampling**. The aliased spectral components represent ambiguous data that can be retrieved only under special conditions. In general, the ambiguity is not resolved and ambiguous data appear in the frequency band between $(f_s - f_m)$ and f_m.

In Figure 2.5, we show a higher sampling rate f_s' to eliminate the aliasing by separating the spectral replicas.

Figures 2.6 and 2.7 show two ways to eliminate aliasing using antialiasing filters. The analog signal is **prefiltered** so that the new maximum frequency f_m is less than or equal to $f_s/2$. Thus, there are no aliasing components seen in Figure 2.6 because $f_s > 2f_m'$. Eliminating aliasing terms prior to sampling is a good engineering practice. When the signal structure is

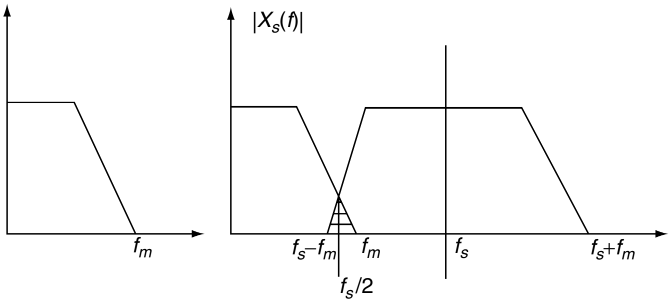

FIGURE 2.4 Sampled Signal Spectrum

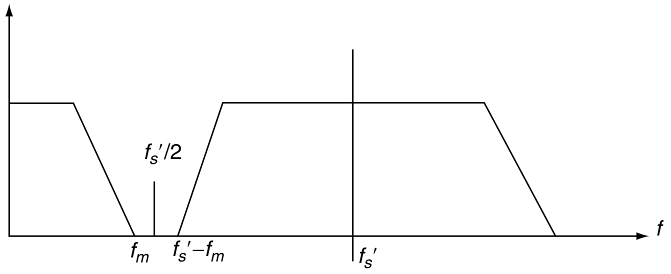

FIGURE 2.5 Higher Sampling Rate to Eliminate Aliasing

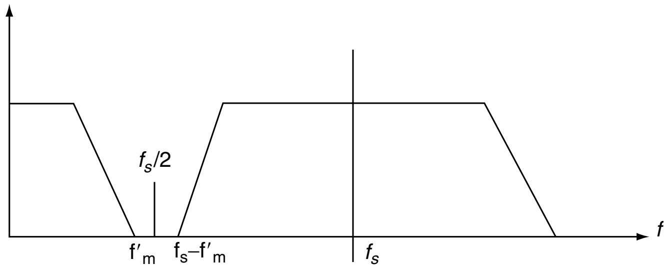

FIGURE 2.6 Prefiltering to Eliminate Aliasing

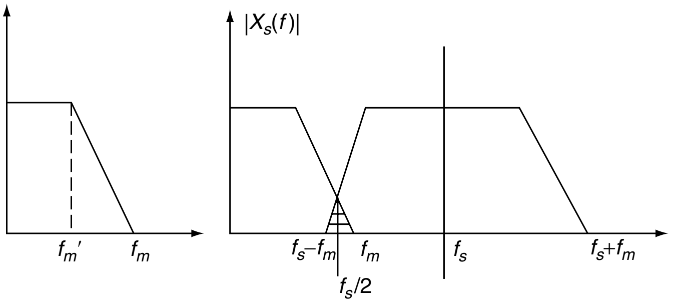

FIGURE 2.7 Postfiltering to Eliminate Aliasing Portion of the Spectrum

well known, the aliased terms can be eliminated after sampling with a linear pass filter (LPF) operating on the sampled data. In this case, the aliased components are removed by **postfiltering** after sampling. The filter cutoff frequency $f_m^{'}$ removes the aliased components; $f_m^{'}$ needs to be less than $(f_s - f_m)$. It should be noted that filtering techniques for eliminating the aliased portion of the spectrum will result in a loss of some signal information. For this reason, the sample rate, cutoff bandwidth, and filter type selected for a particular signal bandwidth are all interrelated.

Realizable filters require a nonzero bandwidth for the transition between the passband and the required out-of-band attenuation. This is called the **transition bandwidth**. To minimize the system sample rate, we desire that the **antialiasing** filter has a small transition bandwidth. Filter complexity and cost rise sharply with narrower transition bandwidth, so a trade-off is needed between the cost of a small transition bandwidth and costs of the higher sampling rate, which are those of more storage and higher transition rates.

In many systems, the answer has been to make the transition bandwidth 10 and 20% of the signal bandwidth. If we account for the 20% transition bandwidth of the antialiasing filter, we have an engineering version of Nyquist sampling rate: $f_s \geq 2.2 f_m$.

Example 3

We want to produce a high-quality digitalization of a 20-kHz bandwidth music signal. The sampling rate of greater than or equal to 22 ksps should be used.

The sampling rate for compact disc digital audio player is 44.1 ksps, and the standard sampling rate for studio-quality audio player is 48 ksps.

2.5 Quantization

In Figure 2.8, each pulse is expressed as a level from a finite number of predetermined levels; each such level can be represented by a symbol from a finite alphabet. The pulses in Figure 2.8 are called **quantized samples**. When the sample values are quantized to a finite set, this format can interface with a digital system. After quantization, the analog waveform can still be recovered but not precisely; improved reconstruction fidelity of the analog waveform can be achieved by increasing the number of quantization levels (requiring increased system bandwidth).

2.6 Pulse Amplitude Modulation

There are two operations involved in the generation of the pulse amplitude modulation (PAM) signal:

(**1**) Instantaneous sampling of the message signal $m(t)$ every T_s sec, where $f_s = 1/T_s$ is selected according to the sampling theorem
(**2**) Lengthening the duration of each sample obtained to some constant value T

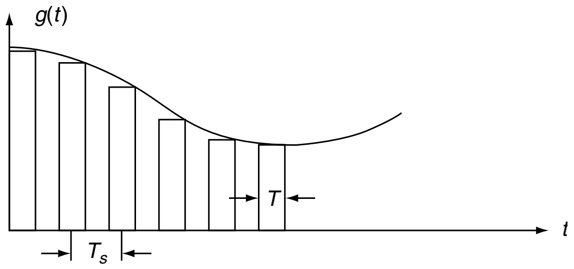

FIGURE 2.8 Flattop Quantization

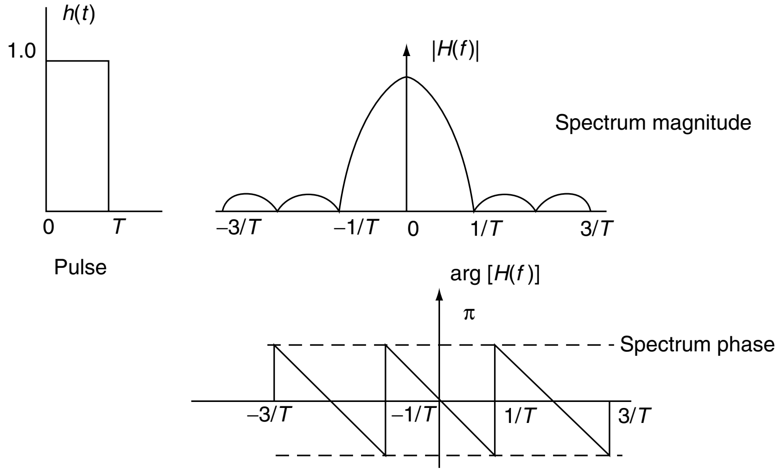

FIGURE 2.9 Rectangular Pulse and Its Spectrum

These two operations are jointly referred to as sample and hold. One important reason for intentionally lengthening the duration of each sample is to avoid the use of an excessive channel bandwidth because bandwidth is inversely proportional to pulse duration.

The Fourier transform of the rectangular pulse $h(t)$ is given as (see Figure 2.9):

$$H(f) = T\mathrm{sinc}(fT)e^{-j2\pi fT}. \tag{2.6}$$

We observe that by using flattop samples to generate a PAM signal, we introduce **amplitude distortion** as well as a **delay** of $T/2$. This effect is similar to the variation in transmission frequency that is caused by the finite size of the scanning aperture in television. The distortion caused by the use of PAM to transmit an analog signal is called the **aperture affect**. This distortion may be corrected by using an **equalizer** (see Figure 2.10). The equalizer has the effect of decreasing the in-band loss of the filter as the frequency increases in such a manner to compensate for the aperture effect. For $T/T_s \leq 0.1$, the amplitude distortion is less than 0.5%, in which case the need of equalization may be omitted altogether.

Example 4

Sampled uniformly and then time-division multiplexed are 24 voice signals. The sampling operation involved flattop samples with 1 μs duration. The multiplexing operation includes provision for synchronization by adding an extra pulse of sufficient amplitude and also 1 μs duration. The highest frequency component of each voice signal is 3.4 kHz.

(1) Assuming a sampling rate of 8 kHz, calculate the spacing between successive pulses of the multiplexed signal.
(2) Repeat your calculations using Nyquist rate sampling.

$$T_s = \frac{10^6}{8000} = 125\ \mu\text{s}.$$

For 25 channels (24 voice channels +1 sync), time allocated for each channel is $125/25 = 5\ \mu$s. Since the pulse duration is 1 μs, the time between pulses is $(5 - 1) = 4\ \mu$s.

The Nyquist rate is 7.48 Hz (2.2×3.4).

In addition:

$$T_s = \frac{10^6}{7480} = 134\ \mu\text{s}.$$

$$T_c = \frac{134}{25} = 5.36\ \mu\text{s}.$$

The time between pulses is 4.36 μs.

2.7 Sources of Corruption

The sources of corruption include sampling and quantization effects as well as channel effects, as described in the following bulleted list.

- **Quantization noise:** The distortion inherent in quantization is a roundoff or truncation error. The process of

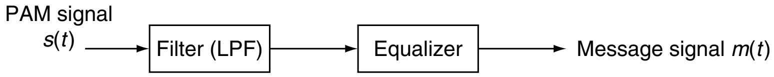

FIGURE 2.10 An Equalizer Application

encoding the PAM waveform into a quantized waveform involves discarding some of the original analog information. This distortion is called quantization noise; the amount of such noise is inversely proportional to the number of levels used in the quantization process.

- **Quantizer saturation:** The quantizer allocates L levels to the task of approximating the continuous range of inputs with a finite set of outputs (see Figure 2.11). The range of inputs for which the difference between the input and output is small is called the **operating range** of the converter. If the input exceeds this range, the difference between the input and output becomes large, and we say that the converter is operating in **saturation**. Saturation errors are more objectionable than quantizing noise. Generally, saturation is avoided by use of automatic gain control (AGC), which effectively extends the operating range of the converter.
- **Timing jitter:** If there is a slight jitter in the position of the sample, the sampling is no longer uniform. The effect of the jitter is equivalent to frequency modulation (FM) of the baseband signal. If the jitter is random, a low-level wideband spectral contribution is induced whose properties are very close to those of the quantizing noise. Timing jitter can be controlled with very good power supply isolation and stable clock reference.
- **Channel noise:** Thermal noise, interference from other users, and interference from circuit switching transients can cause errors in detecting the pulses carrying the digitized samples. Channel-induced errors can degrade the reconstructed signal quality quite quickly. The rapid degradation of the output signal quality with channel-induced errors is called a **threshold effect**.
- **Intersymbol interference:** The channel is always band-limited. A band-limited channel spreads a pulse waveform passing through it. When the channel bandwidth is much greater than pulse bandwidth, the spreading of the pulse will be slight. When the channel bandwidth is close to the signal bandwidth, the spreading will exceed a symbol duration and cause signal pulses to overlap. This overlapping is called **inter-symbol interference** ISI), ISI causes system degradation (higher error rates); it is a particularly insidious form of interference because raising the signal power to overcome interference will not improve the error performance:

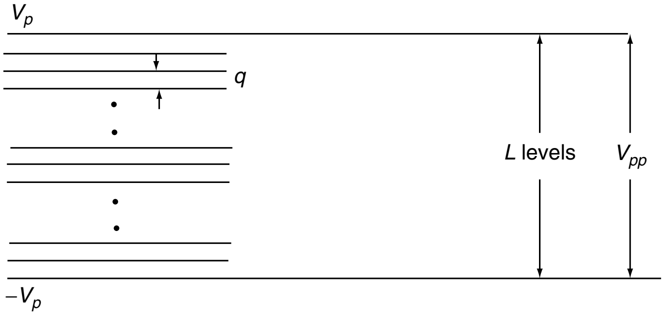

FIGURE 2.11 Uniform Quantization

$$\sigma^2 = \int_{-q/2}^{q/2} e^2 p(e)de = \int_{-q/2}^{q/2} e^2 \frac{1}{q} de = \frac{q^2}{12}$$

$$= \text{average quantization noise power.}$$

$$V_p^2 = \left(\frac{V_{pp}}{2}\right)^2 = \left(\frac{Lq}{2}\right)^2 = \frac{L^2q^2}{4}. \quad (2.7)$$

$$\left(\frac{S}{N}\right)_q = \frac{(L^2q^2)/4}{q^2/12} = 3L^2. \quad (2.8)$$

In the limit as $L \to \infty$, the signal approaches the PAM format (with no quantization error) and signal-to-quantization noise ratio is infinite. In other words, with an infinite number of quantization levels, there is zero quantization error.

Typically $L = 2^R$, $R = Log_2 L$, and $q = \frac{2V_p}{L} = (2V_p)/2^R$.

$$\therefore \sigma^2 = \left(\frac{2V_p}{2^R}\right)^2 /12 = \frac{1}{3}V_p^2 2^{-2R}.$$

Let P denote the average power of the message signal $m(t)$, and then:

$$(SNR)_o = \frac{P}{\sigma^2} = \left(\frac{3P}{V_p^2}\right)2^{2R}. \quad (2.9)$$

The output SNR of the quantizer increases exponentially with increasing number of bits per sample, R. An increase in R requires a proportionate increase in the channel bandwidth.

Example 5

We consider a full-load sinusodial modulating signal of amplitude A that uses all representation levels provided. The average signal power is (assuming a load of 1 Ω):

The equations are written and solved as follows:

$$P = \frac{A^2}{2}.$$

$$\sigma^2 = \frac{1}{3}A^2 2^{-2R}.$$

$$(SNR)_o = \frac{\frac{A^2}{2}}{(1/3A^2 2^{-2R})} = \frac{3}{2}(2^{2R}) = 1.8 + 6R \text{ dB}.$$

L	***R* [bits]**	**SNR [decibels]**
32	5	31.8
64	6	37.8
128	7	43.8
256	8	49.8

2.8 Voice Communication

For most **voice communication**, very low speech volumes predominate; about 50% of the time, the voltage characterizing detected speech energy is less than 1/4 of the root-mean-square (rms) value. Large amplitude values are relatively rare; only 15% of the time does the voltage exceed the rms value. The quantization noise depends on the step size. When the steps are uniform in size, the quantization is called the uniform **quantization**. Such a system would be wasteful for speech signals; many of the quantizing steps would rarely be used. In a system that uses equally spaced quantization levels, the quantization noise is same for all signal magnitudes. Thus, with uniform quantization, the signal-to-noise ratio (SNR) is worse for low-level signals than for high-level signals. Non-**uniform quantization** can provide fine quantization of the weak signals and coarse quantization of the strong signals. Thus, in the case of nonuniform quantization, quantization noise can be made proportional to signal size. Improving the overall SNR by reducing the noise for predominant weak signals, at the expense of an increase in noise, can be done for rarely occurring signals. The nonuniform quantization can be used to make the SNR a constant for all signals within the input range. For voice, the signal dynamic range is 40 dB.

Nonuniform quantization is achieved by first distorting the original signal with logarithmic compression characteristics and then using a uniform quantizer. For small magnitude signals, the compression characteristics have a much steeper slope than the slope for large magnitude signals. Thus, a given signal change at small magnitudes will carry the uniform quantizer through more steps than the same change at large magnitudes. The compression characteristic effectively changes the distribution of the input signal magnitude so there is no preponderance of low-magnitude signals at the output of the compressor. After compression, the distorted signal is used as an input to a uniform quantizer. At the receiver, an inverse compression characteristic, called expansion, is used so that the overall transmission is not distorted. The whole process (compression and expansion) is called **companding**.

- The **μ**-Law, used in North America, is as follows:

$$\frac{y}{y_{\max}} = \frac{\ln\left[1 + |x|/x_{\max}\right]}{\ln\left[1 + \mu\right]} \operatorname{sgn} x. \tag{2.10}$$

$$\operatorname{sgn} x = 1,\ x \geq 0.$$

$$\operatorname{sgn} x = -1,\ x < 0.$$

In equation 2.10, μ is constant, x and y are the input and output voltages, $\mu = 0$ represents uniform quantization, and $\mu = 255$ is the standard value used in North America.

- **A-Law**, used in Europe, is as follows:

$$\frac{y}{y_{\max}} = \frac{A(|x|/x_{\max})}{1 + \ln A} \operatorname{sgn} x, \quad 0 < \frac{|x|}{x_{\max}} \leq \frac{1}{A}. \tag{2.11a}$$

$$= \frac{1 + \ln\left(|x|/x_{\max}\right)}{1 + \ln A} \operatorname{sgn} x, \quad \frac{1}{A} < \frac{|x|}{x_{\max}} < 1. \tag{2.11b}$$

The A is the positive constant, and $A = 87.6$ is the standard value used in Europe.

Example 6

The information in an analog waveform with maximum frequency $f_m = 3\,\text{kHz}$ is transmitted over an M-ary PCM system, where the number of pulse levels is $M = 32$. The quantization distortion is specified not to exceed ± 1% of the peak-to-peak analog signal.

(1) What is minimum number of bits/sample or bits/PCM word that should be used?
(2) What is minimum sampling rate, and what is the resulting transmission rate?
(3) What is the PCM pulse or symbol transmission rate?

Solutions:

$$|e| \leq pV_{pp},$$

where p is fraction of the peak-to-peak analog voltage.

- $|e_{\max}| = \dfrac{V_{pp}}{2L},$

$$\therefore \left(\frac{V_{pp}}{2L} \leq pV_{pp}\right).$$

- $2^R = L \geq \dfrac{1}{2p}.$

$$2^R \geq \frac{1}{2 \times 0.01} = 50,$$

$$\therefore (R \geq 5.64) \quad \text{use } R = 6.$$

- $f_s = 2f_m = 6000$ samples/sec.

$$f_s = 6 \times 6000 = 36\,\text{kbps}.$$

- $M = 2^b = 32.$

$$b = 5\,\text{bits/symbol}.$$

$$R_s = \frac{36000}{5} = 7200\ \text{symbols/sec}.$$

2.9 Encoding

Codeword timeslots are shown in Figure 2.12 in which the codeword is 4-bit representation of each quantized sample. In the bit duration portion of Figure 2.12, each binary 1 is represented by a pulse, and each binary 0 is represented by the absence of a pulse.

If we increase the pulse width to the maximum possible (equal to bit duration, t), we have the waveform shown in the +V and −V bottom portion of Figure 2.12. Rather than describe this waveform as a sequence of present or absent pulses, we can describe it as a sequence of transitions between two levels. When the waveform occupies the upper voltage level, it represents a binary 1; when it occupies the lower voltage, it represents a binary 0.

We need an **encoding** process to translate the discrete sets of sample value to a more appropriate form of signal. Any plan to represent each of the discrete sets of value as a particular arrangement of discrete events is called a **code**. One of the discrete events in a code is called a **code symbol** or **symbol**. A particular arrangement of symbols used in a code to represent a single value of the discrete set is called a **codeword** or **character**.

Most commonly used pulse code modulation (PCM) waveforms are classified into the following groups:

- Nonreturn to zero (NRZ)
- Return to zero (RZ)
- Phase-encoded
- Multilevel binary

The reason for the large selection relates to the differences in performance that characterize each waveform. In selecting a coding scheme for a particular application, some of the parameters worth examining are:

- The dc component
- Self-clocking
- Error detection
- Bandwidth compression
- Noise immunity
- Biphase level (Manchester code)

2.9.1 Encoding Schemes

The following encoding schemes are often used.

(1) **Nonreturn to Zero-Level (NRZ-L)**
- 1 = high level
- 0 = low level

(2) **Nonreturn to Zero-Mark (NRZ-M)**
- 1 = transition at the beginning of interval
- 0 = no transition

(3) **Nonreturn to Zero-Space (NRZ-S)**
- 1 = no transition
- 0 = transition at the beginning of the interval

(4) **Return to Zero (RZ)**
- 1 = pulse in first half of bit interval
- 0 = no pulse

(5) **Biphase-level (Manchester)**
- 1 = transition from high to low in middle of interval
- 0 = transition from low to high in middle of interval

(6) **Biphase–Mark**
- Always a transition at the beginning of interval
- 1 = transition in middle of interval
- 0 = no transition in middle of interval

(7) **Biphase–space**
- Always a transition at the beginning of interval
- 1 = no transition in middle of interval
- 0 = transition in middle of interval

(8) **Differential Manchester**
- Always a transition in middle of interval
- 1 = no transition at the beginning of interval
- 0 = transition at beginning of interval

(9) **Delay modulation (Miller)**
- 1 = transition in middle of interval
- 0 = no transition if followed by 1, or transition at end of interval if followed by 0

(10) **Bipolar**
- 1 = pulse in first half of interval, alternating polarity from pulse to pulse
- 0 = no pulse

Transmission of Digital Signals

Vijay K. Garg
Department of Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, Illinois, USA

Yih-Chen Wang
Lucent Technologies, Naperville, Illinois, USA

3.1 Transmission of Digital Data

We now focus on the transmission of digital data over a baseband channel. Digital data have a broad spectrum with a significant low-frequency content. Baseband transmission of digital data requires the use of a low-pass channel with a bandwidth large enough to include the essential frequency content of the data stream. The channel is dispersive in that its frequency response deviates from that of an ideal low-pass filter. The result of data transmission over such a channel is that each received pulse is affected somewhat by adjacent pulses, thereby giving rise to intersymbol interference (ISI). ISI is a major source of bit errors in the reconstructed data stream at the receiver output. Another source of bit errors in a baseband data transmission system is the ubiquitous channel noise. Noise and ISI arise in the system simultaneously.

3.2 Detection of Binary Signals in Gaussian Noise

After the digital symbols are converted into electrical waveforms, they are transmitted through a channel. During a given signaling interval, T, a binary system transmits one of two waveforms, denoted $s_1(t)$ and $s_2(t)$. The signal, $r(t)$, received by the receiver is represented by these two equations:

$$r(t) = s_1(t) + n(t) \text{ for a binary 1} \quad 0 \leq t \leq T. \tag{3.1}$$

$$r(t) = s_2(t) + n(t) \text{ for a binary 0} \quad 0 \leq t \leq T. \tag{3.2}$$

In equations 3.1 and 3.2, $n(t)$ is a zero-mean additive Gaussian white noise, and T is the symbol duration.

We assume that the receiver has knowledge of the starting and ending times of each transmitted pulse; in other words, the receiver has prior knowledge of the pulse shape but not its polarity. Given the noisy signal, the receiver has to make a decision in each signaling interval as to whether the transmitted symbol is 1 or 0.

We refer to Figure 3.1 **step 1** involves reducing the received waveform to a single number $z(t = T)$. This operation can be performed by a linear filter followed by a sampler or optimally by a matched filter. The initial conditions of the filter are set to zero just before the arrival of each new symbol. At the end of a symbol duration T, the output of step 1 yields the sample $z(T)$:

$$z(T) = a_i(T) + n_0(T) \quad i = 1, 2, \tag{3.3}$$

where $a_i(T)$ is the signal component of $z(T)$ and where $n_0(T)$ is the noise component.

Since noise component $n_0(t)$ is a zero-mean Gaussian random variable, $z(T)$ is also a Gaussian random variable with a mean of either a_1 or a_2 depending on whether a binary 1 or 0 was sent. The probability density function (pdf) of the Gaussian random noise, n_0, can be expressed as:

$$p(n_0) = \frac{1}{\sigma_0\sqrt{2\pi}} e^{-1/2(n_0/\sigma_0)^2}, \tag{3.4}$$

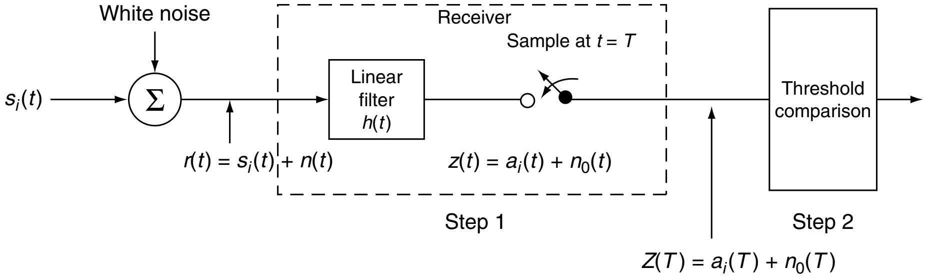

FIGURE 3.1 Detection of Binary Signals in Gaussian Noise

where, σ_0^2 is the noise variance.

The conditional pdfs, p(z s_1) and p(z s_2), can be given as:

$$p(z|s_1) = \frac{1}{\sigma_0\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{z-a_1}{\sigma_0}\right)^2}. \tag{3.5}$$

$$p(z|s_2) = \frac{1}{\sigma_0\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{z-a_2}{\sigma_0}\right)^2}. \tag{3.6}$$

These conditional pdfs are shown in Figure 3.2. The rightmost conditional pdf p(z|s_1), shows the probability density of the detector output, $z(T)$, given that $s_1(t)$ was transmitted. Similarly, the leftmost conditional pdf p(z|s_2), shows the probability density of the detector output $z(T)$, given $s_2(t)$ was transmitted.

Step 2 in signal detection process consists of comparing the $z(T)$ to a threshold level λ in block 2 of Figure 3.1 to estimate which signal, $s_1(t)$ or $s_2(t)$, has been transmitted. The filtering operation in block 1 does not depend on the decision criterion in block 2. Thus, the choice of how best to implement block 1 can be independent of the particular decision choice of the threshold setting, λ. After a received waveform, $r(t)$, is transformed to $z(T)$, the actual shape of the waveform is no longer important. The signal energy (not its shape) is the important parameter in the detection process. Thus, the detection analysis for **baseband signals** is the same as that for **bandpass signals**. The final step in block II is to make the detection.

A popular criterion for choosing the threshold level λ for the binary decision is based on minimizing the probability of error. It can be shown that if $p(s_1) = p(s_2)$, and if the likelihoods $p(z|s_i)$ $(i = 1, 2)$ are symmetrical, the optimum value of λ is given as:

$$\lambda_0 = \frac{a_1 + a_2}{2}, \tag{3.7}$$

where a_1 is the signal component of $z(T)$ when $s_1(t)$ is transmitted and where a_2 is the signal component of $z(T)$ when $s_2(t)$ is transmitted.

The threshold level, λ_0, represented by $(a_1 + a_2)/2$, is the optimum threshold to minimize the probability of making an incorrect decision for this important special case. The strategy is known as the **minimum error criterion**.

3.3 Error Probability

For the binary example in Figure 3.2, there are two ways in which errors can occur. An error, e, will occur when $s_1(t)$ is sent, and the channel noise results in the receiver output signal $z(T)$ being less than λ. The probability of such an occurrence is given as:

$$P(e|s_1) = \int_{-\infty}^{\lambda} p(z|s_1)dz. \tag{3.8}$$

Similarly, an error occurs when $s_2(t)$ is sent, and the channel noise results in the receiver output signal $z(T)$ being greater than λ. The probability of such an occurrence is given as:

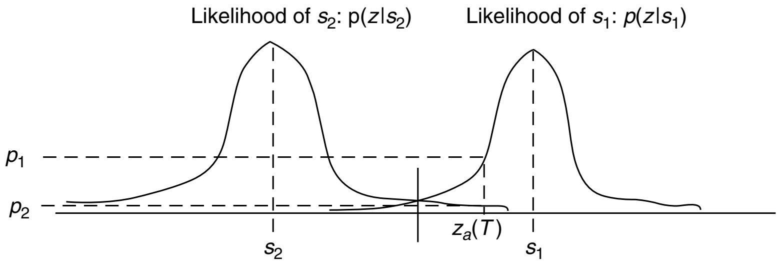

FIGURE 3.2 Conditional Probability Density Functions

$$P(e|s_2) = \int_{\lambda}^{\infty} p(z|s_2)dz. \tag{3.9}$$

Let α and $1-\alpha$ denote the a prior probabilities of transmitting 0 and 1, respectively, and then the average probability of symbol error P_e in the receiver is given by:

$$P_e = \alpha P(e|s_1) + (1-\alpha)P(e|s_2). \tag{3.10}$$

For the special case when 1 and 0 are equiprobable, we have $\alpha = 1/2$:

$$P_e = \frac{1}{2}[P(e|s_1) + P(e|s_2)]. \tag{3.11}$$

Because of the symmetry of pdf:

$$P_e = P(e|s_1) = P(e|s_2). \tag{3.12}$$

The average probability of symbol error with optimum λ_0:

$$P_e = \int_{(a_1+a_2)/2}^{\infty} \frac{1}{\sigma_0\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{z-a_2}{\sigma_0}\right)^2} \tag{3.13}$$

Let:

$$u = (z-a_2)/\sigma_0,$$
$$\therefore \sigma_0 du = dz.$$
$$\therefore P_e = \int_{(a_1-a_2)/2\sigma_0}^{\infty} \frac{1}{\sqrt{2\pi}} e^{-u^2/2} du = Q\left(\frac{a_1-a_2}{2\sigma_0}\right). \tag{3.14}$$

In equation 3.14 (a_1-a_2) is the difference of signal components at the filter output at time $t=T$, and the square of this difference signal is the instantaneous power of difference signal. The $Q(x)$ is the complementary error function, and it is defined as:

$$Q(x) = \frac{1}{\sqrt{2\pi}} \int_{x}^{\infty} e^{-u^2/2} du \approx \frac{1}{x\sqrt{2\pi}} e^{-x^2/2}. \tag{3.15}$$

$$\left(\frac{S}{N}\right) = \frac{(a_1-a_2)^2}{\sigma_0^2} = \frac{E_d}{\left(\frac{N_0}{2}\right)}. \tag{3.16}$$

The E_d is the energy of a difference signal at the filter input:

$$E_d = \int_{0}^{T} [s_1(t) - s_2(t)]^2 dt, \tag{3.17}$$

$$\therefore P_e = Q\left(\sqrt{\frac{E_d}{2N_0}}\right). \tag{3.18}$$

3.4 The Matched Filter

A **matched filter** is a linear filter designed to provide the maximum SNR at its output for a given transmitted symbol waveform. We refer to Figure 3.1 for the ratio of instantaneous signal power to average noise power at time $t = T$; out of the receiver block 1, the following results:

$$\left(\frac{S}{N}\right)_T = \frac{a_i^2}{\sigma_0^2}. \tag{3.19}$$

We want to find the filter transfer function $H_0(f)$ to *maximize* equation 3.19. We express the signal, $a(t)$, at the filter output in terms of the filter transfer function, $H(f)$. The Fourier transform of the input signal will be:

$$a(t) = \int_{-\infty}^{\infty} H(f)S(f)e^{j2\pi ft} dj, \tag{3.20}$$

where $S(f)$ is the Fourier transform of the input signal $s(t)$. With power spectral density of the input noise equal to $N_0/2$, we can express the output noise power as:

$$\sigma_0^2 = \frac{N_0}{2} \int_{-\infty}^{\infty} |H(f)|^2 df. \tag{3.21}$$

Using equations 3.20 and 3.21, we rewrite equation 3.19 as:

$$\left(\frac{S}{N}\right)_T = \frac{\left|\int_{-\infty}^{\infty} H(f)S(f)e^{j2\pi fT} df\right|^2}{N_0/2 \int_{-\infty}^{\infty} |H(f)|^2 df}. \tag{3.22}$$

We must find that value of $H(f) = H_0(f)$ for which the maximum $(S/N)_T$ is achieved, by using **Schwarz's inequality**. One form of the inequality can be stated as:

$$\left|\int_{-\infty}^{\infty} f_1(x)f_2(x)dx\right|^2 \leq \int_{-\infty}^{\infty} |f_1(x)|^2 dx \int_{-\infty}^{\infty} |f_2(x)|^2 d.$$

The equality holds if $f_1(x) = k_2(x)^*$, where k is an arbitrary constant and * indicates complex conjugate. If we identify $H(f)$ with $f_1(x)$ and $S(f)e^{j2\pi ft}$ with $f_2(x)$, we can write:

$$\left|\int_{-\infty}^{\infty} H(f)S(f)e^{j2\pi fT} df\right|^2 \leq \int_{-\infty}^{\infty} |H(f)|^2 df \int_{-\infty}^{\infty} |S(f)|^2 d(f). \tag{3.23}$$

Using equation 3.23 in equation 3.22, we get:

$$\left(\frac{S}{N}\right)_T \leq \frac{2}{N_0}\int_{-\infty}^{\infty}|S(f)|^2 df. \tag{3.24}$$

$$\max \cdot \left(\frac{S}{N}\right)_T = \frac{2}{N_0}E. \tag{3.25}$$

The energy E of the input signal $s(t)$ is the following:

$$E = \int_{-\infty}^{\infty}|S(f)|^2 df \tag{3.26}$$

Thus, the maximum output $(S/N)_T$ depends on the input **signal energy** and power spectral density of the noise, *not* on the *particular shape* of the waveform that is used.

Therefore, the impulse response of a filter that produces the maximum output signal-to-noise ratio is the mirror image of the message signal $s(t)$, delayed by the symbol time duration, T.

3.5 Error Probability Performance of Binary Signaling

In the following sections, we cover the error probability performance of binary signaling.

3.5.1 Unipolar Signaling

$$\begin{array}{lll} s_1(t) = A & 0 \leq t \leq T & \text{for binary 1.} \\ s_2(t) = 0 & 0 \leq t \leq T & \text{for binary 0.} \end{array}$$

$$E_d = \int_0^T A^2 dt = A^2 T.$$

$$\therefore P_e = Q\left(\sqrt{\frac{A^2 T}{2N_0}}\right) = Q\left(\sqrt{\frac{E_b}{N_0}}\right),$$

where $E_b = A^2 T/2$, the average energy per bit (see Figure 3.3).

3.5.2 Bipolar Signaling

$$\begin{array}{lll} s_1(t) = A & 0 \leq t \leq T & \text{for binary 1.} \\ s_2(t) = -A & 0 \leq t \leq T & \text{for binary 0.} \end{array}$$

$$E_d = \int_0^T 4A^2 dt = 4A^2 T.$$

$$\therefore P_e = Q\left(\sqrt{\frac{4A^2 T}{2N_0}}\right) = Q\left(\sqrt{\frac{2A^2 T}{N_0}}\right) = Q\left(\sqrt{\frac{2E_b}{N_0}}\right),$$

where the average energy per bit is $E_b = A^2 T$ (see Figure 3.3).

3.6 Equalizer

In practical systems, the frequency response of the channel is not known with sufficient accuracy to allow for a receiver design that will compensate for ISI for all time. The filter for handling ISI at the receiver contains various parameters that are adjusted on the basis of measurements of the channel

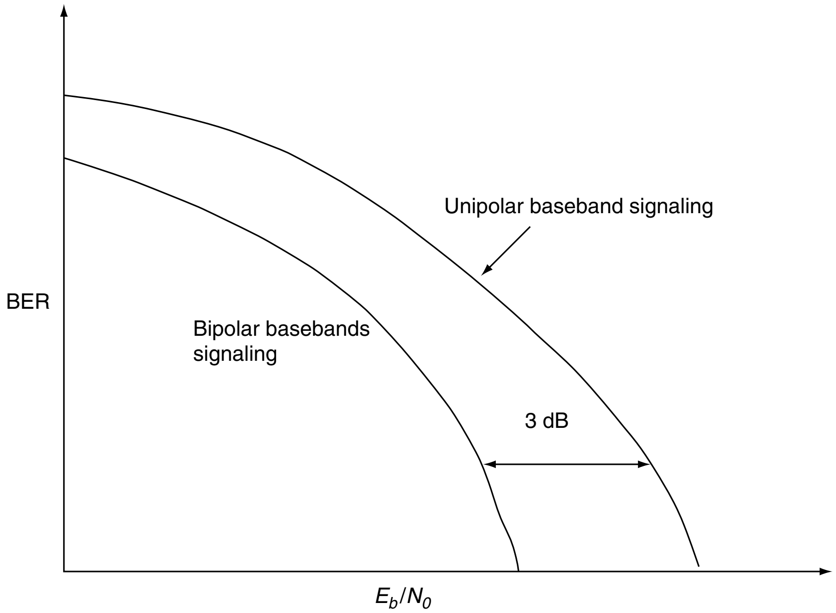

FIGURE 3.3 Bit Error Performance of Unipolar and Bipolar Signaling

characteristics. The process to correct channel-induced distortion is referred to as **equalization**. The adjustable filter is called an **equalizer**. Equalizers may be preset or adaptive. The parameters of a **preset equalizer** are adjusted by making measurements of channel impulse response and solving a set of equations for the parameters using these measurements. An **adaptive equalizer** is automatically adjusted by sending a known signal through the channel and allowing the equalizer to adjust its own parameters in response to this known signal.

A transversal filter—a delay line with T-second taps (where T is the symbol duration)—is a common choice for the equalizer. The outputs of the taps are amplified, summed, and fed to a decision device. The tap coefficients C_n are set to subtract the effects of interference from symbols that are adjacent in time to the desired symbol. The output samples y_k of the equalizer are written as:

$$y_k = \sum_{n=-N}^{N} C_n x_{k-n} \quad k = -2N, \ldots, 2N, \tag{3.27}$$

where:

$$\begin{pmatrix} y_{-2N} \\ \cdot \\ \cdot \\ y_0 \\ \cdot \\ \cdot \\ y_{2N} \end{pmatrix} = \{y_k\};\; C = \begin{pmatrix} C_{-N} \\ \cdot \\ C_0 \\ \cdot \\ C_N \end{pmatrix}, \text{ and}$$

$x = (2N+1) \times (2N+1)$ is the channel response matrix.

We can write the equation in matrix notation as:

$$y = Cx.$$

The impulse response is as follows:

$$h_E(t) = \sum_{n=-N}^{N} C_n \delta(t - nT). \tag{3.28}$$

The frequency response is as follows:

$$H_E(f) = \sum_{n=-N}^{N} C_n e^{-j2\pi nTf}. \tag{3.29}$$

Since there are only $2N+1$ unknown coefficients, it follows that only a finite number of interfering symbols can be nulled or forced to be zero:

$$y_k = 1 \text{ for } k = 0:$$
$$y_k = 0 \text{ for } k = \pm 1, \ \pm 2 \ldots \pm N.$$

The channel response matrix is given as:

$$[x] = \begin{bmatrix} x_{-N} & 0 & 0\cdot\cdot & 0 & 0 \\ x_{-N+1} & x_{-N} & 0\cdot\cdot & 0 & 0 \\ \cdot & \cdot & \cdots & \cdot & \cdot \\ \cdot & \cdot & \cdots & \cdot & \cdot \\ x_N & x_{N-1} & \cdots & x_{-N+1} & x_{-N} \\ 0 & 0 & 0\cdot\cdot & x_N & x_{N-1} \\ 0 & 0 & 0\cdot\cdot & 0 & x_N \end{bmatrix}. \tag{3.30}$$

The zero-forcing equations do not account for the effects of noise. In addition, the finite-length transversal filter equalizer can minimize worst-case ISI only if the peak distortion is less than 100% of the eye opening. Another type of equalizer is the minimum mean square error (MMSE) equalizer. In these equalizers, coefficients are selected to minimize the mean square error that consists of the sum of the square of all the ISI terms plus noise power at the equalizer output. The MMSE equalizer maximizes the signal-to-distortion ratio at its output within the constraints of equalizer length and delay.

Example 7

Consider a channel that uses a five-tap equalizer (see Figure 3.4) to correct ISI. The following measurements were made: $x(0) = 1.0$, $x(-1) = 0.2$, $x(-2) = 0.1$, $x(-3) = 0.05$, $x(-4) = -0.02$, $x(-5) = 0.01$, $x(1) = -0.1$, $x(2) = 0.1$, $x(3) = -0.05$, $x(4) = 0.02$, and $x(5) = 0.005$.

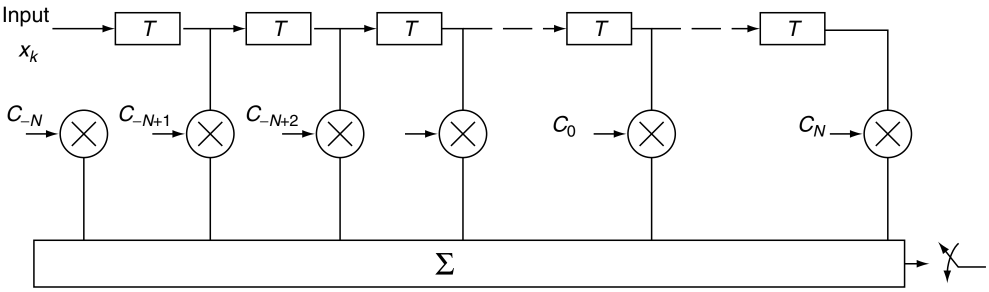

FIGURE 3.4 Tap Equalizer

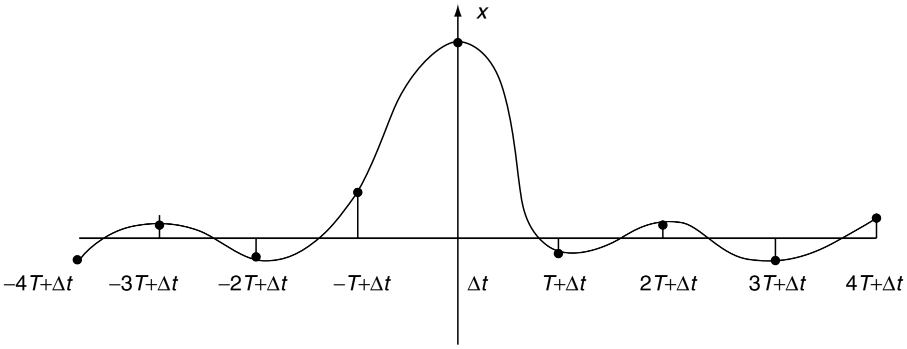

FIGURE 3.5

In addition, note the following results and equations:

$$\begin{bmatrix} x(0) & x(-1) & x(-2) & x(-3) & x(-4) \\ x(1) & x(0) & x(-1) & x(-2) & x(-3) \\ x(2) & x(1) & x(0) & x(-1) & x(-2) \\ x(3) & x(2) & x(1) & x(0) & x(-1) \\ x(4) & x(3) & x(2) & x(1) & x(0) \end{bmatrix} =$$

$$\begin{bmatrix} 1.0 & 0.2 & -0.1 & 0.05 & -0.02 \\ -0.1 & 1.0 & 0.2 & -0.1 & 0.05 \\ 0.1 & -0.1 & 1.0 & 0.2 & -0.1 \\ -0.05 & 0.1 & -0.1 & 1.0 & 0.2 \\ 0.02 & -0.05 & 0.1 & -0.01 & 1.0 \end{bmatrix} = [x].$$

$$[x]^{-1} = \begin{bmatrix} 0.966 & -0.170 & 0.117 & -0.083 & 0.056 \\ 0.118 & 0.945 & -0.158 & 0.112 & -0.083 \\ -0.091 & 0.133 & 0.937 & -0.158 & 0.117 \\ 0.028 & -0.095 & 0.133 & 0.945 & -0.170 \\ -0.002 & 0.028 & -0.091 & 0.118 & 0.966 \end{bmatrix}.$$

$$\{C\} = \begin{bmatrix} 0.117 \\ -0.158 \\ 0.945 \\ 0.133 \\ -0.091 \end{bmatrix} = \begin{bmatrix} C_{-2} \\ C_{-1} \\ C_0 \\ C_1 \\ C_2 \end{bmatrix}.$$

$$\begin{aligned} y_0 &= C_{-2} \cdot x_2 + C_{-1} \cdot x_1 + C_0 \cdot x_0 + C_1 \cdot x_{-1} + C_2 \cdot x_{-2} \\ &= 0.117 \times 0.1 + (-0.158) \times (-0.1) + 0.937 \times 1 \\ &\quad + 0.133 \times 0.2 - 0.091 \times -0.1 = 1.0. \end{aligned}$$

Modulation and Demodulation Technologies

Vijay K. Garg
Department of Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, Illinois, USA

Yih-Chen Wang
Lucent Technologies, Naperville, Illinois, USA

4.1 Modulation and Demodulation

The digital signals that are generated in the process of transmitting voice, data, and signaling information are generated at low data rates. These data rates, typically 1 to 50 kbps, are low enough in frequency that their transmission directly from the transmitter to the receiver would require antennas that are thousands of meters long. Furthermore, the signals from one transmitter would interfere with the signals from another transmitter if they all used the same frequency band. Therefore, the baseband signals are modulated onto a radio frequency carrier for transmission from the transmitter to the receiver. The radio environment at 800 to 2000 MHz is hostile. We must therefore choose modulation methods that are robust in this hostile environment. In addition to the modulation methods, we must also choose encoding algorithms that improve the performance of the system.

In this section, we study three modulation methods: minimum shift keying (MSK), **Gaussian minimum shift keying** (GMSK), and **π/4-differential quadrature phase shift keying** ($\pi/4$-DQPSK). GMSK is the modulation used by Global System of Mobile communications (GSM), GSM-1800, and GSM-1900, and Digital European Cordless Telephone (DECT). MSK is introduced as a first step toward GMSK. PWT and PWT-E, the variations of DECT for the licensed and unlicensed 1900-MHz band in North America, use $\pi/4$-DQPSK. Because each of these methods descend from phase shift keying, we will first study PSK and then show its relationship to the other modulation methods.

4.2 Introduction to Modulation

The baseband data rates of a wireless transmitter are usually a few kilobits per second [kbps] to as high as several hundred kilobits. The wavelengths for those signals vary from a thousand meters to several hundred thousand meters. If we attempted to send these signals directly, the antennas would be very long, and multiple transmitters would interfere with each other.

Therefore, when we want to send signals over any distance, baseband signaling is not sufficient. We must therefore modulate the signals onto a radio frequency (RF) carrier. When we transmit the digital bit stream, we convert the bit stream into the analog signal: $a(t)\cos(\omega t + \theta)$. The characteristic of this signal has amplitude $a(t)$, frequency $\omega/2\pi$, and phase θ; thus, we can change any of the three characteristics to formulate the modulation method. The basic form of the three modulation methods used for transmitting digital signals are these:

- Amplitude shift keying (ASK)
- Frequency shift keying (FSK)
- Phase shift keying (PSK)

When ω and θ remain unchanged, we have ASK. When $A(t)$ and θ remain unchanged, we have binary (or M-ary) FSK. When $A(t)$ and ω remain unchanged, we have binary (or M-ary) PSK (these methods are covered in more detail in Section 2.6). Hybrid systems exist where two characteristics are changed with each new symbol transmitted. The most common method is to fix ω and change $A(t)$ and θ. This method is known as quadrature amplitude modulation (QAM). Each of the modulation methods results in a different transmitter and receiver design, different occupied bandwidth, and different error rates. In the remainder of this section, we examine the methods used for GSM and DECT and calculate their error rates. Since all signals have a theoretical bandwidth that is infinite, all modulation methods must be band-limited. The band-limiting introduces detection errors, and the filter bandwidths must be chosen to optimize trade-offs between bandwidth and error rates.

The baseband outputs of the data transmitters are a series of binary data that cannot be sent directly over a radio link. The communications designer must choose radio signals that represent the binary data and permit the receiver to decode the data with minimal errors. For the simplest binary signaling system, we choose two signals denoted by $s_0(t)$ and $s_1(t)$ to represent the binary values of 0 and 1, respectively. Since no channel is perfect the receiver will also have additive Gaussian white noise, $n(t)$. The data receiver (see Figure 4.1) will then process the signal and noise through a filter, $h(t)$, and at the end of the signaling interval, T, it is possible to make a determination of whether the transmitter sent a 0 or a 1.

If the transmitted pulses are allowed to take on any of M transmitted levels with equal probability, then the information rate per transmitted pulse is $\log_2 M$ bits. For a constant information rate, the bandwidth of the transmitted system can be reduced by the same factor. With M-ary transmission, we will show that the error rates are higher, but if we have sufficient signal-to-noise ratio, then the higher errors rates will not matter. Thus, we are using excess signal-to-noise ratio to code the signal and reduce its bandwidth.

When we add additional levels to a baseband system, we are reducing the distance between detection levels in the receiver output. Thus, the error rate of a multilevel baseband system can be determined by calculating the appropriate reduction in the error distance. If the maximum amplitude is V, the error distance d_e between equally spaced levels at the detector is as follows:

$$d_e = \frac{V}{M-1}, \tag{4.1}$$

where M is the number of levels.

Setting the error distance V of a binary system to that defined in equation 4.1 provides the error probability of the multilevel system:

$$P_e = \frac{1}{\log_2 M}\left[\frac{M-1}{M}\right] erfc\left[\frac{V}{(M-1)\sqrt{2}\sigma}\right], \tag{4.2}$$

where the factor [M − 1/M] reflects that the interior signal levels are vulnerable to both positive and negative noise and where the factor $1/\log_2 M$ arises because the multilevel system is assumed to be coded so symbol errors produce single bit errors ($\log_2 M$ is the number of bits per symbol). The probability of multiple bit errors is assumed to be small and can be neglected.

Equation 4.2 relates error probability to the peak signal power V^2. To determine the P_e with respect to average power, the average power of an M-level system is determined by averaging the power associated with the various pulse amplitude levels:

$$[V^2]_{\text{avg}} = \frac{2}{M}\left[\left(\frac{V}{M-1}\right)^2 + \left(\frac{3V}{M-1}\right)^2 + \ldots + V^2\right]. \tag{4.3}$$

$$[V^2]_{\text{avg}} = \frac{2V^2}{M(M-1)^2}\sum_{j=1}^{M/2}(2j-1)^2. \tag{4.4}$$

FIGURE 4.1 Receiver Structure to Detect Binary Signals in Gaussian White Noise

In equations 4.3 and 4.4, the levels V/M − 1[± 1, ± 3, ± 5, . . . , ± (M − 1)] are assumed to be equally likely.

If T is the signaling interval for a two-level system, the signaling interval T_M for an M-level system providing the same data rate is determined as:

$$T_M = T \log_2 M \tag{4.5}$$

For a raised cosine filter, the noise bandwidth is $B_N = 1/2T_M$. We can write:

$$\sigma^2 = \frac{N_o}{2T_M}. \tag{4.6}$$

$$\sigma = \frac{1}{\sqrt{2}}\left[\frac{N_o}{T_M}\right]^{1/2}. \tag{4.7}$$

Substituting equation 4.7 into equation 4.2, we get:

$$P_e = \left[\frac{1}{\log_2 M}\right]\left[\frac{M-1}{M}\right] erfc\left[\frac{V}{(M-1)(N_o/T_M)^{1/2}}\right]. \tag{4.8}$$

The energy per symbol is $E_s = E_b \log_2 M = V^2 T_M$, where E_b is the energy per bit:

$$\therefore V^2 = \frac{E_b \log_2 M}{T_M}. \tag{4.9}$$

Substituting for V from equation 4.9 into equation 4.8, we get:

$$P_e = \left[\frac{1}{\log_2 M}\right]\left[\frac{M-1}{M}\right] erfc\left[\left(\frac{E_b}{N_o}\right)^{1/2}\frac{(\log_2 M)^{1/2}}{M-1}\right]. \tag{4.10}$$

$$\text{SNR} = \frac{\text{signal power}}{\text{noise power}} = \frac{E_b(\log_2 M)(1/T_M)}{N_o(1/2T_M)}. \tag{4.11}$$

$$\therefore \text{SNR} = 2\log_2 M\left(\frac{E_b}{N_o}\right). \tag{4.12}$$

Another variation of baseband signaling is antipodal baseband signaling (APBBS), where two signals of opposite polarities are sent. If $s_0(t) = -\text{V}$, and $s_1(t) = \text{V}$ for $0 \le t \le T$, then $s_1(t) - s_0(\text{t}) = 2V$.

We then calculate the value of z as:

$$z = \frac{1}{4N_o}\int_0^T (2V)^2 dt = \frac{V^2 T}{N_o} = \frac{E_b}{N_o}, \tag{4.13}$$

where E_b is the energy in either $s_0(t)$ or $s_1(t)$, that is, the bit energy:

$$P_e = \frac{1}{2} erfc\left[\sqrt{\frac{E_b}{N_o}}\right] = Q\left[\sqrt{\frac{2E_b}{N_o}}\right]. \tag{4.14}$$

APBBS is used to modulate some signals, and we will compare its signal-to-noise ratio with other modulation methods.

4.3 Phase Shift Keying

4.3.1 Binary Phase Shift Keying

For binary phase shift keying (BPSK), we transmit two different signals. If the baseband signal is a binary 0, we transmit:

$$A\cos(\omega\text{t} + \pi) = -A\cos(\omega\text{t}), \tag{4.15}$$

and for binary $1'$, we transmit:

$$A\cos(\omega\text{t}). \tag{4.16}$$

BPSK can be considered as a form of amplitude shift keying where each nonreturn to zero (NRZ) data bit of value 0 is mapped into a −1, and each NRZ 1 is mapped into a + 1. The resulting signal is then passed through a filter to limit its bandwidth and then multiplied by the carrier signal $\cos\omega t$ (see Figure 4.2).

We can also define PSK where there are M phases rather than two phases. In M-ary PSK, every n (where $M = 2^n$) bits of the binary bit stream are coded as a signal that is transmitted as $A\sin(\omega\text{t} + \theta_j)$, $j = 1, M$.

The error distance of a PSK system with M phases is $V\sin(\pi/M)$, where V is the signal amplitude at the detector. A detection error occurs if noise of the proper polarity is present at the output of either of the two phase detectors. The probability of error is (Garg and Wilkes, 1996):

$$P_e = \left(\frac{1}{\log_2 M}\right) erfc\left[\sin\left(\frac{\pi}{M}\right)(\log_2 M)^{1/2}\left(\frac{E_b}{N_o}\right)^{1/2}\right]. \tag{4.17}$$

The signal-to-noise ratio is given as:

$$\text{SNR} = \log_2 M\left(\frac{E_b}{N_o}\right)(\text{For } M > 2). \tag{4.18}$$

Each symbol has length T. Therefore, the following is true:

$$E_b = V^2 T/\log_2 M, \tag{4.19}$$

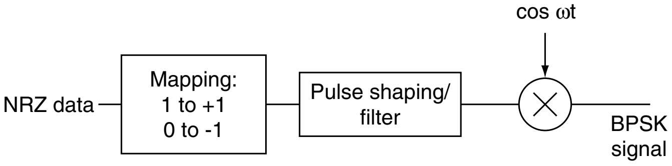

FIGURE 4.2 BPSK Modulator

and the RMS noise σ as:

$$No = \sigma^2 2T, \tag{4.20}$$

for noise in a Nyquist bandwidth.

Also, as shown in the bandwidth efficiency of the *M*-ary PSK is given as:

$$\frac{R}{B_w} = \frac{\log_2 M}{2},$$

where R is the data rate and B_w is the bandwidth.

We will now examine several variations of Phase Shift Keying.

4.4 Quadrature Phase Shift Keying

If we define four signals, each with a phase shift differing by 90° then we have quadrature phase shift keying **(QPSK)**. We have previously calculated the error rates for a general phase shift keying signal with *M* signal points. For QPSK, $M = 4$, so substituting $M = 4$ in equation 4.17, we get:

$$P_e = \left(\frac{1}{\log_2 4}\right) erfc\left[\sin\left(\frac{\pi}{4}\right)(\log_2 4)^{1/2}\left(\frac{E_b}{N_o}\right)^{1/2}\right].$$

$$P_e = \frac{1}{2} erfc\sqrt{\frac{E_b}{N_o}} = Q\left[\sqrt{\frac{2E_b}{N_o}}\right]. \tag{4.21}$$

The input binary bit stream $\{b_k\}$, $b_k = \pm 1$; k = 0, 1, 2, ..., arrives at the modulator input at a rate $1/T$ bits/sec and is separated into two data streams, a_I(t) and a_Q(t), containing even and odd bits, respectively (Figure 4.3). The modulated QPSK signal $s(t)$ is given as:

$$s(t) = \frac{1}{\sqrt{2}} a_I(t)\cos\left(2\pi ft + \frac{\pi}{4}\right) + \frac{1}{\sqrt{2}} a_Q(t)\sin\left(2\pi ft + \frac{\pi}{4}\right). \tag{4.22}$$

$$s(t) = A\cos\left[2\pi ft + \frac{\pi}{4} + \theta(t)\right]. \tag{4.23}$$

In equations 4.22 and 4.23, the following apply:

$$A = \sqrt{(1/2)(a_I^2 + a_Q^2)} = 1.$$

$$\theta(t) = -\text{a}\tan\frac{a_Q(t)}{a_I(t)}.$$

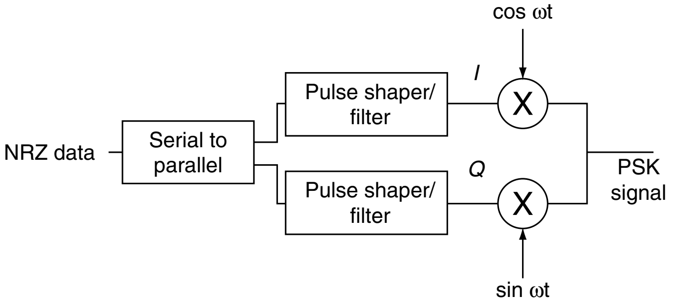

FIGURE 4.3 QPSK Modulator

In Figure 4.3, we show an NRZ data stream of 01110001. We then show the *I*(0100) and *Q* (1101) signals that are generated from the NRZ data stream. Notice that the *I* and *Q* signals have bit lengths that are twice as long as the NRZ data bits. In the figure, there is no delay between the NRZ data and the *I* and *Q* data. In a real implementation, there would be a 1- to 2-bit delay before the *I* and *Q* signals were generated. This delay accounts for the time for two bits to be received and decoded into the *I* and *Q* signals. Finally, we show the QPSK signal that is generated. To make the figure clearer, we chose a carrier frequency that is four times higher than the data rate. In real systems, the carrier frequency would be many times that data rate.

The values of $\theta(t) = 0, -\pi/2, \pi/2, \pi$ represent the four values of $a_I(t)$ and $a_Q(t)$. On the *I*/*Q* plane, QPSK represents four equally spaced points separated by $\pi/2$ (see Figure 4.5). Each of the four possible phases of carriers represents two bits of data. Thus, there are two bits per symbol. Since the symbol rate for QPSK is half of the bit rate, twice the information can be carried in the same amount of channel bandwidth as compared to binary phase shift keying. This is possible because the two signals *I* and *Q* are orthogonal to each other and can be transmitted without interfering with each other.

In QPSK, the carrier phase can change only once every $2T$ seconds. If from one $2T$ interval to the next, neither bit stream changes sign, the carrier phase remains the same. If one component $a_I(t)$ or $a_Q(t)$ changes sign, a phase shift of $\pi/2$ occurs. If both components, *I* and *Q* change sign, however then a phase shift of π or 180° occurs. When this 180° phase shift is filtered by the transmitter and receiver filters, it generates a change in amplitude of the detected signal and causes additional errors. Notice the 180° shift at the end of bit interval 4 in Figure 4.4.

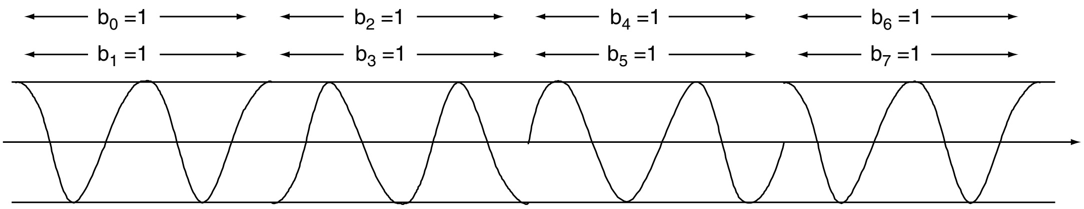

FIGURE 4.4 QPSK Signals

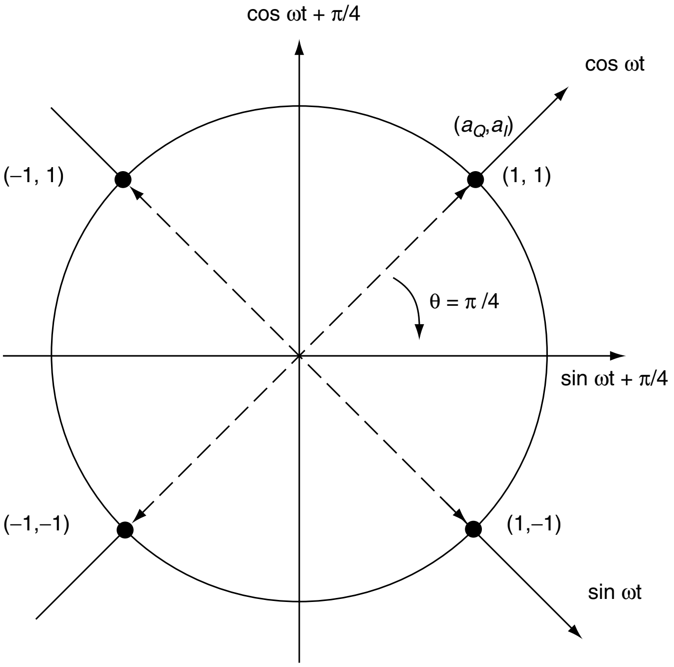

FIGURE 4.5 Signal Constellation for QPSK

If the two bit streams, *I* and *Q*, are offset by 1/2 a bit interval, then the amplitude fluctuations are minimized because the phase never changes by 180° (see Figures 4.6 and 4.7). This modulation scheme, **offset quadrature phase shift keying** (OQPSK), is obtained from the conventional quadrature phase shift keying by delaying the odd-bit stream by a half-bit interval with respect to the even bit stream. Thus, the range of phase transition is 0° and 90° and occurs twice as often but with half the intensity of the quadrature phase shift keying system. Comparing Figure 4.4 with Figure 4.7, notice that the *Q* signal is the same for both QPSK and OQPSK, but the *I* signal is delayed by 1/2 bit. Thus, the 180° phase change at the end of bit interval 4 of the QPSK signal is replaced by a 90° phase change at the end of bit interval 4 of the OQPSK signal. Also notice that phase changes occur more frequently with OQPSK. Although the phase changes will still cause amplitude fluctuations to occur in the transmitter and receiver, they have a smaller magnitude. The bit error rate and bandwidth efficiency of QPSK and OQPSK is the same as for BPSK.

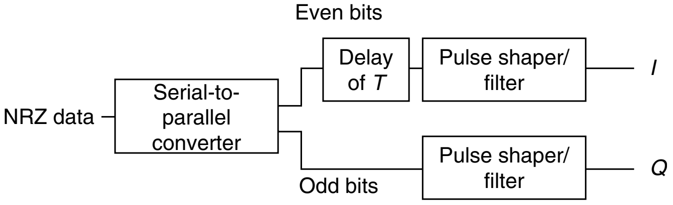

FIGURE 4.6 OQPSK Encoding

In theory, quadrature (or offset quadrature) phase shift keying systems can improve the spectral efficiency of mobile communication. They do, however, require a coherent detector, and in a multipath fading environment, the use of coherent detection is difficult and often results in poor performance over noncoherently based systems. The coherent detection problem can be overcome by using a differential detector, but then OQPSK is subject to intersymbol interference that results in poor system performance. The spectrum of offset QPSK (OQPSK) is the following (Proakis, 1989):

$$P_{\text{QPSK}}(f) = T\left[\frac{\sin \pi f T}{\pi f T}\right]^2. \tag{4.24}$$

4.5 The π/4 Differential Phase Shift Keying

We can design a phase shift keying system to be inherently differential and thus solve the detection problems. The **π/4 differential quadrature phase shift keying** (π/4-DQPSK) is a compromise modulation method because the phase is restricted to fluctuate between ±π/4, and ±3π/4 rather than the ±π/2 phase changes for OQPSK. The method has a spectral efficiency of about 20% more than the Gaussian minimum shift keying (see upcoming section) modulation used for DECT and GSM.

The π/4-DQPSK is essentially a π/4-shifted QPSK with differential encoding of symbol phases. The differential encod-

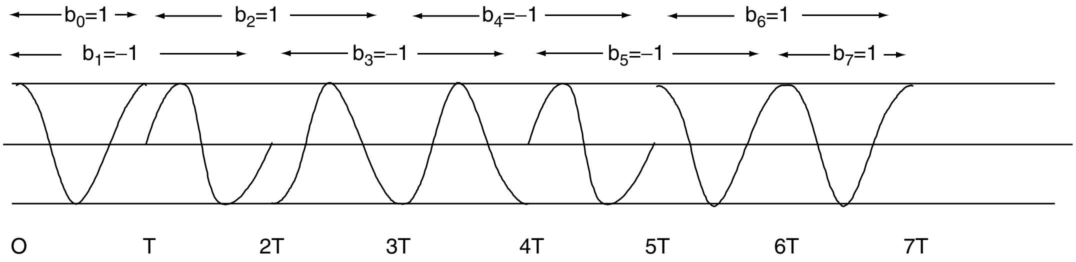

FIGURE 4.7 OQPSK Signals

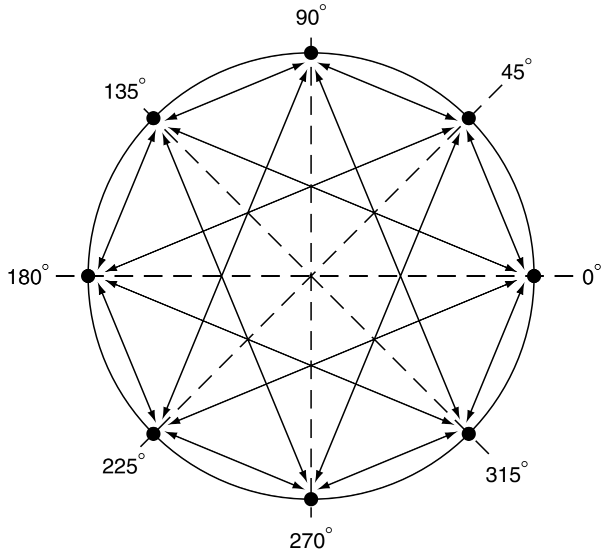

FIGURE 4.8 The $\pi/4$-DQPSK Modulation

ing mitigates loss of data due to phase slips. However, differential encoding results in the loss of a pair of symbols when channel errors occur. This can be translated to approximately a 3-dB loss in E_b/N_o relative to coherent $\pi/4$-QPSK.

A $\pi/4$-shifted QPSK signal constellation in Figure 4.8 consists of symbols corresponding to eight phases. These eight phase points can be considered to be formed by superimposing two QPSK signal constellations, offset by 45 degrees relative to each other. During each symbol period, a phase angle from only one of the two QPSK constellations is transmitted. The two constellations are used alternately to transmit every pair of bits (di-bits). Thus, successive symbols have a relative phase difference that is one of the four phases shown in Table 4.1.

Figure 4.8 shows the $\pi/4$-shifted QPSK signal constellation. When the phase angles of $\pi/4$-shifted QPSK symbols are differentially encoded, the resulting modulation is $\pi/4$-shifted DQPSK. This can be done either by differential encoding of the source bits and mapping them onto absolute phase angles or, alternately, by directly mapping the pairs of input bits onto relative phase ($\pm\pi/4 \pm 3\pi/4$) as shown in Figure 4.8. The binary data stream entering the modulator $b_M(t)$ is converted by a serial-to-parallel converter into two binary streams $b_o(t)$ and $b_e(t)$ before the bits are differentially encoded (see Figure 4.9):

TABLE 4.1 Phase Transitions of $\pi/4$-DQPSK

Symbol	$\pi/4$-DQPSK phase transition
00	45°
01	135°
10	−45°
11	−135°

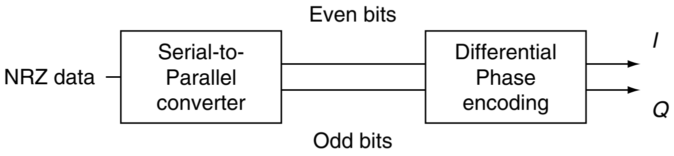

FIGURE 4.9 Differential Encoding of $\pi/4$-DQPSK

$$I_k = I_{k-1}\cos\Delta\phi_k - Q_{k-1}\sin\Delta\phi_k. \tag{4.25}$$

$$Q_k = I_{k-1}\sin\Delta\phi_k + Q_{k-1}\cos\Delta\phi_k. \tag{4.26}$$

The I_k and Q_k are the in-phase and quadrature components of the $\pi/4$-shifted DQPSK signal corresponding to the kth symbol. The amplitudes of I_k and Q_k are $\pm 1, 0, \pm 1/\sqrt{2}$. Because the absolute phase of $(k-1)$th symbol is ϕ_{k-1}, the in-phase and quadrature components can be expressed as:

$$I_k = \cos\phi_{k-1}\cos\Delta\phi_k - \sin\phi_{k-1}\sin\Delta\phi_k = \cos(\phi_{k-1} + \Delta\phi_k). \tag{4.27}$$

$$Q_k = \cos\phi_{k-1}\sin\Delta\phi_k + \sin\phi_{k-1}\cos\Delta\phi_k = \sin(\phi_{k-1} + \Delta\phi_k). \tag{4.28}$$

These component signals (I_k, Q_k) are then passed through baseband filters having a raised cosine frequency response as:

$$|H(f)| = \begin{cases} 1 & 0 \le |f| \le \dfrac{1-\alpha}{2T_s}. \\ \sqrt{\frac{1}{2}\left\{1 - \sin\left[\dfrac{\pi T_s}{\alpha}\left(|f| - \dfrac{1}{2T_s}\right)\right]\right\}} & \dfrac{1-\alpha}{2T_s} \le |f| \le \dfrac{1+\alpha}{2T_s}. \\ 0 & |f| \ge \dfrac{1+\alpha}{2T_s}. \end{cases} \tag{4.29}$$

In equation 4.29 α is the roll-off factor, and T_s is the symbol duration.

If $g(t)$ is the response to pulses I_k and Q_k at the filter input, then the resultant transmitted signal is given as:

$$s(t) = \sum_k g(t - kT_s)\cos\phi_k\cos\omega t - \sum_k g(t - kT_s)\sin\phi_k\sin\omega t, \tag{4.30}$$

$$s(t) = \sum_k g(t - kT_s)\cos(\omega t + \phi_k), \tag{4.31}$$

where $2\pi\omega$ is the carrier frequency of transmission.

The component ϕ_k results from differential encoding (i.e., $\phi_k = \phi_{k-1} + \Delta\phi_k$).

Depending on the detection method (coherent detection or differential detection), the error performance of $\pi/4$-DQPSK can either be the same or 3 dB worse than QPSK.

4.6 Minimum Shift Keying

We previously showed that OQPSK is derived from QPSK by delaying the Q data stream by 1 bit or Tsec with respect to the corresponding I data stream. This delay has no effect on the error rate or bandwidth.

Minimum shift keying (MSK) is derived from OQPSK by replacing the rectangular pulse in amplitude with a half-cycle sinusoidal pulse. Notice that the in-phase and quadrature signals are delayed by interval T from each other.

The MSK signal is defined as:

$$s(t) = a_I(t)\left|\cos\left(\frac{\pi(t-2nT)}{2T}\right)\right| \cos 2\pi ft + a_Q(t) \left|\sin\left(\frac{\pi(t-2nT)}{2T}\right)\right| \sin 2\pi ft. \tag{4.32}$$

$$s(t) = \cos\left[2\pi ft + b_k(t)\frac{\pi(t-2nT)}{2T} + \phi_k\right]. \tag{4.33}$$

In equations 4.32 and 4.33, the following apply:

- $n = 0, 1, 2, 3, \ldots$
- $\mathrm{b_k} = +1$ for $a_I \cdot a_Q = -1$.
- $\mathrm{b_k} = -1$ for $a_I \cdot a_Q = 1$.
- $\phi_k = 0$ for $a_I = 1$.
- $\phi_k = \pi$ for $a_I = -1$.

Note that since the I and Q signals are delayed by one bit interval, the cosine and sine pulse shape in equation 4.32 are actually both in the shape of a sin pulse.

Minimal shift keying has the following properties:

(1) For a modulation bit rate of R, the high tone is $f_H = f + 0.25\mathrm{R}$ when $b_k = 1$, and the low tone is $f_L = f - 0.25\,R$ when $b_k = -1$.

(2) The difference between the high tone and the low tone is $\Delta f = f_H - f_L = 0.5R = 1/(2T)$, where T is the bit interval of the NRZ signal.

(3) The signal has a constant envelope.

The error probability for an ideal minimal shift keying system is:

$$P_e = \frac{1}{2}\,erfc\sqrt{\frac{E_b}{N_o}} = Q\left[\sqrt{\frac{2E_b}{N_o}}\right], \tag{4.34}$$

which is the same as for QPSK/OQPSK.

The minimal shift keying modulation makes the phase change linear and limited to ± $\pi/2$ over a bit interval T. This enables MSK to provide a significant improvement over QPSK. Because of the effect of the linear phase change, the power spectral density has low side lobes that help to control adjacent channel interference. However, the main lobe becomes wider than the quadrature shift keying (see Figure 4.11). Thus, it becomes difficult to satisfy the CCIR recommended value of -60 dB-side lobe power levels. The power spectral density for MSK can be shown (Proakis, 1989) to be as:

$$P_{\mathrm{MSK}}(f) = \frac{16T}{\pi^2}\left[\frac{\cos 2\pi fT}{1-16f^2T^2}\right]^2. \tag{4.35}$$

Figure 4.11 shows the spectral density for both MSK and QPSK. Notice that while the first null in the side lobes occurs at a data rate of R for MSK and $R/2$ for QPSK, the overall side lobes are lower for MSK. Thus, MSK is more spectrally efficient than QPSK.

The detector for MSK (Figure 4.10) is slightly different than for PSK. We must generate the matched filter equivalent to the two transmitted in-phase and quadrature signals. These two reference signals are as follows:

$$i(t) = \cos\left(\frac{\pi t}{2T}\right)\cos \omega t. \tag{4.36}$$

$$q(t) = \sin\left(\frac{\pi t}{2T}\right)\sin \omega t. \tag{4.37}$$

We multiply the received signal by $i(t)$ and $q(t)$ and perform an integration with detection at the end of the bit interval; we then dump the integrator output. This is the standard integrate-and-dump matched filter with the reference signal $i(t)$ and $q(t)$ match to the received waveform. At the end of the bit interval, we make a decision on the state of the bit (+ 1 or − 1) and output the decision as our detected bit. We do this for both the I channel and the Q channel with I and Q out of phase by Tsec to account for the differential nature of MSK.

4.7 Gaussian Minimum Shift Keying

In minimal shift keying, we replace the rectangular data pulse with a sinusoidal pulse. Obviously, other pulse shapes are possible. A Gaussian-shaped impulse response filter generates a signal with low side lobes and a narrower main lobe than the rectangular pulse. Since the filter theoretically has output before input, it can only be approximated by a delayed and shaped impulse response that has a Gaussian-like shape. This modulation is called **Gaussian minimum shift keying** (GMSK).

The relationship between the premodulation filter bandwidth B and the bit period T defines the bandwidth of the system. If $B > 1/T$, then the waveform is essentially minimal shift keying. When $B < 1/T$, the intersymbol interference occurs because the signal cannot react to its next position in the symbol time. However, intersymbol interference can be traded for bandwidth reduction if the system has sufficient

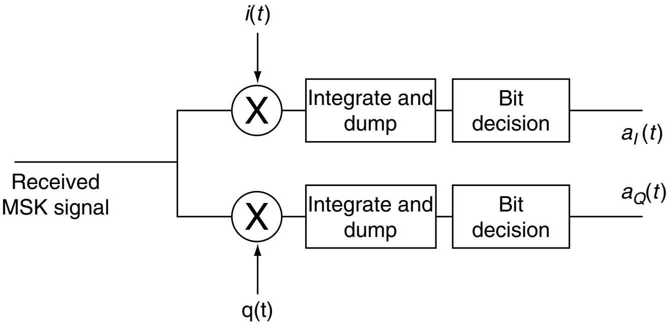

FIGURE 4.10 Optimum MSK Detector

signal-to-noise ratio. GSM designers use a BT of 0.3 with a channel data rate of 270.8 kbps. DECT designers adopt $BT = 0.5$ with a data rate of 1.152 Mbs. A choice of $BT = 0.3$ in GSM is a compromise between bit error rate and out-of-band interference since the narrow filter increases the intersymbol interference and reduces the signal power.

When GMSK was first proposed (Murota and Hirade, 1981), the modulator was based on using frequency modulation (FM), illustrated by Figure 4.12. Since newer integrated circuits are available that enable an I and Q modulator to be easily constructed, a more modern method to generate the GSMK signal is shown in Figure 4.13.

Filtering of the NRZ data by a Gaussian low-pass filter generates a signal that is no longer constrained to one bit interval. Intersymbol interference is generated by the modulator.

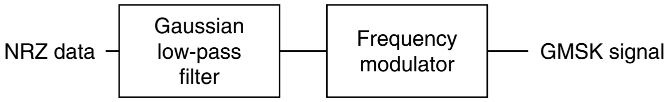

FIGURE 4.12 GMSK Modulator Using Frequency Modulator

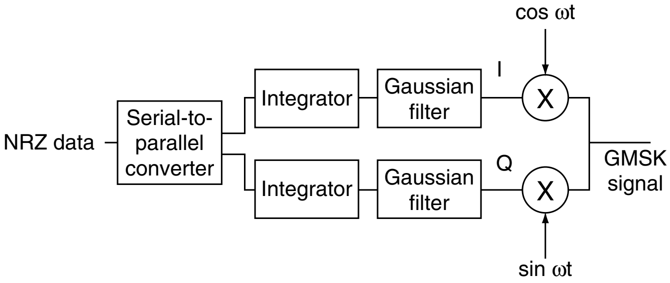

FIGURE 4.13 GMSK Modulator Using Phase Modulator

The bit error rate performance of GMSK can be expressed (Murota and Hirade, 1981) as:

$$P_e = \frac{1}{2} erfc\sqrt{\frac{\alpha E_b}{2N_o}} = Q\left[\sqrt{\frac{\alpha E_b}{N_o}}\right], \tag{4.38}$$

where α depends on the BT product. For GSM where $BT = 0.3$, $\alpha \approx 0.9$; for DECT where $BT = 0.5$, $\alpha \approx 0.97$. For $BT = \infty$, $\alpha = 2$, which is the case of MSK.

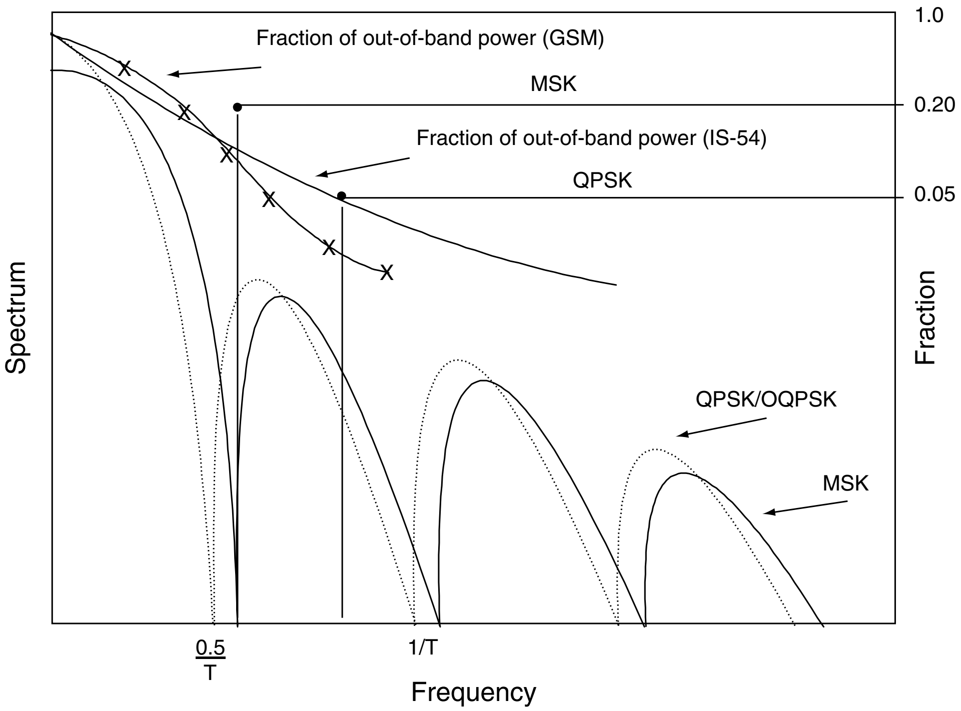

FIGURE 4.11 Spectral Density of QPSK and MSK

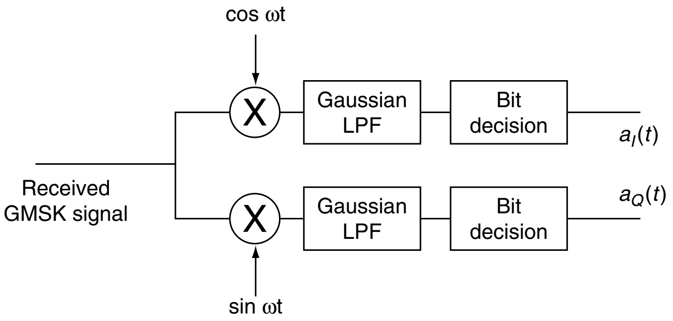

FIGURE 4.14 GMSK Demodulator

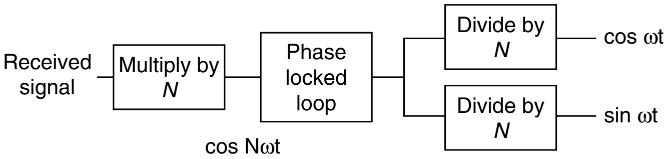

FIGURE 4.15 Carrier Recovery for PSK

Demodulation of GMSK, shown in Figure 4.14, requires multiplication by the in-phase and quadrature carrier signals followed by a low-pass filter with Gaussian shape. At the end of the bit interval, we make a decision on the state of the bit (+1 or −1) and output the decision as our detected bit. As with MSK, we do this for both the *I* channel and the *Q* channel with *I* and *Q* out of phase by *T* seconds to account for the differential nature of GMSK. We ignore the intersymbol interference caused by the longer than 1-bit interval nature of the Gaussian transmitted pulse.

4.8 Synchronization

The demodulation of a signal requires that the receiver be synchronized with the transmitted signal, as received at the input of the receiver. The synchronization must be for:

- **Carrier synchronization:** The receiver is exactly on the same frequency that was transmitted and adjusted for the effects of Doppler shifts.
- **Bit synchronization:** The receiver is aligned with the beginning and end of each bit interval.
- **Word synchronization:** The receiver is aligned with the beginning and end of each word in the transmitted signal.

If the synchronization in the receiver is not precise for any of the above operations, then the bit error rate of the receiver will not be the same as described by the equations in the previous sections. The design of a receiver is an area that standards have traditionally not specified. It is usually an art that enables one company to offer better performance in its equipment compared to a competitor's equipment. The methods of achieving synchronization discussed in this section are the traditional methods. A particular receiver may or may not use any of these methods. Many companies use proprietary methods.

For PSK the carrier signal changes phase every bit interval. If we multiply the received signal by a factor *N*, an integer, we can convert all of the phase changes in the multiplied signal to multiples of 360°. The new signal then has no phase changes, and we can recover it using a narrow band phase locked loop (PLL). After the PLL recovers, the multiplied carrier signal it is divided by *N* to recover the carrier at the proper frequency. By the suitable choice of digital dividing circuits, it is possible to get a precise 90° difference in the output of two dividers and thus generate both the cos ωt and the sin ωt signals needed by the receiver. There are also some down-converter integrated circuits that contain a precise phase shift network. The carrier recovery is typically performed at some lower intermediate frequency rather than directly at the received frequency. For BPSK, we would need an *N* or 2, but an *N* of 4 would be used to enable the sine and cosine term to be generated. For QPSK and its derivatives, an *N* of 4 is necessary, and for π/4-DQPSK, an *N* of 8 would be needed.

After we recover the carrier, we must reestablish the carrier phase to determine the values of the received bits. Somewhere in the transmitted signal must be a known bit pattern that we can use to determine the carrier phase. The bit pattern can be alternating zeros and ones that we use to determine bit timing, or it could be some other known pattern.

The advantage of differential keying (e.g., π/4-DQPSK) is that the knowledge of the absolute carrier phase is not important. Only the change in carrier phase from one symbol to the next is important.

MSK is a form of frequency modulation; therefore, a different method of carrier recovery is needed. In Figure 4.16, the MSK signal has frequency *f* and deviation $\Delta f = 1/2T$. We first multiply the signal by 2, thus doubling the deviation and generating strong frequency components (Pasupathy, 1979) at $2f + 2\Delta f$ and $2f - 2\Delta f$. We use two PLLs to recover these two signals:

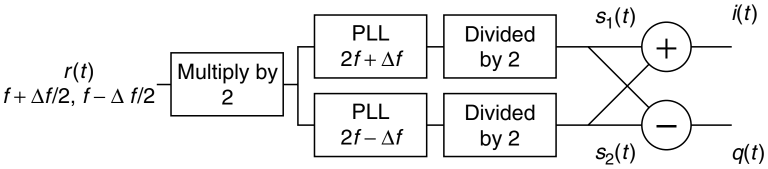

FIGURE 4.16 Carrier Recovery for MSK

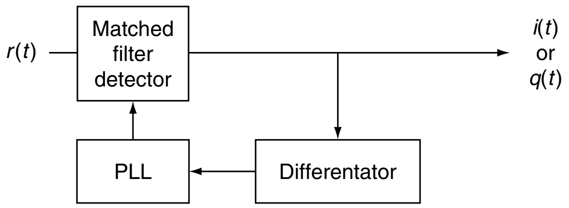

FIGURE 4.17 Generalized Data Timing Recovery Circuit

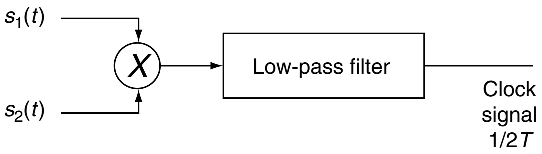

FIGURE 4.18 MSK Data Timing Recovery Circuit

$$s_1(t) = \cos(2\pi ft + 2\pi\Delta ft). \tag{4.39}$$

$$s_2(t) = \cos(2\pi ft - 2\pi\Delta ft). \tag{4.40}$$

We then take the sum and difference of $s_1(t)$ and $s_2(t)$ to generate the desired *i(t)* and $q(t)$ signals:

$$\begin{aligned} i(t) = s_1(t) + s_2(t) = \cos(2\pi ft + \pi\Delta ft) \\ + \cos(2\pi ft - \pi\Delta ft) = 2\cos 2\pi ft \cos \pi\Delta ft. \end{aligned} \tag{4.41}$$

$$\begin{aligned} q(t) = s_1(t) - s_2(t) = \cos(2\pi ft + \pi\Delta ft) \\ - \cos(2\pi ft - \pi\Delta ft) = 2\sin 2\pi ft \sin \pi\Delta ft. \end{aligned} \tag{4.42}$$

The identical circuit can also be used to recover a carrier for a GMSK system. (de Buda, 1972; Murota and Hirade, 1981; Pasupathy, 1979). The next step is to recover data time or bit synchronization. Most communication systems transmit a sequence of zeros and ones in an alternating pattern to enable the receiver to maintain bit synchronization. A PLL operating at the bit timing is used to maintain timing. Once the PLL is synchronized on the received 101010... pattern (Figure 4.17), it will remain synchronized on any other patterns except for long sequences of all zeros or all ones.

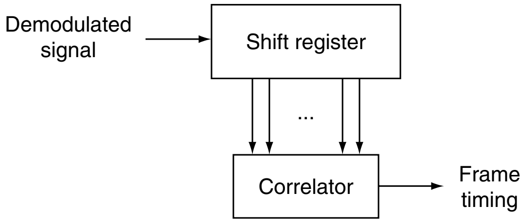

FIGURE 4.19 Generalized Framing Recovery Circuit

MSK uses an additional circuit to achieve bit timing (Figure 4.18). The $s_1(t)$ and $s_2(t)$ signals are multiplied together and low-pass filtered:

$$\begin{aligned} s_1(t)s_2(t) &= \cos(2\pi ft + \pi\Delta ft) \times \cos(2\pi ft - \pi\Delta ft) \\ &= 0.5\cos 4\pi ft + 0.5\cos 2\pi\Delta ft. \end{aligned} \tag{4.43}$$

$$\text{low-pass filtered}[s_1(t)s_2(t)] = 0.5\cos 2\pi\Delta ft = 0.5\cos\frac{\pi t}{T}. \tag{4.44}$$

The output of the low-pass filter is a clock signal at one-half the bit rate, which is the correct rate for demodulation of the signal because the I and Q signals are at one-half of the bit rate.

Word synchronization or framing is determined by correlating on a known bit pattern being transmitted. The receiver then performs an autocorrelation function to determine when the bit pattern is received and outputs a framing pulse (Figure 4.20).

4.9 Equalization

The received signal in a mobile radio environment travels from the transmitter to the receiver over many paths. The signal thus fades in and out and undergoes distortion because of the multipath nature of the channel. For a transmitted signal $s(t) = a(t)\cos(\omega t + \theta(t))$, we can represent the received signal, $r(t)$, as:

$$\begin{aligned} r(t) = \sum_{i=0}^{n} x_i(t-\tau_i)a(t-\tau_i)\cos(\omega(t-\tau_i) + \theta(t-\tau_i)) \\ + y_i(t-\tau_i)a(t-\tau_i)\sin(\omega(t-\tau_i) + \theta(t-\tau_i)). \end{aligned} \tag{4.45}$$

The received signal has Rayleigh fading statistics. But what are the characteristics of the x and y terms in equation 4.45? If the transmitter signal is narrow enough compared to the fine multipath structure of the channel, then the individual fading components, $x_i(t)$ and $y_i(t)$ will also have Rayleigh statistics. If a particular path is dominated by a reflection off of a mountain, hill, building, or similar structure, then the statistics of that path may be Rician rather than Raleigh. If the range of τ_i is small compared to the bit interval, then little distortion of the received signal occurs. If the range of τ_i is greater than a bit interval, then the transmissions from one bit will interfere with the transmissions of another bit. This effect is called **intersymbol interference**.

Spread spectrum systems transmit wideband width signals and attempt to recover the signals in each of the paths and add them together in a diversity receiver. In the discussion in this section, we fowson the transmission of narrow band signals. Therefore, the multipath signals are interference to the desired signal. We need a receiver that removes the effects of the multipath signal or cancels the undesired multipaths.

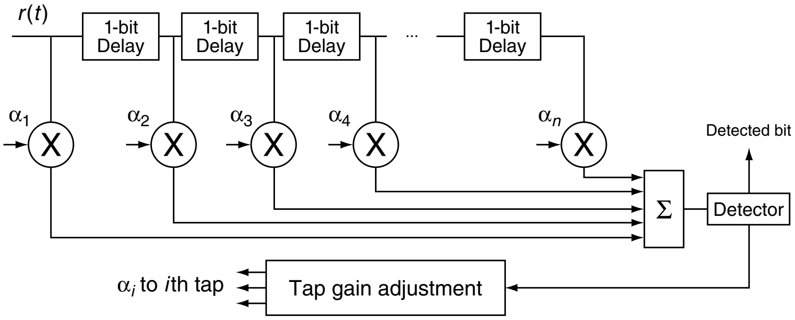

FIGURE 4.20 Block Diagram of Equalizer

Another method to describe the multipath channel is to describe the channel as having an impulse response $h(t)$. The received signal is then written as:

$$r(t) = \int_{-\infty}^{\infty} s(t)h(t-\tau)d\tau. \tag{4.46}$$

We can then recover $s(t)$ if we can determine a transfer function $h^{-1}(t)$, the inverse of $h(t)$. One difficulty in performing the inverse function is that it is time varying. The circuit that performs the inverse transfer function is called an **equalizer**, as shown in Figure 4.20.

Generally, we are interested in minimizing the intersymbol interference at the time when we do our detection (the sample time in a sample and hold circuit). Thus, we can model the equalizer as a series of equal time delays (rather than random as in the general case) with the shortest delay interval being a bit interval. We then construct a receiver that determines r_{eq}, the equalized signal:

$$r_{eq}(t) = \sum_{i=0}^{n} \alpha_i(t-\tau_n)r(t-\tau_n). \tag{4.47}$$

We use our equalized signal r_{eq} as the input to our detector to determine the value of the kth transmitted bit. We must adjust the values of α_i to achieve some measure of performance of the receiver. A typical measure is to minimize the mean square error between the value of the detected bit at the output of the summer and the output of the detector. Other measures for the equalizer are possible. For more details, see Proakis (1989).

4.10 Summary of Modulation and Demodulation Processes

In this section, we studied the modulation and demodulation processes that are applicable to GSM and DECT (and its North American variant PWT). Since baseband signals are can only be transmitted over short distances with wires and require very long antennas to transmit them without wires, the baseband signals are modulated onto radio frequency carriers. First, we studied amplitude shift keying (ASK) to determine its probability of error and methods for demodulation. From ASK, we studied phase modulation and the specific form ($\pi/4$-DQPSK) used for PWT. We showed that $\pi/4$-DQPSK has the same shaped error rate curve as ASK, but the signal-to-noise ratio definition is different. We then studied MSK, a form of frequency modulation, as a first step toward GMSK, which is used for DECT and GSM. Based on the literature, the error performance for GMSK also has the same shaped curve as ASK with the proper definition of a correcting factor α. For GSM where $BT = 0.3, \alpha \approx 0.9$; for DECT where $BT = 0.5$, $\alpha \approx 0.97$.

We then presented methods and block diagrams for recovery of clocks used for the carrier frequency and phase, the bit timing, and the framing for various modulation methods. While our block diagrams are based on hardware approaches, they could just as easily be implemented in software in many cases. We also explained that many manufacturers have proprietary methods for determining clock recovery techniques. Finally, we studied equalization techniques.

Data Communication Concepts

Vijay K. Garg
Department of Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, Illinois, USA

Yih-Chen Wang
Lucent Technologies, Naperville, Illinois, USA

5.1 Introduction to Data Networking

The explosive growth of Internet and its applications have made the use of data networks essential for many people's daily lives. The advanced data networking technologies will soon combine data, voice, and multimedia applications on a single platform for an economic reason. We introduce fundamental concepts of **data communication and networking** and also describe important data networking technologies that will shape the future of communication networks.

5.1.1 Fundamental Concepts and Architecture of Data Communication and Networking

The changing face of the communication industry was started with the marriage of computer and communication technologies in 1984 when AT&T was divided into seven Regional Bell Operation Companies (RBOC). The change has shaped the fabrics of society. Paper mail to electronic mail, shopping mode to online shopping, and libraries to digital libraries have changed day-to-day life. All the changes are the results of advanced communication and networking technologies. In this section, we explain the concepts and terms that will help the reader understand different communication and networking technologies described in the later subsections.

Transmission, Data, and Signals

Transmission is the communication of data that is propagated and processed from one point in a network to another point in the network by means of electrical, electromagnetic, or optical signals. The terms **digital** and **analog** are often used in the contexts of transmission, data, and signals. This leads to the following six definitions:

- **Digital data** is a source entity of which meaning has discrete values, such as the text or integers.
- **Analog data** is a source entity of which meaning has continuous values, such as voice or video.
- **Digital signal** is a sequence of voltage pulses that can only be transmitted over certain wired media.
- **Analog signal** is continuously varying electromagnetic wave that could be transmitted over a variety of wired and wireless media.
- **Digital transmission** is a transmission system that is concerned about the content of data it transmits or receives. It can carry either digital data or analog data with either a digital signal or an analog signal.
- **Analog transmission** is a transmission system that is not concerned about the content of data it transmits or receives. It can carry either analog data or digital data with an analog signal only.

Combinations of Data and Signals

There are four possible combinations of data and signals. For each combination, this discussion provides examples of applications and techniques to encode data. Note that a digital transmission system can use each of the four combinations for its applications, but an analog transmission system can only use an analog signal to carry either digital data or analog data.

Digital Data and Analog Signal

One example of this combination is that a PC or terminal connects to a remote host via a telephone network with a voice-grade modem. The modem modulates digital data to the characteristics of an analog carrier signal. These characteristics are the frequency, amplitude, and phase of the carrier signal. The modem uses one or any combination of the following three basic techniques as shown in Figure 5.1.

- **Amplitude-shift keying (ASK):** In this technique, binary values are represented by two different amplitudes of a carrier signal. The binary value 0 could be represented by a lower amplitude, while a binary 1 could be represented by a higher amplitude.
- **Frequency shift keying (FSK):** In this technique, the two binary values are represented by two different frequencies. In the full duplex FSK, one set of frequencies could be designated for one direction of the communication, while the other set could be designated for an opposite direction of the communication. For example, a set of frequencies (1070 Hz, 1270 Hz) is used for one direction of the communication, and the other set (2070 Hz, 2075 Hz) is used for other direction of the communication.
- **Phase-shift keying:** In this technique, the phase of the carrier signal is shifted to a certain degree of phase to represent the binary value. In the simplest case, no shift can represent the binary 0, while a shift of 180° can represent the binary 1. If a carrier signal can produce four phases, such as no shift, shifting to 90°, shifting to 180° and shifting to 270°, then each phase could represent two bits. Therefore, no shifting can represent 00, the shifting to 90° can represent 01, the shifting to 180° can represent 10, and the shifting to 270° can represent 11.

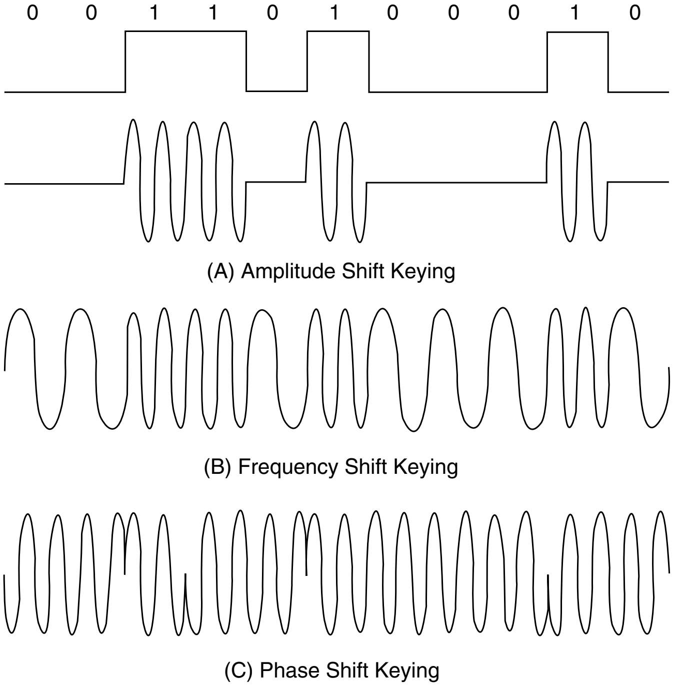

FIGURE 5.1 Three Basic Techniques

Analog Data and Digital Signal

An example of the combination is the *T*1 carrier carrying voice signal from a switching local office to another switching local office via a tandem switch. The voice is converted into a stream of digital bits that are carried by digital signal with some encoding scheme. The receiving system would then convert the stream of digital bits back to the original analog voice. Another example of the combination is compact disc audio.

The basic technique for this combination is called **pulse code modulation** (PCM). PCM takes the samples of analog data at the sampling rate that is twice the highest signal frequency and then assigns each sample to a binary code. The analog data is quantized into 8 steps (0 to 7), an each binary code will have 3 bits assigned to it. According to the Nyquist's sampling theorem, the samples contain all information of the original signal and can be reconstructed from these samples. The generated bit stream will be 011110111111110100011100110.

Digital Data and Digital Signal

One example of the combination is a text file transfer via a baseband ethernet local area network where digital signal is used. There are many different digital encoding techniques for this combination. The techniques are summarized as below:

- Nonreturn to zero level (NRZ-L)
- Nonreturn to zero inverted (NRZI)
- Manchester encoding
- Differential manchester encoding
- Bipolar with 8-zero substitution (B8ZS)
- High-density bipolar 3 zeros (HDB3)

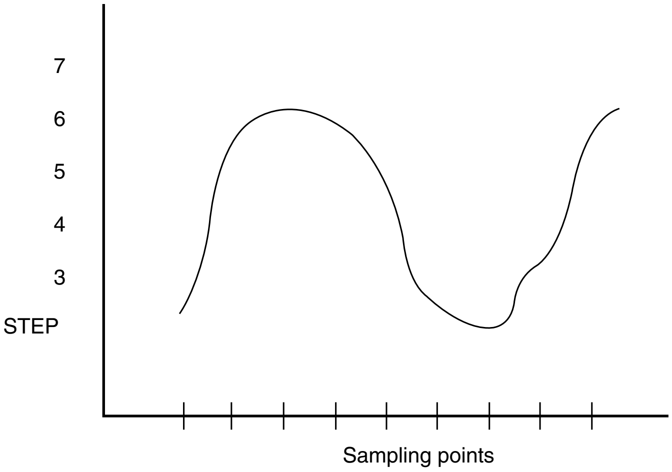

FIGURE 5.2 Pulse Code Modulation

Analog Data and Analog Signal

One example of the combination is the analog CATV or traditional telephone network. The techniques used in this combination are similar **to modulations** of a modem.

The modulation is required to provide a higher frequency for more efficient transmission or allow multiple user transmission using frequency modulation. The three modulation techniques amplitude modulation (AM), phase modulation (PM), and frequency modulation (FM) are used.

5.1.2 Advantages of Digital Transmission

The industry has been gradually converting an analog transmission system into a digital transmission system due to the cost, quality, and capacity of the digital transmission system. The evolution of integrated service digital network (ISDN) and digital subscriber line (DSL) to replace the analog local loop and the conversion of analog CATV into a digital CATV are examples of conversion into a digital transmission system. The following is a list of benefits for a digital transmission system:

- **The digital transmission system is cheaper**. The technique for designing and manufacturing a digital circuitry is more advanced and cheaper. The very large scale integration (VLSI) technique allows for mass production of a circuitry at lower cost.
- **Transmission quality is higher**. With the digital transmission system, transmission noise is not accumulated with the use of a repeater. A repeater recovers an incoming signal based on the content and regenerates a fresh signal; an amplifier used by an analog transmission system amplifies a noise component as well so that noises are accumulated in an analog transmission system.
- **A digital transmission system has higher capacity**. Time division multiplexing (TDM) instead of frequency division multiplexing (FDM) is used in a digital transmission system. TDM shares the entire bandwidth by all users, and the waste of bandwidth can be reduced to a minimum. The granularity for a time slot is also more flexible than a subfrequency of an FDM. Therefore, the bandwidth utilization is much higher for a digital transmission system, allowing digital CTAV to accommodate more than 100 channels.
- **The system enables security and privacy**. The most important tool for transmission security and privacy is the use of encryption. The encryption uses a cipher algorithm to replace information with a ciphertext (output of a cipher algorithm) using some mathematical algorithm. Digital transmission system makes the manipulation of digital information much easier.
- **The system enables easier integration of multiple data types.** The digital transmission system deals with digital information only. This makes for easier control and integration of multimedia applications.

Bit Rate Per Second Versus Baud Rate

Many people use **bit rate per second** (bps) and **baud rate** interchangeably, which is not correct. The bps is defined as the number of binary bits transmitted per second, while Baud rate is defined as the number of signal elements or states transmitted per second. Frequency, amplitude, or phase can be considered as signaling elements. If a modem only uses two frequencies signaling elements in the transmission, the baud rate of the modem is equal to bps, where the higher frequency can represent a binary 1 and a lower frequency can represent a binary 0. If a modem uses four frequencies to represent signaling elements, then each frequency can represent two binary bits. For example, 00 corresponds to the first frequency, 01 corresponds to the second frequency, 10 corresponds to the third frequency, and 11 corresponds to the last frequency. In this case, a baud rate is equal to 2 bps.

Maximum Data Rate

Some factors can limit the maximum transmission rate of a transmission system. Nyquist's theorem specifies the maximum data rate for noiseless condition, whereas the Shannon theorem specifies the maximum data rate under a noise condition.

The **Nyquist theorem** states that a signal with the bandwidth B can be completely reconstructed if 2B samples per second are used. The theorem further states that:

$$R_{\max} = 2B \ \log_2 M, \tag{5.1}$$

where $R_{\max}$ is the maximum data rate and M is the discrete levels of signal.

For example, if a transmission system like the telephone network has 3000 Hz of bandwidth, then the maximum data rate $= 2 \times 3000 \log_2 2 = 6000$ bits/sec (bps).

The **Shannon theorem** states the maximum data rate as follows:

$$R_{\max} = B \ \log_2 (1 + S/N), \tag{5.2}$$

where S is the signal power and N is the noise power.

For example, if a system has bandwidth B = 3 kHz with 30-dB quality of transmission line, then the maximum data rate $= 3000 \log_2 (1 + 1000) = 29,904$ bps.

5.1.3 Asynchronous and Synchronous Transmission

To determine what bits are constituted as an octet (character), two transmission techniques are used.

- **Asynchronous transmission**. In this technique, each character is enclosed with a start bit, 7 or 8 data bits, an optional parity bit, and stop bits. The gap between character transmission is not necessarily fixed in length of time. It is cheaper but is less efficient. For example, assume that there are 1 stop bit and 1 start bit in the asynchronous transmission with 8 bits of character; the efficiency is only 80% (fixed).

- **Synchronous transmission**. In this technique, all characters are blocked together and transmitted without a gap between two characters being transmitted. It requires more complicated hardware to handle buffering and blocking, but this hardware more efficient. For example, assume that there are 240 characters and 3 SYN characters in one block. Then the number of data bits $= 240 \times 8 = 1920$ bits, the number of SYN character bits $= 3 \times 8 = 24$ bits, and efficiency $= 1920/1944 \sim 99\%$ variable efficiency; the larger the block is, the higher the efficiency.

Transmission Impairments

The signal received may differ from the signal transmitted. The effect will degrade the signal quality for analog signals and introduce bit errors for digital signals. There are three types of **transmission impairments**: attenuation, delay distortion, and noise.

(1) **Attenuation:** The impairment is caused by the strength of signals that degrades with distance over a transmission link. Three factors are related to the attenuation:
  - The received signal should have sufficient strength to be intelligently interpreted by a receiver. An amplifier or a repeater is needed to boost the strength of the signal.
  - A signal should be maintained at a level higher than the noise so that error will not be generated. Again, an amplifier or a repeater can be used.
  - Attenuation is an increasing function of frequency, with more attenuation at higher frequency than at lower frequency. An equalizer can smooth out the effect of attenuation across frequency bands, and an amplifier can amplify high frequencies more than low frequencies.

(2) **Delay distortion:** The velocity of propogation of a signal through a guided medium varies with frequencies; it is fast at the center of the frequency, but it falls off at the two edges of frequencies. Equalization techniques can be used to smooth out the delay distortion. Delay distortion is a major reason for the timing jitter problem, where the receiver clock deviates from the incoming signal in a random fashion so that an incoming signal might arrive earlier or late.

(3) **Noise:** Impairment occurs when an unwanted signal is inserted between transmission and reception. There are four types of noises:
  - **Thermal noise:** This noise is a function of temperature and bandwidth. It cannot be eliminated. The thermal noise is proportional to the temperature and bandwidth as shown in the equation: thermal noise $= K$(constant) *temperature *bandwith.
  - **Intermodulation noise** This noise is caused by nonlinearity in the transmission system $f1$; $f2$ frequencies could produce a signal at $f1 + f2$ or ABS $(f1 - f2)$ and affect the frequencies at $f1 + f2$ or ABS $(f1 - f2)$.
  - **Cross talk:** This type of noise is caused by electrical coupling in the near by twisted pair or by unwanted signal picked by microwave antennas. For example, sometimes when you are on the telephone, you might hear someone else's conversation due to the cross talk problem.
  - **Impulse noise:** Irregular pulses and short duration of relative high amplitude cause impulse noise. This noise is also caused by lightning and faults in the communication system. It is not an annoyance for analog data, but it is an annoyance for digital data. For example, 0.01 sec at 4800 bps causes 50 bits of distortion.

Error Detection and Recovery

Due to the transmission impairments, a message arriving at the receiving station might be in error. The receiving station will detect the error and might ask the sending station for a retransmission. It is very rare that the receiving station would correct errors. The approach for requesting a retransmission when an error is detected is called **forward correction**. The error detection is mostly done at the data link layer that is the second layer of the network architecture although some error detection schemes might be done at the first layer, the physical layer of the network architecture. The error detection schemes that have been used are described below. The cyclic redundancy check (CRC) is a most commonly used error detection scheme at the data link layer.

- **Single parity checking:** This scheme appends a parity bit to the character to be transmitted to make the total number of binary ones in one character be either odd or even. An odd parity checking or an even parity checking has to be agreed between a transmitter and receiver. The problem of this approach is that the even number of bits changed will make the number of ones for being odd or even, and the parity bit error cannot be detected.
- **Two coordinated parity checking:** The scheme checks for the parities for a block of characters and not just for a single character. The parities are added horizontally and vertically within a block of characters to produce a block check character (BCC). BCC is appended to the end of a block to be transmitted. Table 5.1 illustrates the error detection scheme. Assume that odd parity checking is used.

TABLE 5.1 Error Detection Scheme

Data bits	Parity
0010010	1
1001001	0
0100101	0
0000001	0

In Table 5.1 the last row with numbers 00000010 (including the parity bit) is the BCC. The scheme will not work if there are an even number of bits changed horizontally and/or vertically. Even the BCC will be different, but all is correct for the odd parity checking.

Cyclic Redundancy Check

For a **cyclic redundancy check**, the scheme selects a standard defined 8 bits, 10 bits, 12 bits, 16 bits, or 32 bits of a constant check data. A constant check data is normally represented as a polynomial constant. For example, the polynomial $x^3 + x^2 + 1$ is the check data bit of 1101. A data message that could be thousands of bytes is divided by the polynomial constant with exclusive or bit-by-bit operation. The remainder of the division is the CRC that is appended at the end of a frame or block. With the above example, the CRC will be 3 bits long. The receiving station takes the data it receives and performs the same computation with the same polynomial constant. If the computed CRC is equal to the CRC in the received message, it is fine; otherwise an error has occurred. The CRC error detection scheme cannot detect all errors at all times. In the case of an error pattern being the multiples of the polynomial constant, the error cannot be detected. Therefore, it is very important to select a polynomial constant that has low probability of being generated in a transmission environment.

5.1.4 Sharing of Network Nodes and Transmission Facility Resources

It is very economically infeasible to have one dedicated physical link between any two computers on a network. Networking nodes and the transmission facility must be shared. **Multiplexing** allows for a physical link to be shared by multiple users to fully use the link and reduce the number of input/output (I/O) ports required for a computer. Switching techniques avoid a creation of the mesh or complete topology where two computers are directly connected in a network. Direct connection increase the cost of I/O ports on each computer and transmission links. Multiplexing is also very inflexible without the use of switching if the direct link between two computers is broken.

Multiplexing

As the list below indicates, there are three multiplexing techniques.

- Time division multiplexing (TDM)—synchronous TDM: Multiple digital signals or analog signals carrying digital data can be carried on a single transmission path by interleaving portions of each signal in time. The interleaving interval can be one bit, one octet, or one block of a fixed size of octets. Each signal or connection path takes a fixed time slot but use the whole bandwidth of the link. "Dummy" information will be sent on the slot even if there is no data for the connection. This wastes the capacity of the transmission bandwidth.
- Frequency division multiplexing (FDM): A number of signals can be carried simultaneously on the same transmission link with each signal being modulated into a separate frequency. The bandwidth of each signal is reduced due to the division of multiple channels. Digital and analog data can both be supported. CATV is an example of the use of FDM.
- Statistical TDM (asynchronous TDM or intelligent TDM): The time slots are not preassigned for a signal or connection path. They are allocated on a demand basis. There is no waste of bandwidth. A terminal number is included in the message to identify where the message came from. The output rate is designed to be less than the sum of data rates of all inputs. At the peak load, total inputs might exceed output capacity, then backlog will be built. The trade-off is between the size of buffers and the rates of total inputs to be supported.

5.1.5 Switching

Switching techniques avoid direct connections between any two computers on a network. These techniques not only save the cost of transmission links but also provide the flexible and reliable connections between any two computers on the network. There are two major switching techniques: one is mainly used in the telephone network, and the other is used in data and other telecommunication networks. The message switching is rarely used, but it is described here for completeness.

Circuit Switching

A connection between the calling station and the called station is established on demand for exclusive use of the physical connection. Three phases of a circuit switching connection exist; (1) connection establishment phase requires a separate setup signal to send and the acknowledgement signal to receive; (2) The data transfer phase has no interruption to the data transfer; and (3) the termination phase allows the release of the resource so that other connection, can use the resource. The switching technique does not require buffers or queues and is free of congestion. Long setup time may cause undesirable delay, which is rather inefficient if no data are being transferred. Appropriate applications may have relatively continuous flow, such as voice, sensor, and telemetry inputs.

Message Switching

An entire message, like an e-mail or a file, is transmitted to an intermediate point, stored for a period of time, and an transmitted again toward its destination. The address of the destination is included in the message.

No dedicated path is established between two stations. The delay at each intermediate point is the time to wait for all messages to arrive; plus, there is a queuing delay in waiting for the opportunity to retransmit to next node.

The line efficiency for message switching is greater than for circuit switching because the transmission line is shared over time but not at the same time for multiple messages. Simultaneous availability of sender and receiver is not required, and the message priority can be established in the message switching. Because a connection is not needed, the line has a flexible routing capability and the capability for sending the same message to multiple destinations. With buffering capability, congestion problems will be reduced. Any error detected requires retransmission of the entire message. If the message is a megabytes file, the whole file will need to be retransmitted. No overlap of transmission is possible. Message switching is generally not suitable for the interactive traffic due to a long delay.

Packet Switching

A message is divided into a number of smaller packets, and one packet at a time is sent through the network. There are two approaches in packet switching: (1) **datagram** will not need to establish a connection path, and each packet is treated independently; and (2) the **virtual circuit** approach requires that a connection be established, and all packets will need to go over that connection path. There is less overhead on the retransmission as the packet is smaller; overlap of the transmission is possible. Virtual circuit is more suitable for interactive traffic because it has smaller delay.

Communication Network Architecture

Vijay K. Garg
Department of Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, Illinois, USA

Yih-Chen Wang
Lucent Technologies, Naperville, Illinois, USA

6.1 Computer Network Architecture

Computer network architecture refers to a set of rules that allow for connectivity among a large number of computers. This set of rules is also called **communication protocols**. To simplify the complexity of network design, the communication functions are divided into several levels of abstractions. Each level or layer of the protocol is designed in such a way that the change to one layer normally does not affect adjacent layers. The services of higher layers are implemented to use the services provided at lower layers. There are two interfaces at each layer. One is the peer-to-peer protocol between two computers. The other is the service interface to its adjacent layers on the same computer. Peer-to-peer protocol between two computers mostly regards indirect communication, and the direct communication only occurs at the lowest layer or hardware level. Each higher layer of protocol adds its own header information to the data message it receives from its higher layer of protocol before it passes the data message to its lower layer. This process is called **encapsulation**. The receiving system reverses the process, called **decapsulation**, by removing the header at each layer before passing the data message to its upper layer. Two prevalent network architectures are described in this section.

6.1.1 Open System Interconnection

Open System Interconnection (OSI) is an International Standard Organization (ISO) standard that defines computer communication network architecture. It is a well-defined network architecture, but the implementation of its network protocols is very rare. When its draft standard came out in 1985, many predicated that the implementation of network protocols would predominate in the industry. The prediction was incorrect due to the wide use of Internet protocols in 1985. However, OSI represents a very powerful network reference model to which all communication technologies refer their architecture (see Figure 6.1). This also includes the most popular TCP/IP architecture.

OSI divides the communication functions into seven layers of which functions are described in the following list.

- **Physical layer**: This layer is responsible for activating and deactivating physical connections upon request from the data link layer and transmitting bits over a physical connection in a synchronous or asynchronous mode. It also handles very limited error control, like single-character parity checking.
- **Data link layer:** This layer is responsible for establishing and releasing data link connections for use by the network layer.

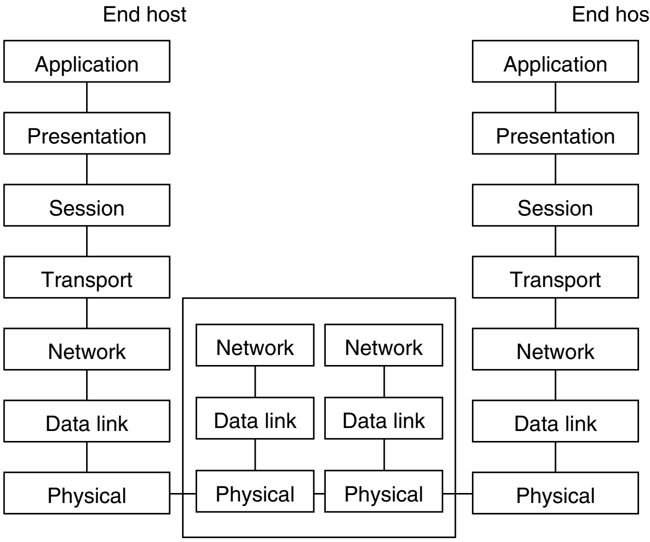

FIGURE 6.1 OSI Network Reference Model

- Network layer: Responsibilities of this layer include providing the data integrity transmission for a point-to-point connection so that data will not be lost or duplicated. The layer accomplishes this task by maintaining a sequential order of frames that are transmitted over a data link connection and detecting and correcting transmission errors with retransmission of the frames, if necessary. The other important function in the data link layer is to provide flow control, which is a way to allow the receiving station to inform the sending station of stopping transmission for a moment so that the receiver will not overload its buffers.
- Network (packet) layer: Two major functions in the network layer are **routing control** and **congestion control**. Routing control is the process for maintaining a routing table and determining optimum routing over a network connection. Congestion control is needed when there are too many packets queued for a system and there is no space to store them. This is normally happens in a datagram-type of connection, where the network resources for a connection are not preallocated. The network layer is also responsible for multiplexing multiple network connections over a data link connection to maximize its use. Flow control is provided at the network layer as well.
- Transport layer: This layer provides error-free end user transmission. To improve the utilization, it multiplexes multiple transport connections over a network connection. It controls data flow to prevent from overloading network resources just like the flow control function provided at the data link and network layers. This layer and layers above it are end-to-end, peer-to-peer protocols, for which their protocol data units (PDU) are processed between two end systems. The layers below the transport layers are the point-to-point, peer-to-peer protocol where the PDUs are processed only between two computer systems connecting together.
- Session layer: Providing management activities for transaction based applications, this layer ties these application streams, together to form an integrated application. For example, a multimedia application may consist of the transport of data, fax, and video streams that are all managed at the session layer as a single application.
- Presentation layer: This layer is responsible for performing any required text formatting or text compression. It negotiates the choice of syntax to be used for data transfer.
- Application layer: To provide an entry point for using OSI protocols is one task of this layer. This task can be accomplished by providing either the Application Programming Interface (API) or standard UNIX I/O functions, like open(0), close(0), read(), and write() functions.

The layer also performs common application functions, such as connection management, and provides specific application functions, like file transfer using File Transfer and Access Management (FTAM), Electronic Mail (X.400), and Virtual Terminal Protocol (VTP).

6.1.2 TCP/IP Network Architecture

The **TCP/IP network architecture** also refers to the Internet architecture. The Transmission Control Protocol (TCP) is a transport layer protocol, and the Internet Protocol (IP) is a network layer protocol. Both protocols were evolved from a earlier packet switching network called ARPANET that was funded by the Department of Defense. The TCP/IP network has been the center of many networking technologies and applications. Many network protocols and applications are running at the top of the TCP/IP protocol. For example, the Voice over IP (VOIP) and the Video Conference application using MBONE are the applications running over the TCP/IP network. The TCP/IP network has the corresponding five layers in the OSI reference model. Figure 6.2 shows the

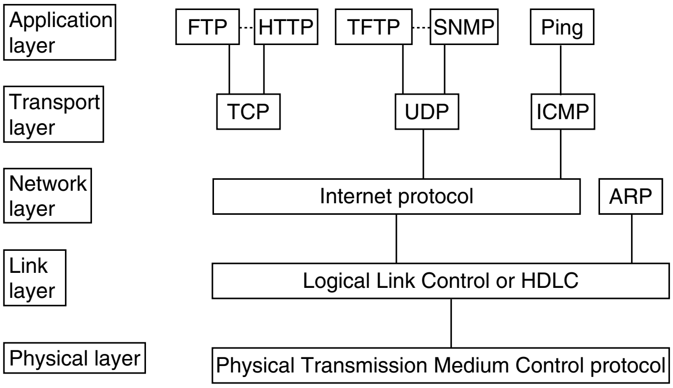

FIGURE 6.2 TCP/IP Network Architecture and Applications

layers of the TCP/IP network and some applications that might exist on the TCP/IP networks. The standard organization for the TCP/IP-related standard is the Internet Engineering Task Force (IETF), which issues Request-for-Comment (RFC) documents. Normally, IETF requires that a prototype implementation be completed before an RFC can be submitted for comments.

6.2 Local Networking Technologies

This section describes the **local area network** (LAN) and **metropolitan area network** (MAN) technologies. The dramatic and continuing decrease in computer hardware cost and an increase in computer capability have increased the usage of single-function systems or workstations. One has the desire to interconnect these single function systems and workstations together for variety reasons. The major reasons are to exchange data between systems, to share expensive resources, to improve the performance for real-time applications, and to improve the productivity of the employees.

LAN is a communication network that supports variety of devices within a small area. The small area could be a single building or a campus. MAN is the communication network that spans a larger geographic area than LAN and could be an area consisting of a few blocks of buildings or even a large metropolitan area. The characteristics of LAN are high data rate, short distance, low error rate, shared medium, and single organization ownership (typically).

This section describes the general technologies used by a LAN, the internetworking with bridges and routers, and the performance of local network. General technologies include the transmission media, topologies, and Medium Access Control (MAC) protocol.

6.2.1 Technologies of Local Networks

The nature of a local network is very closely tied to the technologies it uses. The key technologies are the topology, transmission medium, and MAC protocol. Unlike a wide area network (WAN), LAN is a shared medium network, and the choice of a transmission medium impacts the topology it can use. These key technologies are closely related to each other. For example, a twisted pair medium is more suitable for the star topology. Each type of technology is described in separate subsection in this chapter.

Local Network Topologies

Topology is the manner in which network interface devices and transmission links are interconnected. There are two reasons to study the topologies for LAN as well as for WAN. One is that the mesh (complete) topology, which allows for every two devices to be directly connected via a dedicate link, is economically infeasible. The other reason is that different topologies would provide flexibility for applications and the reliability for the connections.

For each topology, one should consider the **characteristics**, **reliability**, **expandability**, and **performance**. The characteristics of a topology should consider the connectivity of devices, the components required (e.g., tap or splitter, etc.), and the transmission. The reliability addresses how a node failure or cable break would affect the operation of the network. The expandability addresses the ease of adding a new station to the network, and the performance should consider the delay characteristics of the topology. The topologies used in the local networks are star, ring, and bus/tree. Table 6.1 summaries these topologies.

Transmission Media

The **transmission medium** is a physical transmission path between two devices. A transmission medium could be a guided hard-wired medium (e.g., the twisted pair cable used in the telephone network), a coaxial cable used by CATV, or optical fiber. It could be an unguided medium through atmosphere, such as microwave, laser, or infrared. Most LANs use the guided transmission medium in a building. The unguided medium would be used when there is a need to connect two LANs in different buildings and when the digging of the ground between two buildings is very difficult. Until recently, wireless LAN using microwave radio at the same building or nearby buildings has become a very popular way to connect portable devices together in the network with the data rate up to 10 Mbps.

Of the three hard-wired media (e.g., the twisted pair, coaxial cable, and optical fiber), the use of coaxial cable in local networks has started to phase out due to its heavier weight and inflexibility to bend. The twisted pair is popular for lower speeds (100 Mbps or less) of a local network, whereas the optical fiber is more suitable for higher speeds (hundreds of megabits per second or higher) of a local network. Of two unguided media used in local networks, the microwave is used to connect two LANs at different buildings, but both microwave and infrared can be used for wireless LANs.

In choosing a transmission medium for a local network, one should consider the following factors:

- Cost of installation of transmission medium
- Connectivity
- Transmission characteristics
- Topology constraints
- Distance coverage
- Environmental constraints

Medium Access Control Protocol for Local Networks

In the local network environment, multiple stations on the network share a transmission medium. If more than one station is transmitting at the same time, the transmission will be corrupted. **Medium Access Control** (MAC) protocol is

TABLE 6.1 Various Topologies for LAN

Topology	Star	Ring	Bus/Tree
Characteristics	Stations are connected to a central hub or star coupler, which serves as a relay point.	Each station is connected to a repeater, and all repeaters are connected to form a closed loop or ring. Signal is traveling unidirectional along the ring. There is no buffering at each repeater.	More than one station is connected to a shared medium. When a signal is transmitted on the medium, it will travel in both directions; then the signal is absorbed at both ends by the terminators.
Reliability	Station failure would not cause a failure of the network, but a failure on the hub or coupler would disable the network operation. A break of the cable would isolate only one station from the network.	Station failure would not affect the network, but the repeater failure may disable the network unless repeater bypass logic is implemented. A cable break would disable the network transmission unless a self-configuration dual ring network is installed.	Station failure would not affect the network operation, but the cable break would disconnect the network and produce the reflection that could interfere with the transmission.
Expandability	Adding a new station to the network involves only wiring from the station to the hob or the coupler.	If a multiple access unit (MAU) is equipped, the adding of a new station just involves the wiring between the station and the MAU.	The addition of a new station is easier and would not need to bring down the network for addition of a new station.
Performance	The number of ports on hubs or couplers limits the capacity of the network. The delay on a hub or coupler is very small.	There is a least 1-bit delay at each repeater. The round-trip delay would include the propagation delay, transmission delay, and repeater delay. The number of stations on a ring network is limited for the performance concern.	The performance of LAN using bus/tree topology depends on the bandwidth of the network, the number of active stations on the network, and the kind of medium access protocol being used.

needed to regulate an access to the common medium. There are two approaches for control of the multiple transmissions. In the **centralized approach**, a station on the network is designated as a primary station, and the rest of the stations are the secondary stations. All communications have to be polled and selected by the primary station. The primary station polls for a secondary station on the network for transmission and then selects a specific secondary station for the reception of a message. There is no direct transmission between any two secondary stations. In the **distributed approach**, each station has a MAC to decide when it can transmit, and the direct transmission occurs between any two stations. The distributed approach is currently used by most local networks. The advantages and disadvantages of the centralized approach are in the following list. Note that the opposite of the advantages and disadvantages on the list would become the disadvantages and advantages of the distributed approach, respectively.

The advantages of **centralized approach** are as follows:

- Greater control over access for providing priorities, overrides, and bandwidth allocation
- Simple logic at each station
- Avoidance of the coordination problem

The disadvantages of centralized approach are as follows:

- Disabling of entire network due to single point of failure
- Reduction of the efficiency of network operation caused by overhead imposed on the primary station

The MAC protocols for local networks are specified in a series of IEEE802 standards. The fiber data distribution interface (FDDI) for MAN is specified in the ANSI ASC X3T9.5 committee. The popular local network standards are listed as follows:

- IEEE 802.2—Logical Link Control
- IEEE 802.3—Carrier Sense Multiple Access/Collision Detection (CSMA/CD)
- IEEE 802.4—Token Passing Bus
- IEEE 802.5—Token Passing Ring
- IEEE 802.1—Wireless LAN
- ANSI X3T9.5—Fiber Data Distribution Interface

Before we describe each local network standard, we describe the local network architecture. The following subsections address the architecture and each standard.

6.2.2 Local Network Reference Model

Open System Interconnection (OSI) is an International Standard Organization (ISO) standard that defines computer communication network architecture. As mentioned before, all networking technologies describe their network architecture within the OSI reference model. How does a local network fit into the OSI's reference model? We need to determine what layers are required for a local network. The MAC protocol exists for each local network type and is considered part of the data link layer. The MAC protocol has the following deficiencies:

- The protocol only guarantees the transmission of frame onto the medium.
- There is no frame sequencing, and most MAC protocols do not acknowledge the receiving of a frame.
- There is no flow control between two stations.
- There is no retransmission for discard packets.
- It is a data gram-type of protocol, and frame can be lost.

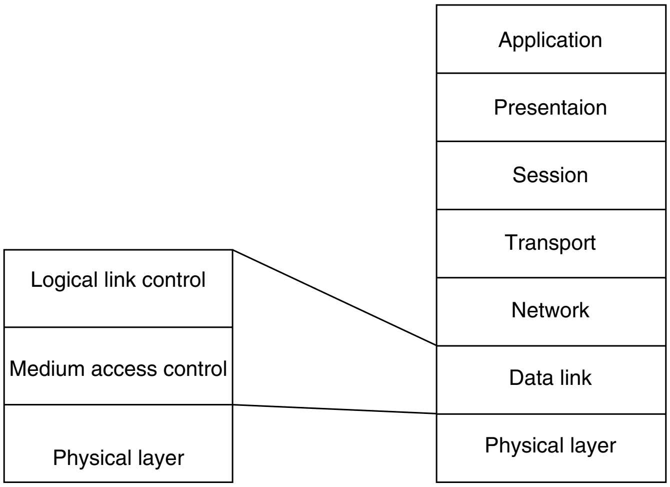

FIGURE 6.3 Local Network Reference Model

With these deficiencies, we need a data link layer above the MAC protocol to make up these deficiencies. Each frame carries the source and destination address in a local network, and all stations on the network will receive the frame through the shared transmission medium. Therefore, a routing function of the network layer within a local network is not required. Figure 6.3 depicts the local network architecture.

6.2.3 IEEE 802.2—Logical Link Control

Logical Link Control (LLC) provides conventional data link protocol functions, such as error control and flow control. LLC is very similar to several famous data link protocols, like Synchronous Data Link Control (SDLC) or High Level Data Link Control (HDLC) protocols. The only difference is that LCC includes the service access points (SAP) information in the frame to allow for multiple applications (programs) on one station to communicate simultaneously with other applications on other stations in the network.

LLC provides the following three services for a local network application:

(1) **Unacknowledged connectionless service**: This is a data gram-type of service, so there is no overhead to establish a connection. It provides no acknowledgment to ensure the delivery of a frame.
(2) **Acknowledged connectionless service**: This service provides acknowledgment to a frame received to relieve the burden in the higher layer.
(3) **Connection-oriented service**: This service provides flow control, sequencing, and error recovery between SAPs. It also allows for multiplexing logical endpoints over a single physical link.

6.2.4 IEEE 802.3—Carrier Sense Multiple Access Collision Detection

Ethernet LAN, which was initially developed by Xerox, Digital, and Intel, used Carrier Sense Multiple Access/Collision Detection (CSMA/CD) technology many years ago. There has been a long evolution path for the CSMA/CD Medium Access Protocol. The following describes the precursors of CSMA/CD technology.

Pure ALOHA

Pure ALOHA technology was developed at the University of Hawaii to interconnect a packet radio network across multiple islands in Hawaii. The protocol has the following procedure:

(1) Frames are transmitted at will.
(2) The sending station listens for the time equal to the maximum possible round-trip delay.
(3) The station that receives the frame has to send an acknowledgment. If the acknowledgment is not received before the timer expires, the frame is retransmitted.
(4) The error is checked at the receiving station, which ignores all of erroneous frames.

The successful transmission for Pure ALOHA is only 18%.

Slotted ALOHA

Improvement of Pure ALOHA led to the creation of Slotted ALOHA. The procedures of the algorithm are as follows:

(1) Time on the channel is organized into a uniform slot, and each slot size is equal to a frame transmission time.
(2) A frame is transmitted only at the beginning of the time slot
(3) If the frame does not go through, the frame is sent again after a random amount of time.

The performance of the Slotted ALOHA is 37% empty slots, 37% success, and 26% collisions. This yields the successful transmission of 37%.

There are three problems with the ALOHA schemes. The first problem is the station not listening to the transmission medium before sending a packet. The second problem regards the station not listening to the transmission medium during the sending of the packet. The last problem involves the station not taking advantage of a much shorter propagation delay than the frame transmission time. The shorter propagation delay provides a fast feedback for the state of the current transmission. Various versions of CSMA have been proposed to solve only the first problem. The variants of CSMA schemes are dealing with what to do if the transmission medium is sensed to be busy. These CSMA schemes are described next.

Nonpersistent CSMA

In **nonpersistent CSMA**, if a frame is waiting for transmission, a station checks if the medium is idle and transmits the frame right away if the medium is idle. If the medium is busy, the station waits for a random amount of time and then repeats the same procedure to check if the medium is idle. The algorithm can reduce the possibility collisions, but there is waste due to the idle time.

1-Persistent CSMA

For **1-persistent CSMA**, the algorithm is used as part of the CSMA/CD. The procedure is as follows:

(1) A station checks if the transmission medium is idle, and then it transmits the frame if it is idle.
(2) If the medium is busy, the station continues to listen until the channel is idle, and then it transmits right away.
(3) If no acknowledgment is received, the station waits for a random amount of time and repeats the same procedure to check if the transmission medium is idle.

The scheme would guarantee a collision if more than one station were waiting for transmitting frames.

P-Persistent CSMA

The **p-persistent CSMA** algorithm takes a moderate approach between nonpersistent and 1-persistent CSMA. It specifies a value; the probability of transmission after detecting the medium is idle. The station first checks if the medium is idle, transmits a frame with the probability P if it is idle, and delays one time unit of maximum propagation delay with 1-P. If the medium is busy, the station continues to listen until the channel is idle and repeats the same procedure when the medium is idle. In general, at the heavier load, decreasing P would reduce the number of collisions. At the lighter load, increasing P would avoid the delay and improve the utilization. The value of P can be dynamically adjusted based on the traffic load of the network.

CSMA/CD is the result of the evolution of these earlier protocols and the additions of two capabilities to CSMA protocols. The first capability is the listening during the transmission; the second one is the transmission of the minimum frame size to ensure that the transmission time is longer than the propagation delay so that the state of the transmission can be determined. CSMA/CD detects a collision and avoids the unusable transmission of damaged frames. The following describes the procedures of CSMA/CD:

(1) If the medium is idle, the frame is transmitted.
(2) The medium is listened to during the transmission; if collision is detected, a special jamming signal is sent to inform all of stations of the collisions.
(3) After a random amount of time (back-off), there is an attempt to transmit with 1-persistent CSMA.

The **back-off algorithm** uses the delay of 0 to 2 time units for the first 11 attempts and 0 to 1023 time units for 12 to 16 attempts. The transmitting station gives up when it reaches the 16th attempt. This is the **last-in first-out unfair algorithm** and requires imposing the minimum frame size for the purpose of collision detection. In principle, the minimum frame size is based on the signal propagation delay on the network and is different between baseband and broadband networks. The baseband network uses digital signaling, and there is only one channel used for the transmission, while the broadband network uses analog signaling, and it can have more than one channel. One channel is used for transmitting, and another channel can be used for receiving. The baseband network has two times the propagation delay between the farthest stations in the network, and the broadband network has four times the propagation delay from the station to the headend, with two stations close to each other and as far as possible from the "headend." The delay is the minimum transmission time and can be converted into the minimum frame size.

The comparison of baseband and broadband in CSMA/CD schemes is as follows:

- **Different carrier sense (CS)**: Baseband detects the presence of transition between binary 1 and binary 0 on the channels, but broadband performs the actual carrier sense, just like the technique used in the telephone network.
- **Different collision detection (CD) techniques**: Baseband compares the received signal with a collision detection (CD) threshold. If the received signal exceeds the threshold, it claims that the collision is detected. It may fail to detect a collision due to signal attenuation. Broadband performs a bit-by-bit comparison or lets the headend perform collision detection by checking whether higher signal strength is received at the headend. If the headend detects a collision, it sends a jamming signal to the outbound channel.

High-Speed Ethernet-Like LAN

When an ethernet LAN has the speed of 100 Mbps or higher, it is classified as a high-speed ethernet LAN. The **high-speed ethernet-like LAN** is a natural evolution of low-speed traditional 10-Mbps LAN. IEEE specified two standards: 100BASE-T and 100VG-AnyLAN. Table 6.2 provides a comparison between 100BASE-T and 100VG-AnyLAN

TABLE 6.2 Comparison Between 100BASE-T and 100VG-ANYLN

	100BASE-T	100VG-AnyLAN
Standard	Part of IEEE802.3	IEEE802.12
Access protocol	CSMA/CD	Round Robin
Frame format	CSMA/CD 10BASE	CDMA/CD 10BASE or Token Ring
Maximum number of stations	1024	Unspecified
Frame size	1500 octets	1500 or 4500 octets
Distance coverage	210 m	2.5 Km
Topology	Star Wired	Hierarchical Star/Tree

The 100BASE-T network has several options of cabling schemes that are listed as follows:

- **100BASE-TX**: Each station uses two category 5 Unshielded Twisted Pair (UTP) or Shielded Twisted Pair (STP). One pair is for transmitting, and the other pair is for receiving.
- **100BASE-FX**: Each station uses two optical fibers. One is for transmitting, and the other is for receiving.
- **100BASE-T4**: Each station uses four pairs of category 3 UTP, three pairs for transmission, and one pair for collision detection.

Each station is connected to a multipoint repeater, and each input to the repeater is repeated on every output link. If two inputs overlap, a jam signal is transmitted on all output links. The class 1 repeater can support mixtures of transmission media types; a class 2 repeater can support only the same transmission media type, but it can interconnect with another class 2 repeater. Each network can be configured as either a **full duplex** or **half duplex**. The full duplex operation requires a switch hub and not a multipoint repeater. In the full duplex operation, each station would own the entire bandwidth of the network. In the half duplex operation, each station would share the bandwidth of the transmission medium. To support a mixture of speeds on a network, each device can send link integrity pulses to indicate the speed it supports. The process is called **autonegotiation**. The priority order in the technology ability field used in the 100BASE-T autonegotiation scheme is based on the highest common denominator regarding abilities. The 100BASE-T4 medium has the higher priority than the 100BASE-FX, and the 100BASE-T4 provides for the operation over a wider range of twisted pair cables and, therefore, is more flexible. The 10BASE-T is the lowest common denominator and has the lowest priority. In general, a full-duplex capability can also operate in half duplex mode and, hence, has a higher priority. The priority is assigned in the following order from highest to lowest:

- 100BASE-TX full duplex
- 100BASE-T4
- 100BASE-TX
- 10BASE-T full duplex
- 10BASE-T

Gigabit Ethernet

Due to the popularity of ethernet, the IEEE802 committee has also defined the standard for **gigabit ethernet**. A 10-gigabit ethernet has been made commercially available. Some of the requirements for this gigabit ethernet are as follows. This ethernet:

(1) Needs high speed for backbone network;
(2) Should provide a smooth migration from a 100-Mbps ethernet to gigabit ethernet;
(3) Is an alternative to ATM and FDDI for backbone connection; and
(4) Should work for copper wires and optical fiber.

A gigabit ethernet uses the same CSMA/CD protocol in a same-frame format. It can provide for a 100-Mbps traffic load as a backbone network. There are some differences however, with a previous version of ethernet, which are listed as follows:

1. A separate Gigabit Medium Independent Interface (GMII) defines an independent 8-bit parallel transmission and receives synchronous data interface. GMII is optional for all of transmission media except UTP. It is a chip-to-chip interface between MAC and physical hardware.
2. Two encoding schemes are 8B/10B for fiber and shielded copper and a 4-Dimensional 5-Level Pulse Amplitude Modulation are (4D-PAM5) for UTP.
3. A Carrier Extension Enhancement appends a set of symbols to a short MAC frame to a resulting block of at least 4096 bits, so transmission time is longer than the propagation time.

6.2.5 IEEE 802.4—Token Passing Bus Protocol

With the **IEEE 802.4 Token Passing Bus Protocol**, each station is assigned a logical position in an ordered sequence in a physical bus topology and a logical ring. Each station knows its logical preceding and successor addresses. A token frame regulates the access of medium. When finishing a transmission or when time elapses, a token is passed to the next station in the logical ordering. Each station can only transmit a frame when it holds a token *except* when a non token-holding station responds to a poll or a request for acknowledgment. There are several token maintenance events described in the following paragraphs.

Ring Initialization

This event occurs when a logical ring is broken or a network has just powered up and the system needs to determine which station can hold the token first. The event will trigger the following steps at each station:

(1) Arbitrary length (multiples of time slots) of a claim token is issued based on the first two bits of its address field. For example, 00 will be mapped to one time slot, 01 will be mapped to two time slots, 10 will be mapped to three time slots, and 11 will be mapped to four time slots.
(2) A station drops its claim after transmitting its claim token and then hears anything transmitted on the bus; otherwise, it tries to claim a token at the next iteration with the next two address bits. A station uses all of its address bits; if the station succeeds on the last iteration, it is considered a token holder.

Addition to Ring

The occurrence of an event is used for the expansion of a network. This occurrence is used to grant opportunity for a nonparticipating station to join in the network. The event follows these steps:

1. Each station periodically issues a solicit-successor frame to invite any nonparticipating station to join in the network.
2. If there is no response, the station transfers the token to its successor. If there is only one response, the station sets its successor to the requesting station and passes the token to the requesting node. It also indicates who is the requesting station's successor.
3. The station sends a contention resolution frame for the multiple responses and waits for any valid response. Each station can only respond in one of four time slot windows based on its two address bits and refrains from its claim if it hears anything before its window slot arrives. If the token holder station receives a valid set-successor frame, it passes the token to the demander. Otherwise, it tries for the next iteration. Only the stations that responded the previous time are allowed to respond.
4. If an invalid response is received, the station goes into an idle or listening state to avoid the conflict situation in which another station thinks it holds a token.

Deletion of a Station

The occurrence of event is when a station wants to separate itself from the network. The event triggers the following procedures:

1. A station waits for a token to arrive and then sends a set-successor frame to its preceding station to splice its successor.
2. The token holder station passes the token to its current successor as usual.
3. The station will then be deleted from the network in the next go-around.

A duplicated address or a broken logical ring would trigger the error recovery for the token bus protocol. Table 6.3 illustraties the error recovery procedures:

TABLE 6.3 Token Bus Error Recovery Procedures

Condition	Action
Multiple tokens	Drops tokens to 1 or 0
Unaccepted token (no valid frame is received)	Retries the sending token two times
Failed station after two tries of sending token	Sends the message of who follows the failed station frame
Failed receiver after another two tries of sending the message of who follows the frame	Enters listen state
No token activity	Becomes inactive with time out and initializes ring

Comparison of CSMA/CD and Token Bus

An ethernet using CSMA/CD is much more popular than a Token Bus network. The main reasons for this popularity are the cheaper cost for installation and ease of administration. This section compares the pros and cons of the protocols and not the products.

Advantages of CSMA/CD

- Simple algorithm
- Widely used to provide favorable cost and reliability
- Fair access
- Good performance at low to medium load

Disadvantages of CSMA/CD

- Collision detection issues/requirements
- Limit on minimum packet size (72 bytes minimum)
- Nondeterministic delay

Advantages of Token Bus

- Excellent throughput performance
- No special requirements for signal strength
- Deterministic delay
- Class of services with priority schemes
- Stability at higher loads

Disadvantages of Token Bus

- Complicated algorithms
- Overhead for passing token even with *light* traffic

6.2.6 IEEE 802.5 Token Passing Ring Protocol

The **IEEE 802.5 Token Passing Ring** protocol uses the ring topology where repeaters are connected via a transmission medium to form a closed path. Data are transmitted serially bit by bit through the transmission media, and they regenerate the bits at each repeater before they are sent to the next repeater on the ring. Data are transmitted in packets. A repeater should perform the packet reception, transmission, and removal functions. A repeater can be one of three states: **listen**, **transmit**, and **bypass** states. A user station is connected to the repeater and contains the MAPs, which is summarized below:

(1) A station can only transmit data when it holds a free token.
(2) A free token turns into a busy token followed by a packet to be transmitted.
(3) The originating station purges the packet and releases a free token.
(4) To determine when to release the free token, there are three approaches. The **Single Token** protocol does not

release the free token unless the leading edge of the busy token is returned. The **Multiple Token** protocol releases the free token as soon as it has completed transmitting release occurs even if the busy token has not returned). The **Single Frame** protocol waits until all of data has been purged and then releases a free token. In general, if the frame length is smaller than the ring length measured in bit time, the multiple protocols have better throughput. Regardless of which protocol is used, the length of a ring should be long enough to hold a free token.

The token Passing Ring protocol uses two subfields in the frame to recognize whether the frame is copied successfully by the destination and whether a duplicated address is detected. When a frame is returned to the sender, the subfield *C* indicates that the frame is copied to the destination buffer, and the subfield *A* indicates if the duplicated address condition has been detected. A destination station detects the duplicated address condition when it finds out that some other station already marks the *C* bit. Unlike CSMA/CD, Token Passing Ring protocol provides the priority and reservation algorithms in the protocol. The following steps outline the algorithm with notations **Pm**, which is the priority of the message to transmit; **Pr**, which is the priority of the token protocol; and **Rr**, which is the receive reservation priority.

1. A station waits for a free token with a *Pr* less than or equal to *Pm* and then seizes it. If the free token has higher priority (i.e., Pm < Pr), the station can set the Rr field to Pm *only if* Rr is less than Pm and Pm is less than Pr.
2. A station reserves the priority at a busy token by setting the Pm to the Rr field *if* the Rr is less than the Pm.
3. After seizing a token, the token indicator bit is set to 1, the Rr field is set to 0, Pr is unchanged.
4. When releasing a free token, the Pr field is set to the max(Pr, Rr, Pm), and the Rr field is set to max(Rr, Pm).
5. Each station downgrades the priority of a free token to a former level stored in a stack.

Just like the Token Passing Bus protocol, the Token Passing Ring protocol has a token maintenance problem when a station detects no token activity or detects a persistently circulating busy token by issuing a new token. When a station detects no token activity for a period of time, the network enters the initialization procedure to claim a token. A monitor station on the network sets the monitor bit in the frame. It will then remove the frame and issue a new token if the monitor station has seen the monitor bit set. This ring protocol enables a fair access with a "round robin" scheme, but it is inefficient under a lightly loaded system because the station that has a frame to be transmitted has to wait for the token to arrive. Unlike CSMA/CD, a station can transmit a frame right away as long as no other station is transmitting. A ring network, however, has many advantages over a bus network. Some major advantages are less noise and larger distance coverage resulting from the use of repeaters and a high-speed link for the use of optical fiber. The major problem with a ring network is the accumulation of a timing jitter along the ring and across multiple repeaters. This effect significantly limits the size of a ring network.

6.2.7 IEEE 802.11—Wireless LANs

The increased demands for mobility and flexibility in daily life are demands that lead the development from wired LANs to wireless LANs (WLANs). Today a WLAN can offer users high bit rates to meet the requirements of bandwidth consuming services, such as video conferences and streaming videos. With this in mind, a user of a WLAN will have high demands on the system and will not accept too much degradation in performance to achieve mobility and flexibility. This will in turn put high demands on the design of WLANs of the future. In this section we first discuss the WLAN architecture, deployment and security issues. Finally, future trends in wireless technology are also discussed.

Architecture of WLAN

WLAN consists of access points and terminals that have a WLAN connectivity. Finding the optimal locations for access points is important and can be achieved by measuring the relative signal strength of the access points. Placing the access points in a corporation network opens an access way to the resources in an intranet. With wired LANs, an intruder must first gain physical access to the building before he or she can plug a computer to the network and eavesdrop on the traffic. The intranet is typically considered secure even though employees can cause security breaches and data are transmitted unencrypted. If the information transmitted in the corporation network is extremely valuable to the corporation, the WLAN interface should be protected from unauthorized users and eavesdropping. The obvious way to extend the intranet with a wireless LAN is to connect the access points directly to the intranet as illustrated in Figure 6.4.

The WLAN standard is defined in the **IEEE 802.11 WLAN protocol**, an extension of the IEEE 802.3 standard for wired LAN. The term LAN applies to any type of WLAN. It can be based on 802.11a, 802.11b, and 802.11g. A new standard called IEEE 802.11n is evolving to provide hundreds of megabits per second data rate. Another name for WLAN is wireless fidelity (Wi-Fi). Hotspots are another big development in the Wi-Fi field. Hot spots are usually public spaces such as libraries, malls, parks, beaches, airports, hotels, coffee shops, and restaurants where Wi-Fi Internet access is offered for a price or, even in some cases, offered for free. It is predicted that the number of hot spots could peak at 150,000 by 2005 before eventually declining because of unprofitable hot spots being deactivated. Of course, sometimes these hot spots can be

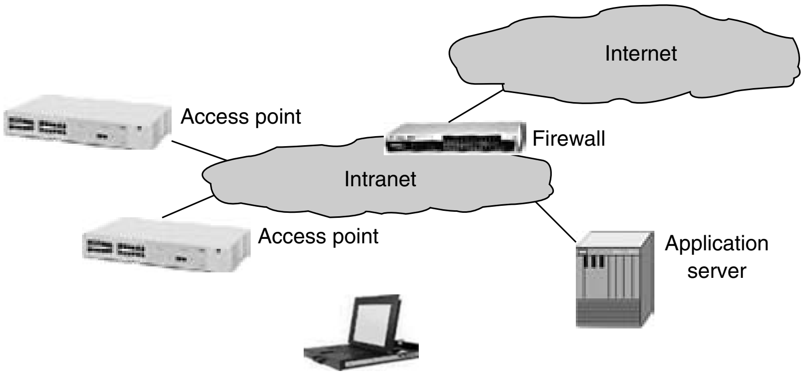

FIGURE 6.4 Access Points of WLAN

somewhat confining because of one needs to make payment arrangements and also obtain a password for each use. Different hot spots are also often run by different Internet service providers, so paying just one provider will not always guarantee service at all hot spot zones. In addition, most hot spots only offer minimal if any security. Most clerks at these places have no idea of how to turn on the security features of their deployed WLAN. IEEE 802.11 network architecture can be configured in two different ways. One way is the **independent basic service set** (IBSS), also often referred to as an ad hoc network or even a peer-to-peer mode (see Figure 6.5). In an ad hoc network, 802.11 wireless stations in the same cell or in the transmission range of each other communicate directly with one another without using any connection to a wired network. This kind of network is usually only formed on a temporary basis and put up and taken down rather quickly. These networks usually are of small size and have a focused purpose. A business meeting in a conference room where employees bring laptops to share information is a good example of this type of network.

The second way and the most frequent way an IEEE 802.11 network architecture can be configured is by the **basic service set** (BSS), also often referred to as an infrastructure network (see Figure 6.6). In an infrastructure network, one station, called an access point (AP), acts as a central station for each cell, and many overlapping cells can make up a network. If there is more than one cell, the network is actually called an extended service set (ESS), and each cell is actually considered a basic service set (BSS) (see Figure 6.7). In an ESS, each BSS is connected together by means of a distribution system (DS). So these types of networks can have one or more access points. These access points serve as an ethernet bridge between the wireless LAN and a wired network infrastructure. These access points are not mobile and are considered part of the wired network infrastructure. The wireless stations can be mobile and can roam from one cell to the next, allowing for seamless coverage throughout the whole service area of the ESS.

WLAN Security and Deployment Issues

WLAN technology provides tremendous convenience to many mobile users, but the initial deployment rate was not as expected. Security has represented the major obstacle to the

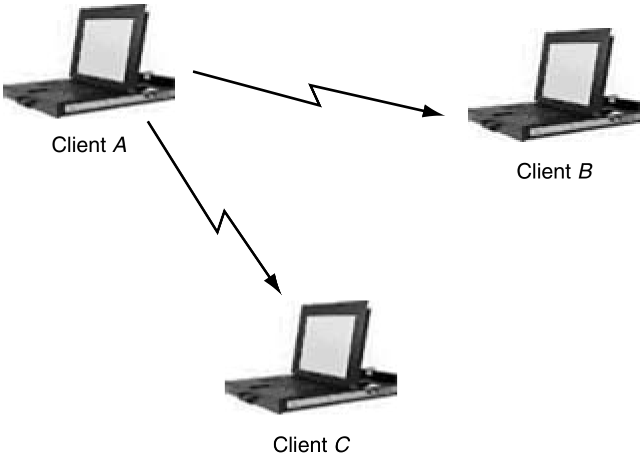

FIGURE 6.5 Example Ad Hoc Network

FIGURE 6.7 Extended Service Set—Infrastructure Mode

widespread adoption of WLAN. About 50% of IT managers still consider WLAN security being a major concern to deploy the technology throughout the company. Two popular security standards have been implemented in WLAN networks. They are WEP (Wireless Equivalent Protocol) and WPA (Wi-Fi Protected Access).

WEP is implanted in 802.11b protocol and works at Layer 2 to encrypt all over the air transmission using 40/64 bit keys. Unfortunately, these keys are not strong and are easier to break. Furthermore, it only authenticates a device, not a user. **WPA** is a security enhancement that tries to solve two problems of WEP—weak data encryption and lack of user authentication capability. In order to provide a stronger encryption algorithm, WPA employs Temporal key Integrity Protocol (TKIP), which provides per-packet key to make the hacker's job more difficult. WPA also implements the Extensible Authentication Protocol (ESP), which works with a RADIUS authentication server to authenticate and authorize a user using WLAN. Virtual Private Network (VPN) can also be used to regulate access to a company's corporate network from WLAN, either in a private network or public access network. VPN is placed behind the wireless access points to authenticate and authorize a user.

WLAN deployment can be either centralized or distributed. In the central approach, the access points are mainly dumb devices with the intelligence existing in a central switch. The access points are just radio stations. In the distributed approach, each access point has intelligence and is configured with access-control information, user authentication, and policy administration. The centralized approach may save operational cost but may not be as efficient as the distributed approach.

Future WLAN Technological Developments

Although it is very risky to speculate on future developments in a field that is changing as fast as wireless communications, there does seem to be a certain amount of consensus about broad trends.

Communicating Anytime, Anywhere, and in Any Mode

There seems to be a wide acceptance of the notion of being able to communicate anywhere, anytime, and in any mode. Software programmable radios allow a subscriber unit to adapt its modulation, multiple-access method, and other characteristics to be able to communicate with a wide range of different systems and more efficiently support diverse voice, data, image, and video requirements. Likewise, a single base station unit will be able to adapt its characteristics to support older generations of subscriber equipment while retaining the ability to support future developments through software changes.

Extending Multimedia and Broadband Services to Mobile Users

Providing for the electronic transport of multimedia services is a challenging one because of the inherent differences in voice, data, image, and video traffic as explained earlier. Extending multimedia and bandwidth on-demand capabilities into the wireless environment presents a number of challenges. In the mobile, wireless world, available bandwidths (and, hence, transmission rates) are typically limited by spectrum scarcity, and the transmission links between the mobile and base stations are often characterized by high error rates and rapidly changing performance. In addition, a mobile terminal that is connected to one port on the network at one moment may be connected to another one the next moment. Despite these

Octets	1	1	1	6	6	≥0	4	1	1
	SD	AC	FC	DA	SA	Data unit	FCS	ED	FS

SD = Starting delimiter
AC = Access control
FC = Frame control

DA = Destination address
SA = Source address
FCS = Frame check sequence

ED = Ending delimiter
FS = Frame status

(A) **IEEE 802.5 Frame**

	Preamble	SD	FC	DA	SA	Info	FCS	ED	FS

(B) **FDDI Frame**

FIGURE 6.8 Frame Formats of IEEE 802.5 and FDDI.

challenges, there is a considerable amount of research interest in wireless ATM, and an entire issue of *IEEE Personal Communications* was devoted to the topic.

Embedded Radios

There is also a long-term trend toward, for want of a better term, **embedded radios**. This trend is comparable to the trend in microelectronics that is resulting in computer chips being installed in such ordinary items as automobiles, washing machines, sewing machines, and other consumer appliances and office equipment. Radios are even being installed in humans in the form of pacemakers and heart monitors. These devices are less visible than personal computers, computer workstations, and mainframe computers, but their impact on everyday life is significant nevertheless.

6.2.8 ANSI X3T9.5—Fiber Data Distribution Interface

The other type of LAN is called **metropolitan area network** (MAN). MAN has characteristics of high capacity of supporting at least 100-Mbps speed and more than 500 stations on the network. It has a larger geographic scope than LAN provides support for integrated data types, and has the provision of dual cables to improve throughput and reliability

Fiber data distribution interface (FDDI) is an example of MAN that is an **ANSI X3T9.5 standard**, proposed by the ANSI XT9.5 study group. Each field in the MAC frame can either be represented as a symbol (4 bits, for nondata) or in bits format (data or address). The IEEE 802.5 token ring frame format is similar to the FDDI frame format. The FDDI frame includes a preamble to help in clocking because this is desirable for high-speed communication. FDDI does not include an access control (AC) field that is used for priority reservation scheme. FDDI uses a capacity allocation scheme instead of priority reservation. Figure 6.8 shows the frame formats of IEEE 802.5 and FDDI.

FDDI MAC protocol is very similar to IEEE 802.5–Token Passing Ring protocol, but there are differences described as follows:

- After absorbing the free token, an FDDI station starts to transmit data frames. In IEEE 802.5—Token Passing Ring MAC, the token type bit is changed to a busy token type, and the data is appended to the token.
- An FDDI station frees the token right after transmission of a data frame, and it will not wait for the data frame return. In IEEE 802.5, a station will not free a token until the leading edge of the data frame returns.
- FDDI MAC uses the Time-Token Protocol (TTP) for both synchronous and asynchronous services to all stations. If a token arrives earlier based on the rotation timer, a station can optionally send the asynchronous data. If the token is late, only the synchronous data can be sent. In IEEE 802.5, MAC protocol is based on explicit priority reservation. Both protocols allow the network to respond to changes in traffic load, but FDDI supports more steady load because lower-priority traffic may have more opportunity to send when a token arrives early.
- The use of a restricted token will allow for two stations to have multiframe dialog capability to interchange long sequences of data frames and acknowledgments. This would improve the performance of the application that uses the capability.

The data-encoding scheme used by FDDI is called 4B/5B, which encodes 4-bit data within a 5-bit cell. There is no more than three consecutive zero bits in a cell, and at least two transitions occur in a 5-bit cell. The binary bit values are represented with non return to zero inverted (NRZI), where the transition at the beginning of the bit time denotes a binary 1 for that bit time, and no transition indicates a binary 0. Only 16 out of 32 code patterns are used for data, and other patterns are used for control symbols. Timing jitter is one of transmission impairments in the data communication. The deviation of clock recovery occurs when a receiver attempts to recover clocking as well as data. Due to the high speed of transmission, the deviation of the clock is more severe for FDDI than for IEEE 802.5. The centralized clocking used by the IEEE 802.5 network is inappropriate for 100 Mbps, and it requires a complicated and expensive phase lock loop circuitry. Distributed clocking is therefore used by FDDI. With distributed clocking, each station recovers a clock from its incoming signal and transmits out at station clock speed. Each station also maintains its own elastic buffer, unlike the IEEE 802.5 network that only designates one station to have the elastic buffer.

FDDI specifies three reliability requirements of providing an automatic bypass for a bad or power-off station, using dual rings for easy reconfiguration when one ring is broken, and installing a wiring concentrator. Table 6.4 summarizes the comparison between IEEE 802.5 Token Passing Ring and ANSI X3T9.5 FDDI.

FDDI is more reliable than other local network systems, but it is discouraged due to its high cost. There is a trend to migrate FDDI into switched backbone fast ethernet for the following additional reasons:

- More bandwidth to the desktops would require increasing the backbone capacity
- Because of continued evolution of ethernet architecture and its speed, it would make business and technical sense to migrate FDDI backbone into switched fast ethernet. Table 6.5 shows the comparison of FDDI and fast ethernet.

TABLE 6.4 Comparing IEEE 802.5 and X3T9.5 FDDI

ANSI X3T9.5 FDDI	IEEE 802.5 Token Passing Ring
Fiber or twisted pair as transmission medium	Twisted pair or optical fiber as transmission medium
100 Mbps	4, 16, or 100 Mbps
Reliability specification	No reliability specification
Maximum of 1000 stations	Maximum of 250 stations
4B/5B encoding	Differential Manchester
Distributed clocking	Centralized clocking
Maximum of 4500 octets of frame sizes	Maximum of 4550 octets for a 4-Mbps network and 18200 octets for 16-Mbps and 100-Mbps networks
Time token rotation	Priority reservation
Token release right after the transmission	Token release after busy token comes back

TABLE 6.5 Comparing FDDI and Fast Ethernet

	FDDI	Fast ethernet
Reliability	Self-healing dual rings	Can provide one backup connection
Maximum frame size	4500 octets	1518 octets
Performance	Sustained performance with increasing number of stations	Whole network owned by each user with the switched Ethernet
Distance	Up to 32 Km with fiber	Up to 32 Km with fiber
Price	Close to $1000/port	$100–$150/port

6.3 Local Network Internetworking Using Bridges or Routers

A bridge is a device that operates at the MAC level to connect with a similar type of local network, and a router is a device that operates at the third layer of protocol to connect dissimilar types of local networks, including a WAN. Internetworking using **bridge**: or **routers** are required for Communication with multiple LANs in the organization, Communication with a LAN in a different location, and communication with the Internet.

A simple bridge contains just the forwarding function, but a more sophisticated bridge would offer additional functions, like dynamic routing, priority, and congestion control. There are several reasons to use a bridge for connecting multiple LANs:

- **Reliability**: To avoid a single point of failure, a network can be divided into several self-contained units.
- **Performance**: Placing users into several smaller LANs rather than in a large LAN would reduce the contention time and improve the performance.
- **Security**: It is more desirable to keep different types of traffic separate to improve security (e.g., work group communication can be on the same LAN).
- **Location**: Different floors or buildings requires a bridge to connect these locations.

The communication path between two LANs/MANs can be connected either by a single bridge or multiple bridges. In the case of connecting with multiple bridges, a point-to-point protocol, like High-Level Data Link Control (HDLC) or an X.25 connection, can be used between two bridges. Bridges do not modify the content of the frames they receive but must contain addressing and routing intelligence. The bridge can also act as a multiple port switch connecting more than two LANs.

The routing approaches of bridges are as complicated as routers. The basic routing operation is to avoid forwarding frames in a closed loop. Each bridge should make a decision about whether the frame should be forwarded and what LAN should forward the frame next. The following approaches are used for routing with bridges:

- **Fixed routing**: A central routing directory is created at the network control computer. The directory contains the source-destination pairs of LANs and the bridge ID for each pair of LANs. Each bridge on the network has a table that contains the source-destination pairs of LAN for each of LANs attached to the bridge.
- **Transparent bridge**: The algorithm was developed by IEEE 802.1 and intended to interconnect similar LAN or dissimilar LAN (IEEE 802.3, IEEE 802.4, and IEEE 802.5) and learn in which side of LAN a MAC station would reside by examining the source and destination addresses. The main idea is for the bridges to select the ports over which they will forward frames. The algorithm uses graph theory to construct a spanning tree to avoid a closed loop to forward the frame. The algorithm selects one root bridge for the network, one designated port for each bridge, and one designated bridge for each LAN. All frames will be forwarded toward the root bridge via the designated bridge and the designated port. The root bridge then forwards the frames via all of its ports. The root bridge has the smallest ID, and each bridge computes the shortest path to the root and notes which port is on the path. The designated port is the preferred path to the root. Each LAN selects a designated bridge that will be responsible for forwarding frames toward the root bridge. The winner is the bridge closer to the root and has the smaller ID.
- **Source routing**: The routing algorithm was developed by IEEE 802.5. Each source station determines the route that the frame will take and includes a sequence of LAN and bridge identifiers in the route information field (RIF). The route information is obtained by discovery of broadcast frames sent by a source station. The approach requires the changes (additional bits) to the MAC frame format
- **Source routing transparent** (SRT): This approach allows for the interconnection of LANs by a mixture of source routing and transparent bridging. The route information indicator (RII) bit in MAC source address determines which algorithm will be used. If the RII is equal to 0, then the frame is handled by transparent bridge logic; if it equals to 1, it is handled by the source routing logic.

Routers in a LAN are used to connect LANs and the Internet. The addressing scope of the router is at the network layer (e.g., IP). A router makes a decision about how to route the packets. The routing protocol can be either internal within a domain network or external between two domain networks.

6.3.1 Performance of Local Networks

The objectives to study the performance of a LAN is to understand the factors that affect the performance of a local network, to understand the relative performance of various local network protocols, and to apply the knowledge in the design and configuration of a local network. The common characteristics between LAN and MAN are that a shared medium is used, the packet switching technique is used, and the MAP is used. The common measurable parameters for LAN and MAN are described as follows:

- **Delay** (D): The time period between when the time a frame is ready for transmission from a station and the completion of the successful transmission
- **Throughput** (S): Total rate of data being successfully transmitted between stations
- **Utilization** (U): The fraction of total network capacity being used
- **Offered load** (G): The total rate of data presented to network for transmission
- **Input load** (I): The rate of data generated by the stations attached to a local network

How are these parameters are related? The S and U are proportional to G, but they are flat when network capacity is exceeded. The D increases when the number of active users or I is increased.

A local network distinguishes itself as short distance; therefore, the smaller propagation delay would provide instant feedback about the state of a transmission. The frame size could determine the transmission time and also plays an important role in the designing network and affects the performance of a local network. The parameter a is obtained by dividing the propagation time by the transmission time and is the most important single parameter that affects the performance of the local network. The smaller a is, the better performance the network has. If transmission time is normalized to 1, a should indicate the propagation delay of a network. The parameter a can also be used as a good indication of effects on utilization and throughput. In general, the utilization varies inversely with a ($\mathrm{U} = 1/(1 + \mathrm{a})$) regardless of which MAC protocol is used. Throughput is affected by the parameter a regardless of the offered load (G). The larger the a is, the lower throughput the network has.

Different MAC protocols produce different types of overhead. For the contention protocols, like ALOHA, CSMA, and CSMA/CD, the overheads are collisions, acknowledgment, and waste of slot time. For the token bus protocol, the overheads are the passing token (even when the network is idle), token transmission, and acknowledgment. For the token ring protocol, the overhead is just waiting for the token when the other station has no data to send.

The factors that affect the performance of LAN/MAN are listed as follows:

- **Capacity**: Affects the parameter a
- **Propagation delay**: Affects the parameter a
- **Frame size**: Affects the parameter a
- **MAC protocols**: Affects throughput and delay

- **Offered load**: Affects throughput and utilization
- **Number of stations**: Affects delay, input load, offered load, and throughput
- **Error rate**: Not quite an issue for LAN/MAN performance

The number of active users in a local network is an important parameter that affects the bound of the performance. Understanding the bounds of the performance would help to determine the size of a LAN. The stability of a LAN can be at the state of either low delay, where the capacity is greater than the offered load; of high delay, where more time is spent on controlling access to network, and little time is spent on actual data transmission; or the unbound delay, where the offered load is greater than the capacity. The state of the unbound delay must be avoided in the design. In general, delay is bounded by the number of users (N) multiplied by the transmission time of **Tmsg**. The throughput is bounded by $N/(\text{Tidle} + N^*\text{Tmsg})$, where the **Tidle** is the mean idle time. The number of active stations can be determined by the following equation:

$$N = \text{Tidle}/\text{Tmsg}.$$

Generally, the study of LAN performance made by the IEEE 802 Committee suggests that smaller frame sizes have greater differences in the throughput between token passing and CSMA/CD. CSMA/CD strongly depends on the value of a. Token ring is the least sensitive to the workload. CSMA/CD has the shortest delay under the light load and is most sensitive to the heavy load.

6.4 Conclusion

The International Standard Organization's (ISO) Open System Interconnection (OSI) continues to be the de facto standard for network reference model. All of existing networks and future evolving networks continue to model their network based on OSI's reference model. This chapter introduces a general network architecture using OSI and provides a more detailed description of Local Network and Wireless Local Area Network. WLAN has been extensively used in home/office network and there are increasing numbers of public hotspots worldwide. The seamless interoperability between WLAN and mobile cellular networks has been on the way. It is expected that utilizing IP network to deliver various types of applications becomes a norm. IP Multimedia Subsystem (IMS) is intended to deliver ALL IP network architecture for all types of applications.

Glossary

4B/5B	Encoding scheme to encode 4 bits of data into a 5-bit cell
ANSI	American National Standard Institute
ATM	Asynchronous Transfer Mode
CSMA	Carrier Sense Multiple Access
CSMA/CD	Carrier Sense Multiple Access with Collision Detection
FDDI	Fiber Data Distribution Interface

7.1 Access Technologies

The problem of a cellular system boils down to the choice of the way to share a common pool of radio channels between users. Users can gain access to any channel (each user is not always assigned to the same channel). A channel can be thought of as merely a portion of the limited radio resource that is temporarily allocated for a specific purpose, such as someone's phone call. A multiple access method is a definition of how the radio spectrum is divided into channels and how channels are allocated to the many users of the systems. The sharing of spectrum is required to achieve high capacity by simultaneously allocating the available bandwidth to multiple users. There are three possible multiple access methods: **frequency-division multiple access** (FDMA), **time-division multiple access** (TDMA), and **code-division multiple access** (CDMA).

7.1.1 FDMA

FDMA assigns individual channels to individual users. It can be seen from Figure 7.1 that each user is allocated a unique frequency channel. These channels are assigned on demand to subscribers who request service. Guard bands are maintained between adjacent signal spectra to minimize cross talk between channels. During the period of the call, no other user can share the same frequency band. In frequency division duplex (FDD) systems, the users are assigned a channel as a pair of frequencies; one frequency is used for the upward channel, while the other frequency is used for the downward channel.

FDMA is used by analog systems, such as AMPS, NMT, or Radiocom 2000. The **advantages of FDMA** are the following:

- The complexity of FDMA systems is lower when compared to TDMA and CDMA systems, though this is changing as digital signal processing methods improve for TDMA and CDMA.
- FDMA it is technically simple to implement.
- A capacity increase can be obtained by reducing the information bit rate and using efficient digital codes.
- Since FDMA is a continuous transmission scheme, fewer bits are needed for overhead purposes as compared to TDMA.

The **disadvantages of FDMA** include the following:

- Only modest capacity improvements could be expected from a given spectrum allocation.
- FDMA wastes bandwidth. If an FDMA channel is not in use, then it sits idle and cannot be used by other users to increase or share capacity.
- FDMA systems have higher cell site system costs compared to TDMA systems because of the need to use costly bandpass filters to eliminate spurious radiation at the base station.
- The FDMA mobile unit uses duplexers since both the transmitter and receiver operate at the same time. A duplexer adds weight, size, and cost to a radio transmitter and can limit the minimum size of a subscriber unit.
- FDMA requires tight RF filtering to minimize adjacent channel interference.

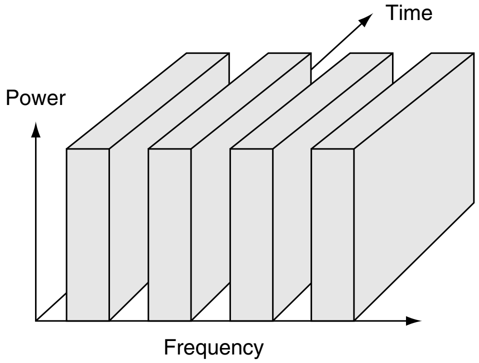

FIGURE 7.1 Frequency-Division Multiple Access (FDMA)

- The maximum bit rate per channel is fixed and small, inhibiting the flexibility in bit-rate capability that may be a requirement for 3G applications in the future.

7.1.2 TDMA

TDMA relies on the fact that the audio signal has been digitized (i.e., divided into a number of millisecond-long packets). It allocates a single frequency channel for a short period of time and then moves to another channel. The digital samples from a single transmitter occupy different time slots in several bands at the same time, as shown in Figure 7.2.

In a TDMA system, the radio spectrum is divided into time slots, and in each slot, only one user is allowed to either transmit or receive. It can be seen from Figure 7.2 that each user occupies a cyclically repeating time slot, so a channel may be thought of as a particular time slot that reoccurs every frame, where several time slots make up a frame. Since the transmission for any user is noncontinuous, digital modulation must be used with TDMA. The transmission from various users is interlaced into a repeating frame structure as shown in Figure 7.3. Each frame is made up of a preamble, information bits addressed to various stations, and trail bits. The function of the **preamble** is to provide identification and incidental information and to allow synchronization of the slot at the intended receiver. Guard times are used between each user's transmission to minimize cross talk between channels. In a TDMA/TDD system, half of the time slots in the frame information message would be used for the forward link channels and half would be used for reverse link channels. In TDMA/FDD systems, an identical or similar frame structure would be used for either forward or reverse transmission, but the carrier frequencies would be different for the forward and reverse links.

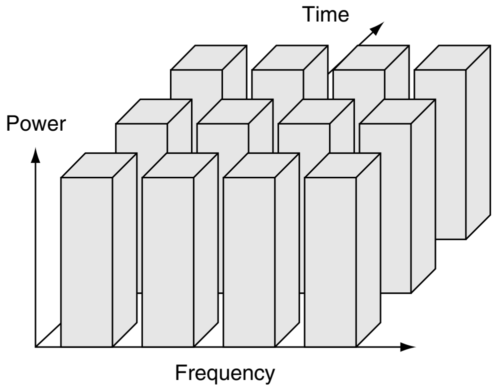

FIGURE 7.2 Time-Division Multiple Access (TDMA)

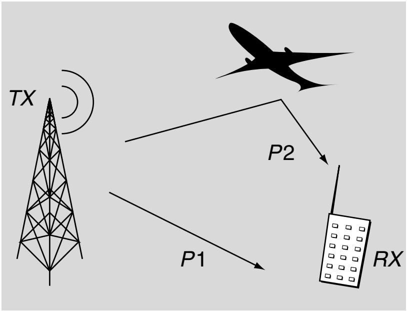

FIGURE 7.3 Multipath Interference

GSM uses a TDMA technique, where the carrier is 200 kHz wide and supports eight full rate channels. A channel (roughly) consists of the recurrence every 4.6 ms of a time slot of 0.58 ms.

The **advantages of TDMA** are the following:

- TDMA permits a flexible bit rate, not only for multiples of a basic single channel rate but also submultiples for low bit-rate multicast traffic.
- The handoff process in TDMA is much simpler for a subscriber unit because it is able to listen for other base stations during idle time slots.
- TDMA potentially integrates into VLSI without narrow band filters, giving a low-cost floor in volume production.
- TDMA uses different time slots for transmission and reception; thus, duplexers are not required.
- TDMA has the advantage in that it enables allocation of different numbers of time slots per frame to different users. Thus, bandwidth can be supplied on demand to different users by concatenating or reassigning time slots based on priority.
- TDMA can be easily adapted to the transmission of data as well as voice communication.
- TDMA offers the ability to carry data rates of 64 kbps to 120 Mbps (expandable in multiples of 64 kbps). This enables operators to offer personal communication-like services including fax, voice-band data, and short message services (SMSs) as well as bandwidth-intensive applications, such as multimedia and videoconferencing.
- Unlike spread-spectrum techniques that can suffer from interference among users, all of whom are on the same frequency band and transmitting at the same time, TDMA's technology, which separates users in time,

ensures that they will not experience interference from other simultaneous transmissions.
- TDMA also provides the user with extended battery life and talk time because the mobile is only transmitting a portion of the time (From one-third to one-tenth) during conversations.
- TDMA installations offer substantial savings in base-station equipment, space, and maintenance, an important factor as cell sizes grow ever smaller.
- TDMA is the most cost-effective technology for upgrading a current analog system to digital.
- TDMA is the only technology that offers an efficient use of hierarchical cell structures (HCSs) offering pico, micro, and macrocells. HCSs allow coverage for the system to be tailored to support specific traffic and service needs. By using this approach, system capacities of more than 40-times AMPS can be achieved in a cost-efficient way.
- Because of its inherent compatibility with FDMA analog systems, TDMA allows service compatibility with the use of dual-mode handsets.

The **disadvantages of TDMA** are listed here:

- TDMA requires a substantial amount of signal processing for matched filtering and correlation detection for synchronizing with a time slot.
- each user has a predefined time slot. However, users roaming from one cell to another are not allotted a time slot. Thus, if all the time slots in the next cell are already occupied, a call might well be disconnected. Likewise, if all the time slots in the cell in which a user happens to be are already occupied, a user will not receive a dial tone.
- TDMA is subjected to multipath distortion. A signal coming from a tower to a handset might come from any one of several directions. It might have bounced off several different buildings before arriving (see Figure 7.3), which can cause interference.

One way of getting around this interference is to put a time limit on the system. The system will be designed to receive, treat, and process a signal within a certain time limit. After the time limit has expired, the system ignores signals. The sensitivity of the system depends on how far it processes the multipath frequencies. Even at thousandths of seconds, these multipath signals cause problems.

All cellular architectures, whether microcell- or macrocell-based, have a unique set of propagation problems. Macrocells are particularly affected by multipath signal loss—a phenomenon usually occurring at the cell fringes where reflection and refraction may weaken or cancel a signal.

Frequency and time division multiplexing can be combined (i.e., a channel can use a certain frequency band for a certain amount of time). This scheme is more robust against frequency selective interference (i.e., interference in a certain small frequency band). In addition, this scheme provides some (weak) protection against tapping. GSM uses this combination of frequency and time division multiplexing for transmission between a mobile phone and a base station.

7.1.3 CDMA

In CDMA, each user is assigned a unique code sequence for encoding an information-bearing signal. The receiver, knowing the code sequences of the user, decodes a received signal after reception and recovers the original data. This is possible since the cross correlations between the code of the desired user and the codes of the other users are small. Because the bandwidth of the code signal is chosen to be much larger than the bandwidth of the information-bearing signal, the encoding process enlarges (spreads) the spectrum of the signal and is therefore also known as **spread-spectrum modulation**. The resulting signal is also called a spread-spectrum signal.

CDMA is commonly explained by the “cocktail party image,” where groups of people of different languages can communicate simultaneously, despite the surrounding noise. For a group of people speaking the same language, the rest of the people in the room are received as noise. Knowing the language they are talking allows them to filter out this noise and understand each other. If someone records the “noise,” and knows different languages, he or she will be able, playing the tape several times, to extract the various conversations taking place in the various languages. With sufficient processing capacity, all conversations can be extracted simultaneously.

CDMA receivers separate communication channels by means of a pesudo-random modulation that is applied and removed in the digital domain (with these famous codes), not on the basis of frequency. Multiple users occupy the same frequency band.

The use of CDMA permits average interference among all users, thus avoiding the dimension of a network for the worst case. It thus permits to optimize the use of spectrum efficiency. It also efficiently supports variable bit-rate services.

This multiple access method reduces the peak transmitter power, thus reducing the power amplifier consumption and then increasing the battery efficiency.

CDMA reduces the average transmitted power, and increases the battery efficiency. It allows a reuse factor of 1 (i.e., the same frequency is used in adjacent cells), thus avoiding the need for frequency planning. On the other hand, code planning is required, but this is less difficult than frequency planning, as the code reuse pattern is much larger than the frequency reuse pattern commonly encountered in FDMA systems.

However, CDMA requires in particular a complex and very accurate power control, which is a key factor for the system capacity and its proper operation.

In direct sequence CDMA (DS-CDMA), the modulated data signal is directly modulated by a digital, discrete-time, discrete-valued code signal. The data signal can be either analog or digital; in most cases, it is digital. In the case of a digital signal, the data modulation is often omitted, and the data signal is directly multiplied by the code signal; the resulting signal modulates the wideband carrier.

Basic DS-CMA elements include the RAKE receiver, power control, soft handover, interfrequency handover, and multiuser detection. Key CDMA system attributes include increased frequency reuse, efficient variable rate speech compression, enhanced RF power control, lower average transmit power, ability to simultaneously receive and combine several signals to increase service reliability, seamless handoff, extended battery life, and advanced features.

IS-95 CDMA

The IS-95 CDMA air interface standard, after the first revision in 1995, was termed **IS-95A**; it specifies the air interface for cellular, 800-MHz frequency band. ANSI J-STD-008 specifies the air interface for 1900 MHz in PCS. It differs from IS-95A primarily in the frequency plan and in call processing related to subscriber station identity, such as paging and call origination. TSB74 specifies the Rate Set 2 standard. IS-95B merges the IS-95A, ANSI J-STD-008, and TSB74 standards. In addition, it specifies high-speed data operation using up to eight parallel codes, resulting in a maximum bit rate of 115.2 Kb/s. **Table 7.1** lists the main parameters of the IS-95 CDMA air interface.

Wideband CDMA

The 3G air interface standardization for the schemes based on CMA focuses on two main types of wideband CDMA: **network asynchronous** and **network synchronous**. In network asynchronous schemes, the base stations are not synchronized; in network synchronous schemes, the base stations are synchronized to each other within a few microseconds.

A network asynchronous CDMA proposal is WCDMA in European Telecommunication Standard Institute (ETSI) and Association of Radio Industries and Businesses (ARIB). A network synchronous wideband CDMA scheme has been proposed by CDMA2000. The main technical approaches of WCDMA and CDMA2000 systems are chip rate, downlink channel structure, and network synchronization. CDMA2000 uses a chip rate of 3.6864 Mc/s for the 5-MHz band allocation with the direct spread downlink and a 1.2288 Mc/s chip rate for the multicarrier downlink. WCDMA uses direct spread with a chip rate of 4.096 Mc/s.

TABLE 7.1 IS-95 CDMA Air Interface Parameters

Bandwidth	1.25 MHz
Chip rate	1.2288 Mc/s
Frequency band uplink	• 869–894 MHz • 1930–1980 MHz
Frequency band downlink	• 824–849 MHz • 1850–1910 MHz
Frame length	20 ms
Bit rates	• Rate set 1: 9.6 kb/s • Rate set 2: 14.4 kb/s • IS-95B: 115.2 kb/s
Speech code	• QCELP 8 kb/s • ACELP 13 kb/s
Soft handover	Yes
Power control	• Uplink: Open loop + fast closed loop • Downlink: Slow quality loop
Number of RAKE fingers	Four
Spreading codes	Walsh + long *M*-sequence

WCDMA

The WCDMA scheme was developed as a joint effort between ETSI and ARIB in 1997. The ETSI WCDMA scheme was developed from the FMA2 scheme in Europe and the ARIB WCDMA from the Core-A scheme in Japan. The uplink of the WCDMA scheme is based mainly on the FMA2 scheme and the downlink on the Core-A scheme. **Table 7.2** lists the main parameters of WCDMA.

CDMA2000

Within standardization committee TIA TR45.4, the subcommittee TR45.5.4 was responsible for the selection of the basic CDMA2000 concept. For all the other wideband CMA schemes, the goal has been to provide data rates for the IMT-2000 performance requirements of at least 144 Kb/s in a vehicular environments, 384 Kb/s in a pedestrian environment, and 2.048 Mb/s in an indoor office environment. The main

TABLE 7.2 Parameters of WCDMA

Channel bandwidth	1.25, 5, 10, 20 MHz
Downlink RF channel structure	Direct spread
Chip rate	1.024/4.096/8.192/16.384 Mc/s
Roll-off factor for chip shaping	0.22
Frame length	10 ms/20 ms (optional)
Spreading modulation	• Balanced QPSK (downlink) • Dual channel (uplink) • Complex spreading circuit
Coherent detection	User-dedicated time multiplexed pilot (downlink and uplink); no common pilot in downlink
Channel multiplexing in uplink	Control and pilot channel time multiplexed *I* and *Q* multiplexing for data and control channel
Multirate	Variable spreading and multicode
Spreading factors	4–256
Power control	Open- and fast-closed loop (1.6 KHz)
Spreading (downlink)	Variable length orthogonal sequences for channel separation Gold sequence 2^{18} for cell and user separation (truncated cycle 10 ms)
Spreading (uplink)	Variable-length orthogonal sequences for channel separation Gold sequence 2^{41} for user separation (different time shifts in *I* and *Q* channel, truncated cycle 10 ms)
Handover	• Soft handover • Interfrequency handover

TABLE 7.3 CDMA2000 Parameter Summary

Channel bandwidth	1.25, 5, 10, 20 MHz
Downlink RF channel structure	Direct spread or multicarrier
Chip rate	• 1.2288/3.6864/7.3728/11.0593/14.7456 Mc/s for direct spread • $n\times$ 1.2288 Mc/s ($n = 1, 3, 6, 9, 12$) for multicarrier
Roll-off factor	Similar to IS-95
Frame length	• 20 ms for data and control • 5 ms for control information on the fundamental and dedicated control channel
Spreading modulation	• Balanced QPSK (downlink) • Dual channel QPSK (uplink) • Complex spreading circuit
Coherent detection	• Pilot time multiplexed with PC and EIB (uplink) • Common continuous pilot channel and auxiliary pilot (downlink)
Channel multiplexing in uplink	• Control, pilot, fundamental, and supplemental code multiplexed • *I* and *O* multiplexing for data and control channel
Multirate	Variable spreading and multicode
Spreading factors	4–256
Power control	Open- and fast-closed loop (800 Hz, higher rates under study)
Spreading (downlink)	Variable-length Walsh sequences for channel separation, *M*-sequence 2^{15} (same sequence with time shift used in different cells, different sequence in *I* and *Q* channel)
Spreading (uplink)	• Variable-length orthogonal sequences for channel separation *M*-sequence 2^{15} (same sequence for all users, different sequence in *I* and *Q* channels) *M*-sequence $2^{41} - 1$ for user separation (different time shifts for different users)
Handover	• Soft handover • Interfrequency handover

TABLE 7.4 Comparison of FDMA, TDMA, and CDMA

Approach	FDMA	TDMA	CDMA
Idea	Segment the frequency band into disjoint sub-bands	Segment sending time into disjoint time slots, demanding driven or fixed patterns	Spread of the spectrum using orthogonal codes
Terminals	Every terminal with own frequency, uninterrupted	All terminals active for short periods of time on the same frequency	All terminals can be active at the same place at the same time, uninterrupted
Signal separation	Filtering in the frequency domain	Synchronization in the time domain	Code plus RAKE receivers
Advantages	Simple, established, robust	Established, fully digital, flexible	Flexible, less planning needed, soft handover
Disadvantages	Inflexible, wasteful of spectrum	Guard space needed, synchronization difficult	Complex receivers, needs more complicated power control for senders

focus of standardization has been providing 144 Kb/s and 384 Kb/s with approximately 5-MHz bandwidth. The main parameters of CDMA2000 are listed in Table 7.3

7.2 Comparisons of FDMA, TDMA, and CDMA

To conclude this section, we make a comparison of the three basic access technologies discussed in Table 7.4. The table shows the MAC schemes without combination with other schemes. However, in real systems, the MAC schemes always occur in combinations such as those used in GSM and IS-95.

The primary advantage of DS-CDMA is its ability to tolerate a fair amount of interfering signals compared to FDMA and TDMA, which typically cannot tolerate any such interference. With DS-CMA, adjacent microcells share the same frequencies, whereas with FDMA and TDMA, it is not feasible for adjacent microcells to share the same frequencies because of interference.

Convergence of Networking Technologies

Vijay K. Garg
Department of Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, Illinois, USA

Yih-Chen Wang
Lucent Technologies, Naperville, Illinois, USA

8.1 Convergence

The next generation of wireless networks will be flexible, open, and standards-based. These networks will facilitate the convergence of wireless networks, the PSTN, and the Internet and will provide voice, data, and video services to platforms such as cell phones, PDAs, laptops, PCs, digital cameras, and a plethora of new portable devices.

Advances in optical networking will increase the capacity of a core network by stuffing vastly more information into each fiber. Next-generation media interface protocols, such as SIP and MEGACO, have already proven more effective than SS7 and H.323 in a convergence network of wireless systems, wireline systems, and the Internet.

The key to wireless convergence is IP and softswitch. This software-on-a-switch is the heart of the next-generation wireless networks that provides integration of the wireless networks, the Internet, and the PSTN. This is the elusive Holy Grail of communications—any-to-any end point interoperability, enhanced services, and flexible billing are all on one network.

8.1.1 Session Initiation Protocol

Session initiation protocol (SIP) is an **application-layer signaling protocol** for creating, modifying, and terminating sessions with one or more participants. SIP **sessions** include Internet multimedia conferences, Internet telephone calls, and multimedia distribution. SIP invitations create sessions carrying **session descriptions**, which allow participants to agree on a set of compatible media types. SIP supports **user mobility** by proxying and redirecting requests to the user's current location. Users can **register** their current locations. SIP makes minimal assumptions about the underlying transport protocol. It can be extended easily with additional capabilities and is an enabling technology for providing innovative new services that integrate multimedia with Internet services such as the World Wide Web, e-mail, instant messaging, and presence.

The core SIP protocol, specified in Internet Engineering Task Force (IETF) Request for Comments (RFC) 2543, is built on foundation IP protocols, such as HTTP and Simple Mail Transfer Protocol (SMTP). As such, it supports a request/response transaction model that is text-based, similar to e-mail, and self-describing; in addition, SIP inherited many of the features from standard Internet protocols. For example, it uses many of HTTPv1.1 header fields, supports Uniform Resource Identifier/Universal Resource Locator (URI/URL) for addressing, and employs the Multimedia Internet Mail Encapsulation (MIME) protocol for message payload description. It is lightweight as the baseline SIP consists only of six methods. Extensions are being proposed by adding new methods, new headers, and new message body types to support additional applications such as interworking with legacy systems, cable, or wireless applications. An SIP initiation scenario is shown in Figure 8.1.

The standard SIP architectural components are the following:

- **An SIP client** is an end system with the SIP **User Agent** (**UA**) residing in it. The user agent consists of two

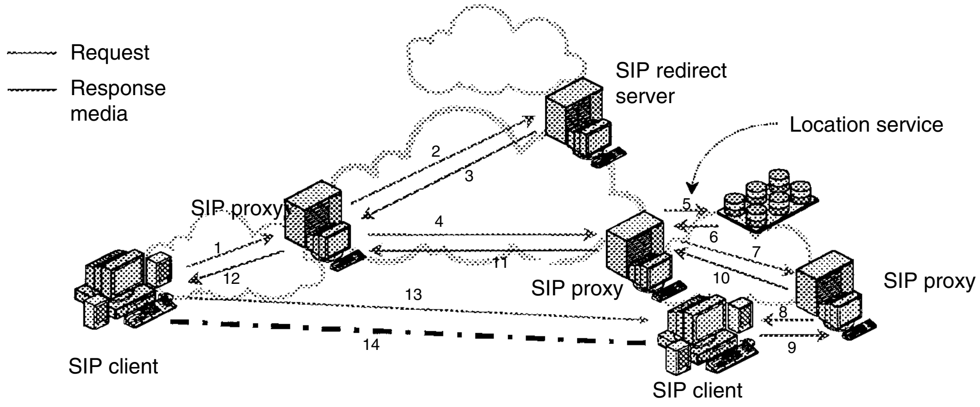

FIGURE 8.1 Session Initiation in SIP

components: the **User Agent Client** (**UAC**) is responsible for sending SIP requests, and the **User Agent Server** (**UAS**) listens for incoming requests, and prompts a user or executes a program to determine responses.

- **A proxy server** is responsible for routing and delivering messages to the called party. It receives requests and forwards them to another server (called a **next-hop server**), which may be another proxy server, a UAS, or a redirect server. It can *fork* a request, sending copies to multiple next-hop servers at once. This allows a call setup request to try many different locations at once. It can also forward the invitation to a multicast group. A proxy server can be call-stateful, stateful (transaction-stateful), or stateless.
- **A redirect server** also receives requests and determines net-hop server(s). Instead of forwarding the request there, however, it returns the address(es) of the next-hop server(s) to the sender.
- **A locator service** is used by an SIP server to obtain information about a callee's possible locations. It is outside the scope of SIP. It can be anything, such as LDAP, whois, whois++, POST corporate database, local file, or result of program execution (IN).
- **A registration server** receives updates on the current locations of users. It is typically colocated with a proxy redirect server. The server may make its information available through the location server.

Often hailed as more flexible than H.323, SIP is an application-layer control protocol that can establish, modify, and terminate sessions or calls. SIP is text-based and light-

weight, and it uses a simple invitation–acceptance message structure. Other benefits of SIP over H.323 include scalability, service richness, lower latency, faster speed, and ability to distribute for carrier-grade reliability.

SIP is a new protocol currently under development. The core SIP application specified in IETF RFC 2543 is being implemented and tested in SIP bake-offs. Many extensions of SIP are being proposed and are under discussion. Holes and gaps exist for system-level deployment. For example, QoS, security, services, and operations issues are still being debated. Interworking mappings of SIP with H.323 and ISUP/BICC are not yet finalized (Internet draft status).

8.1.2 Softswitch

Softswitch is an all-encompassing term for the next-generation communications systems that employ open standards to create integrated networks with a decoupled service intelligence capable of carrying voice, video, and data traffic more efficiently and with far greater value-added service potential than is possible with existing circuit-switched networks. Softswitch-based networks will enable service providers to support new, enhanced voice service features as well as offer new types of multimedia applications in addition to integrating existing wireline and wireless voice services with advanced data and video services.

The separation of call control and services (Figure 8.2) from the underlying transport network is a key enabling feature of softswitch-based networks. Indeed, the very approach of building switched networks with extracted service intelligence represents a major break-through when compared to the circuit-switched approach of combining the transport hardware, call control, and service logic together into a single, proprietary piece of equipment.

Softswitches can be used in 3G and 4G core networks to provide call control, mobility management, and an open service creation environment for carriers. A softswitch can deliver foundation mobility functions of roaming, location updates, subscriber profile management, intersystem handover, and RAN interworking to wireless service providers.

8.1.3 All IP Architecture

The Internet is unprecedented in its impact on the world community of industries, institutions, and individuals. In some way, the Internet has touched most of our lives in terms of how we communicate, how we promote our products, how we teach our children, and how we invest our time. No media adoption curve has been faster than the Internet's. In the United States alone, it took almost 40 years for 50 million people to use radio and 15 years for 50 million people to use Television and cellular communications. Internet users reached the 50-million mark in just 5 years.

During that time, the world became increasingly mobile, defined by the "take-it-with-you philosophy" we have developed regarding information and our access to it. For the wireless cellular industry, that shift in attitude has created the opportunity to add mobility to Internet accessibility—effectively allowing subscribers to carry the power of the Internet with them anywhere at any time.

The convergence of wireless and Internet usage is already underway. Globally, Internet users as a whole are projected to increase from about 200 million at present to almost 1 billion by the year 2005. During the same period of time, global wireless subscribers are expected to increase from 300 million to over a billion.

With these market dynamics in mind, several industry-leading businesses have agreed that next-generation wireless

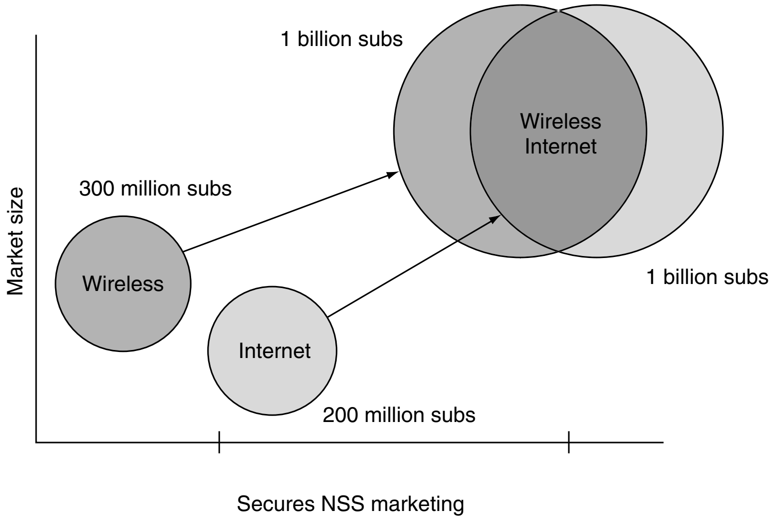

FIGURE 8.3 Projected Wireless Internet Convergence

networks will leverage the packet-based technology of IP. This strategy provides operators with the unique opportunity to deliver a multitude of new services to mobile cellular subscribers in a manner more customizable than previously possible (see Figure 8.3).

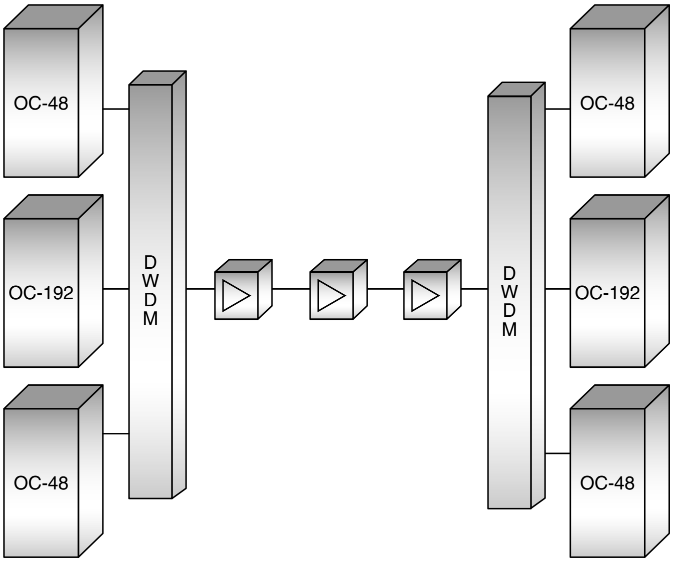

FIGURE 8.4 DWDM Systems and Optical Amplifiers

As the industry continues to invest heavily in advancing IP technology for supporting real-time applications such as voice with reliable service and toll quality, it is expected to further accelerate the introduction of new network capabilities that are defined within IP standards for network implementations.

8.2 Optical Networking

As networks face increasing bandwidth demand and diminishing fiber availability, network providers are moving toward a crucial milestone in network evolution: the **optical network**. Optical networks, based on the emergence of the optical layer in transport networks, provide higher capacity and reduced costs for new applications such as the Internet, video and multimedia interaction, and advanced digital services.

Optical networks began with wavelength division multiplexing (WDM), which arose to provide additional capacity on existing fibers. The components of the optical network are defined according to how the wavelengths are transmitted, groomed, or implemented in the network. Viewing the network from a layered approach, the optical network requires the addition of an optical layer. To help define network functionality, networks are divided into several different physical or virtual layers. The first layer, the **services layer,** is where the services—such as data traffic—enter the telecommunications network. The next layer, **SONET,** provides restoration, performance monitoring, and provisioning that is transparent to the first layer.

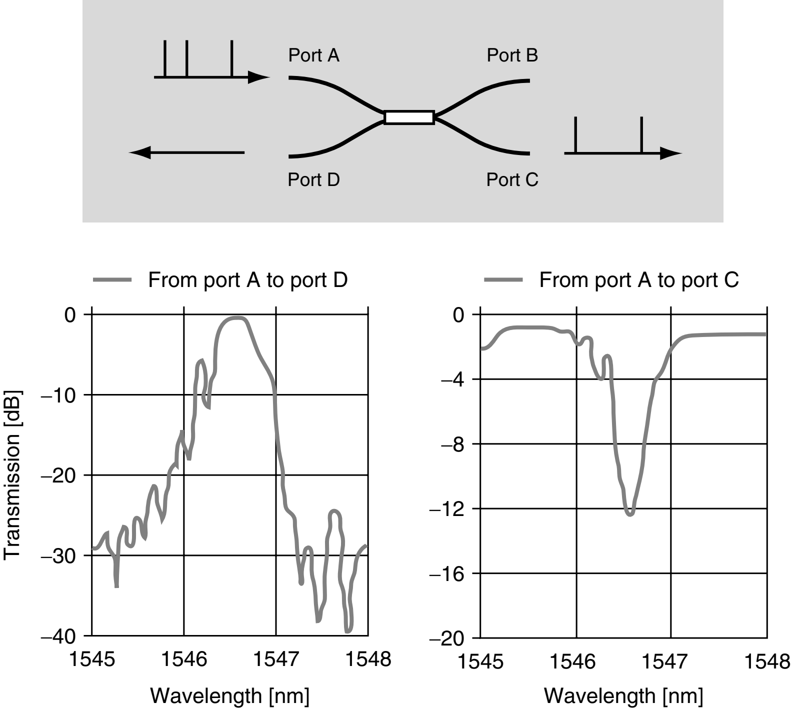

FIGURE 8.5 In Fiber Bragg Grating Technology: Optical A/D Multiplexer

8.2.1 Dense Wavelength Division Multiplexing

As optical filters and laser technology improved, the ability to combine more than two signal wavelengths on a fiber became a reality. **Dense wavelength division multiplexing** (DWDM) combines multiple signals on the same fiber, ranging up to 40 or 80 channels. By implementing DWDM systems and optical amplifiers, networks can provide a variety of bit rates (i.e., OC–48 or OC–192) and a multitude of channels over a single fiber (see Figure 8.4). The wavelengths used are all in the range in which optical amplifiers perform optimally, typically from about 1530 nm to 1565 nm.

Optical Amplifiers

The performance of **optical amplifiers** has improved significantly—with current amplifiers providing significantly lower noise and flatter gain—which is essential to DWDM systems. The total power of amplifiers also has steadily increased, with amplifiers approaching +20-dBm outputs, which is many orders of magnitude more powerful than the first amplifiers.

Narrow Band Lasers

Without a narrow, stable, and coherent light source, none of the optical components would be of any value in the optical network. Advanced **lasers with narrow bandwidths** provide the narrow wavelength source that is the individual channel in optical networks. Typically, long-haul applications use externally modulated lasers, while shorter applications can use integrated laser technologies.

Fiber Bragg Gratings

Commercially available **fiber Bragg gratings** have been important components for enabling WDM and optical networks. A fiber Bragg grating is a small section of fiber that has been modified to create periodic changes in the index of refraction. Depending on the space between the changes, a certain frequency of light—the Bragg resonance wavelength—is reflected back, while all other wavelengths pass through (see Figure 8.5). The wavelength-specific properties of the grating make fiber Bragg gratings useful in implementing optical add/drop multiplexers. Bragg gratings also are being developed to aid in dispersion compensation and signal filtering as well.

Thin-Film Substrates

Another essential technology for optical networks is the **thin-film substrate**. By coating a thin glass or polymer substrate with a thin interference film of dielectric material, the substrate can be made to pass through only a specific wavelength and reflect all others. By integrating several of these components, many optical network devices are created, including multiplexers, demultiplexers, and add/drop devices.

IX

CONTROLS AND SYSTEMS

Michael Sain
Department of Electrical Engineering,
University of Notre Dame,
Notre Dame, Indiana, USA

The question of feedback in circuits and systems can be viewed in a denumerable number of different ways. It is, therefore, no longer possible to give a coherent, yet brief, overview of the subject. I am reminded of the story of the hotel with an infinite number of rooms. In such a hotel, there is always room for another guest. To accommodate the next guest, even if all the rooms are occupied, one has only to ask each room occupant to move to the room with the next higher number. When this is done, all the current occupants will again be in a room, and room one will be available for the new guest!

Nonetheless, one can set up some equivalence classes on feedback in circuits and systems. In one of these constructions, it is possible to focus upon whether the feedback was introduced deliberately by the designer, or whether it just happened to be present in a circuit or system which was not designed with any particular notion of feedback in mind. A great many readers will likely identify with the first of these two classes, in which the feedback has been incorporated by specific choice, with sensors and actuators and processors which transform measurements into commands to achieve a given set of goals. Indeed, this way of looking at things was apparent early in the modern literature. Circuit persons will also recognize the second class of possibilities, in as much as feedback in electronic amplifiers was being discussed almost at the same time that the systems viewpoint was being put into place.

By now we realize that feedback is a question of relationships. When we have, for instance, two equations in two unknowns, the age-old process of eliminating one of the two unknowns can be interpreted as a feedback construction. The more interrelationships which exist, the more "feedback'" that exists. Feedback, then, is present whether we explicitly plan for it or not. It would seem provident, therefore, to become better acquainted with some of the features and uses of feedback, so that we can understand more clearly what it is doing in our circuit or system, even if we did not have feedback in mind.

To obtain this type of insight, we shall focus primarily upon the first class above, in which the feedback is deliberately put into play. In such situations, one big variable is the nature of the process which is being controlled by the use of feedback. One may be controlling speed, or pressure, or temperature, or voltage, or current, or just about any variable that one can imagine. To capture at least a bit of this flavor of the subject, the chapter addresses a wide range of different processes which are being placed under control. A second big variable is the design purpose for which the feedback is applied. Perhaps it is for stabilization, tracking, or amplification. Perhaps it is for coping with process model errors which arise because the process is too complicated to model exactly—assuming that we have the knowledge to do so. Perhaps it is for coping with disturbances, such as noise interfering with the transfer of data from one portal of a circuit to another. Or perhaps it is because we cannot get good estimates of key circuit and system parameters, or we cannot obtain a big enough budget to make all the measurements we want, or to install all the actuators we wish.

In the face of all these sorts of issues, we approach the task here by creating a diverse sample of the sorts of issues which can arise. One can create entire handbooks on controls; and that has been done. In fact, one can create encyclopedias on controls; and that has been done. Here we have only a section, and we approach the question by taking samples. This is entirely in the spirit of the subject; and the task of the reader is to try to master the behavior of the whole body of knowledge from these samples! Welcome to the experience of feedback circuits and systems!!!

Algebraic Topics in Control

Cheryl B. Schrader
College of Engineering,
Boise State University,
Boise, Idaho, USA

1.1 Introduction

Control engineers often are referred to as mathematicians in disguise. Indeed, a firm foundation in mathematics is essential for success in the control arena. Many practicing control engineers delve into the intricacies of one or more particular fields of mathematics. Consequently, many of the sections in this chapter on controls rely heavily on algebraic considerations or have algebraic roots. This chapter purports to provide a lively introduction for such investigations by discussing common algebraic topics that occur in control. Along the way, examples of engineering applications are pointed out to the interested reader.

From its very first introduction in elementary school, the term **algebra** conveys a certain level of abstraction. Most people associate algebra with a collection of arithmetic operations combined with representative symbols such as x and y. As undergraduate students, engineers become comfortable with a discussion of fields and vector spaces along with their axiomatic relationships, and this chapter begins here. In the true sense, vector spaces do not form an algebra equation without the additional concept of vector multiplication (tensor product), as mentioned later in Section 1.3. However, square matrices of dimension $n \times n$ do form an algebra equation although it is not commutative. How the associated operations are defined in this algebra along with interesting and important characteristics, are illustrated in some detail. This discussion provides a firm foundation for an understanding of algebra for the engineer. Concluding this chapter are examples of other types of algebras and applications of interest to the control engineer.

Control theory and the tools used in control theory are particularly useful in the study of biomedical engineering and medicine, and the applications extend from the "head to the toes." Implantable organs, such as the heart, ear, kidney, and retina, all require exacting control systems that are designed with a significant number of parameters and need to work reliably 100% of the time. Other capabilities under development, such as remote surgery, also require extensive control systems because a minor slip could be life-threatening. The controller needs to be able to differentiate between intentional hand movement and a tremor on the part of the surgeon.

Standard algebraic notation is employed and should not be unfamiliar to the informed reader. MATLAB, the tool many engineers use for testing and development (and that is used here for numerical examples) was first developed in the late

1970s and written in Fortran. The name originated from the term *matrix laboratory*. The examples are generated using Version 5.3 (release 11), and the same vectors and matrices are carried throughout this chapter. MATLAB is a powerful problem-solving environment with many built-in debugging tools. It can generate world-class graphics that can be imported to almost any file format for inclusion in reports and presentations. As the reader will no doubt observe, MATLAB is quickly assimilable; with a little knowledge of history and intuition, actual MATLAB commands are easy to identify. For a detailed introduction on MATLAB, see Higham and Higham (2000).

1.2 Vector Spaces Over Fields and Modules Over Rings

It is assumed that the reader already has some knowledge and experience with vector spaces and fields. What may not be as readily apparent is that the reader, subsequently, also has experience with modules and rings. This section briefly describes the essence of these ideas in a mathematical sense.

Real numbers, complex numbers, and binary numbers all are **fields**. Specifically a field F is a nonempty set F and two binary operations, addition ($+$) and multiplication, that together satisfy the following properties for all $a, b, c \in F$:

1. **Associativity**: $(a+b)+c = a+(b+c); (ab)c = a(bc)$.
2. **Commutativity**: $a+b = b+a$; $ab = ba$.
3. **Distributivity**: $a(b+c) = (ab)+(ac)$.
4. **Additive identity**: $\exists 0 \in F \ni a+0 = a$.
5. **Multiplicative identity**: $\exists 1 \in F \ni a1 = a$.
6. **Additive inverse**: For every $a \in F, \exists b \in F \ni a+b = 0$. [Notation note: $b = -a$].
7. **Multiplicative inverse**: For every nonzero, $a \in F$, $\exists b \in F \ni ab = 1$. [Notation note: $b = a^{-1}$].

It is commonly known with real numbers that multiplication distributes over addition, and both additive and multiplicative inverses exist. In the case where a multiplicative inverse does not exist, but properties 1 through 6 hold (such as with integers), then the set does not form a field but is categorized as a **commutative ring**. If property 2 also does not hold, then the correct terminology is a **ring**.

To speak of an **additive group**, a single operation is used (addition) along with a nonempty set G, satisfying additive properties 1, 4, and 6. If in addition the operation is commutative (as described in property 2), then the additive group is **abelian**.

To discuss an F-**vector space** V, one simply requires a nonempty set V and a field F that together with binary operations $+ : V \times V \rightarrow V$ and $* : F \times V \rightarrow V$ satisfy the following axioms for all elements $v, w \in V$ and $a, b \in F$:

1. V and $+$ form an additive abelian group.
2. $a*(v+w) = (a*v)+(a*w)$.
3. $(a+b)*v = (a*v)+(b*v)$.
4. $(ab)*v = a*(b*v)$.
5. $1*v = v$.

Vectors are elements of V, and scalars are elements of F. Often, one uses the terminology **vector space** V **over the field** F. What form vectors may take will be examined more closely in Section 1.3. For the purposes of this treatise, and for the following MATLAB examples, the field of real numbers, $\Re$, will be used most often. The reader is urged to remember that any choice of field is allowed.

As a direct generalization of a vector space, a **module** M replaces the underlying field by a ring R. Technically speaking, M is a **left module** because the scalar appears left of the module element. In an analogous fashion, a **module** M **over the ring** R is an R-**module** M. From this discussion, it is apparent that if R is also a field, R-modules are merely vector spaces. In working with modules, it is important to remember to avoid any vector space results relying on division by a nonzero scalar. It is precisely this notion that leads to the extremely powerful application of modules in system analysis, controllability, and observability.

1.3 Matrices and Matrix Algebra

1.3.1 Standard Matrix Notions and Examples

By the time an engineer completes his or her undergraduate studies, familiarity exists with matrices and matrix operations through multivariable calculus or linear algebra. Moreover, a graduate should have a firm understanding of the importance in regarding matrices as representations of linear operators. For a detailed discussion of linear operations and their related matrix representations, see Schrader and Sain (2000). Of course, standard matrix notions can be generalized and expressed using rings and fields, which is the approach used here.

Consider the set of **arrays** (or **matrices**):

$$A = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}, \tag{1.1}$$

with m rows, n columns, and **elements** a_{ij} from a field F (or alternatively, $A \in F^{m\times n}$). Define **matrix addition** $(A+B = C)$ element-wise $(a_{ij}+b_{ij} = c_{ij})$ for $A, B,$ and $C \in F^{m\times n}$; $i = 1, 2, \ldots, m$; and $j = 1, 2, \ldots, n$. An additive identity is the zero matrix, an $m \times n$ matrix whose every element is the additive identity in F. For example, if F is the ring of integers or the field of real or complex numbers, then every element is simply 0. An additive inverse of a matrix A with elements $a_{ij} \in F$ is found element by element by solving for $b_{ij} \in F$ in $a_{ij} + b_{ij} = 0$. Thus, $b_{ij} = -a_{ij}$ and the notation generalizes to the matrix level; that is, $B = -A$.

Such a discussion leads naturally to the concept of **scalar multiplication**. Consider a field element $r \in F$ and a matrix over the same field $A \in F^{m \times n}$. The product $P = rA \in F^{m \times n}$ is calculated element-wise:

$$p_{ij} = ra_{ij};\ i = 1, 2, \ldots, m,\ j = 1, 2, \ldots, n. \tag{1.2}$$

It is simple to see that the additive inverse $B = -A$ is merely the scalar multiplication by -1 of the matrix A.

Example 1

```
>> a = [1 2 3]; b = [4; 5; 6]; c = [7 8 9];
>> a + b
??? Error using ==> +
Matrix dimensions must agree.
>> a + c
ans =
    8    10    12
>> -b
ans =
    -4
    -5
    -6
```

$$a = \begin{bmatrix} 1 & 2 & 3 \end{bmatrix}. \quad b = \begin{bmatrix} 4 \\ 5 \\ 6 \end{bmatrix}. \quad c = \begin{bmatrix} 7 & 8 & 9 \end{bmatrix}.$$

To discuss the multiplication of two matrices A and B over the same field F represented by AB, one is restricted to choose matrices where the number of columns of A equal the number of rows of B. Such matrices are said to be **conformable**. The resultant matrix, $C = AB$, has its number of rows equal to the number of rows of A and its number of columns equal to the number of columns of B. Hence:

$$A \in F^{m \times n} \text{ and } B \in F^{n \times p} \Rightarrow C \in F^{m \times p}. \tag{1.3}$$

Each element in C is found using one row of A and one column of B at a time:

$$c_{ij} = \sum_{k=1}^{n} a_{ik} b_{kj}. \tag{1.4}$$

It is important to note that **matrix multiplication** is not commutative, in general, although it is associative and distributive with respect to matrix addition.

Example 2

```
Consider the same a, b, and c from Example 1.
>> a * b
ans =
    32
>> b * a
ans =
    4   8  12
    5  10  12
    6  12  18
>> a * c
??? Error using ==> *
Inner matrix dimensions must agree.
```

$$a = \begin{bmatrix} 1 & 2 & 3 \end{bmatrix}. \quad b = \begin{bmatrix} 4 \\ 5 \\ 6 \end{bmatrix}. \quad c = \begin{bmatrix} 7 & 8 & 9 \end{bmatrix}.$$

For the special case where A has the same number of rows as columns (A is **square**) and:

$$A = \begin{bmatrix} 1 & 0 & \ldots & 0 \\ 0 & 1 & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & 1 \end{bmatrix}, \tag{1.5}$$

$AB = B$ regardless of choice of B. In such case, A is said to be the **identity matrix** and is most often represented by the symbol I. The identity matrix is an example of a **diagonal matrix**, where all $a_{ij} = 0$ when $i \neq j$, written as $A = \operatorname{diag}\{1, 1, \ldots, 1\}$. In MATLAB, $I^{n \times n}$ is generated with the command **eye** (n). Taken all together, the set of square matrices over F, matrix addition, matrix multiplication, and the zero and identity matrices satisfy the six properties of a ring. A discussion of a multiplicative inverse in the context of matrices is left for Section 1.4.

Example 3

```
>> d = [1 1 1; 1 2 3; 1 3 6]; e = [1 1 1; 4 2 1; 9 3 1];
>> d * e
ans =
 14   6   3
 36  14   6
 67  25  10
>> e * d
ans =
  3   6  10
  7  11  16
 13  18  24
>> d * eye (3)
ans =
 1  1  1
 1  2  3
 1  3  6
```

$$d = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 2 & 3 \\ 1 & 3 & 6 \end{bmatrix}. \quad e = \begin{bmatrix} 1 & 1 & 1 \\ 4 & 2 & 1 \\ 9 & 3 & 1 \end{bmatrix}.$$

A matrix with one column or one row is commonly referred to as a **column vector** or **row vector**, respectively. It can be shown easily that the set of all n tuples for $n > 0$ satisfies the axioms of a vector space over the field of real numbers.

Although many engineers tend to think of this *n*tuple example as synonymous with the definition of a vector space, this interpretation is limiting. For example, the set of polynomials of degree less than $m > 0$ with real coefficients satisfies all axioms of a vector space taking into account standard polynomial addition and multiplication. Section 1.5 will examine polynomials in greater detail.

The most interesting observation when considering *n*tuple vectors is that while one can multiply scalars together or multiply vectors by scalars, one simply cannot multiply two vectors together. Example 2 illustrates this dilemma. The concept of vector multiplication together with a vector space extends to the concept of an **algebra**. This is the additional mathematical understanding one must master to incorporate the common manifestation of vector multiplication found in the **tensor product**.

1.4 Square Matrix Functions: Determinants and Inverses

Square matrices ($n \times n$) have many special properties and functions associated with them. In this section, determinants will be examined first because they are important in the study of matrices and their control applications. Following a discussion of determinants, this section will examine more fully the concept of a matrix multiplicative inverse.

1.4.1 Determinants

Determinants can be viewed quite naturally using a detailed description of vector multiplication and the tensor product. For details regarding this approach, the reader is referred to Sain and Schrader (2000). In the current examination, determinants will be approached from the matrix algebra perspective.

Originally attributed to Vandermonde, a determinant is a scalar value or single algebraic expression resulting from a square matrix. It is, therefore, appropriate to begin with square matrices that are also scalars, $A = F^{1\times 1}$. In such case, the **determinant** of A, more commonly written as det (A) or $|A|$, is the scalar itself:

$$\det(A) = \det([a_{11}]) = a_{11}. \tag{1.6}$$

Now consider $A \in F^{2\times 2}$ and introduce the concept of the **minor** of a_{ij}, which is defined as the determinant of the submatrix that results when row i and column j are removed. For a general 2×2 matrix:

$$A = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}, \tag{1.7}$$

and it is obvious that:

- minor of $a_{11} = \det(a_{22}) = a_{22}$.
- minor of $a_{12} = \det(a_{21}) = a_{21}$.
- minor of $a_{21} = \det(a_{12}) = a_{12}$.
- minor of $a_{22} = \det(a_{11}) = a_{11}$.

The actual calculation of the determinant of equation 1.7 relies on minors according to the algorithm following:

Step 1. Choose any row i (or column j).
Step 2. Multiply each element a_{ik} (or a_{kj}) in that row (or column) by its minor and by $(-1)^{i+k}$ (or $(-1)^{k+j}$).
Step 3. Add the results from step 2.

The multiplication of a minor by ±1, appropriately, is termed a **cofactor**. Following the previous algorithm, the choice of column 2 ($j = 2$) yields:

$$a_{12}a_{21}(-1) + a_{22}a_{11}(+1). \tag{1.8}$$

The value of the determinant is independent of the choice of row or column; it makes no difference whatsoever. Determinants of 2×2 matrices are fairly straightforward in that the two elements along the main diagonal are multiplied together and then the product of the remaining two elements is subtracted.

An explanation of determinants for matrices larger than 2×2 is best understood first with 3×3 matrices to help grasp the notation, which can then be expanded to $n \times n$ matrices in general. Consider first:

$$\det(A) = \begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix}, \tag{1.9}$$

and expand about row 1 according to the three-step algorithm. Then:

$$\det(A) = a_{11}\begin{vmatrix} a_{22} & a_{23} \\ a_{32} & a_{33} \end{vmatrix} - a_{12}\begin{vmatrix} a_{21} & a_{23} \\ a_{31} & a_{33} \end{vmatrix} + a_{13}\begin{vmatrix} a_{21} & a_{22} \\ a_{31} & a_{32} \end{vmatrix} \tag{1.10}$$

$$\begin{aligned} &= a_{11}(a_{22}a_{33} - a_{23}a_{32}) - a_{12}(a_{21}a_{33} - a_{23}a_{31}) \\ &\quad + a_{13}(a_{21}a_{32} - a_{22}a_{31}) \end{aligned} \tag{1.11}$$

$$\begin{aligned} &= a_{11}a_{22}a_{33} + a_{12}a_{23}a_{31} + a_{13}a_{21}a_{32} \\ &\quad - a_{12}a_{21}a_{33} - a_{11}a_{23}a_{32} - a_{13}a_{22}a_{31}. \end{aligned} \tag{1.12}$$

Similar to the 2×2 case, there exists a relatively simple way to find the determinant of equation 1.9. Write the first two columns next to the original columns as follows:

$$\begin{matrix} a_{11} & a_{12} & a_{13} & a_{11} & a_{12} \\ a_{21} & a_{22} & a_{23} & a_{21} & a_{22} \\ a_{31} & a_{32} & a_{33} & a_{31} & a_{32} \end{matrix}. \tag{1.13}$$

Form the first three products of equation 1.12 by starting with a_{11} in equation 1.13 and drawing a diagonal downward to the right. Repeat with a_{12} and with a_{13}, forming two more diagonals. The last three products of equation 1.12 are formed by subtracting left diagonals. Begin with a_{12}, draw a diagonal down to the left, and then repeat with a_{11} and a_{13}. For $n \times n$ matrices where $n > 3$, such simple characterizations do not exist. Thus, one is forced to define determinants in general using symbols to describe the expansions illustrated in equations 1.10 through 1.12.

In general, determinants of $n \times n$ matrices can be computed using cofactors, which in turn require finding determinants of $(n-1) \times (n-1)$ matrices and so on. Such is the case for $n = 2$ and $n = 3$. Define A_{ij} as the cofactor formed by (1) deleting the ith row and the jth column of A, (2) calculating the determinant of the $(n-1) \times (n-1)$ submatrix, and (3) multiplying by $(-1)^{i+j}$. Expanding about any row i produces:

$$\det(A) = \sum_{k=1}^{n} a_{ik} A_{ik}, \tag{1.14}$$

or about any column j:

$$\det(A) = \sum_{k=1}^{n} a_{kj} A_{kj}. \tag{1.15}$$

1.4.2 Inverses

Any square matrix $A \in F^{n\times n}$ with a nonzero determinant has a unique inverse $A^{-1} \in F^{n\times n}$, which satisfies:

$$AA^{-1} = A^{-1}A = I. \tag{1.16}$$

Matrix inverses can be determined by forming the **cofactor matrix**:

$$\tilde{A} = \begin{bmatrix} A_{11} & A_{12} & \dots & A_{1n} \\ A_{21} & A_{22} & \dots & A_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ A_{n1} & A_{n2} & \dots & A_{nn} \end{bmatrix}, \tag{1.17}$$

taking its transpose, $\tilde{A}^T$ (by interchanging the rows and columns of $\tilde{A}$), and scaling:

$$A^{-1} = \frac{\tilde{A}^T}{\det(A)}. \tag{1.18}$$

The matrix $\tilde{A}^T$ is termed the **adjoint** of A and is calculated in MATLAB using **adj (*A*)**.

Matrices with nonzero determinants are said to be **nonsingular** or of **full rank**. For nonsquare matrices $A \in F^{m\times n}$, the rank is the number of linearly independent columns of A over the field F and is $\leq \min(m, n)$. Related commands in MATLAB are **rank** and **null**. Simultaneous linear equations may have a different number of solutions, and how many solutions exist is related to the rank of A. To solve simultaneous equations, MATLAB provides the backslash command (\) to determine a vector $x \in F^n$, satisfying $Ax = y$ for $A \in F^{m\times n}$ and $y \in F^m$. Given $A \in F^{m\times n}$ and $Y \in F^{m\times p}$, the backslash operator can be used to solve for $X \in F^{n\times p}$ in $AX = Y$. Directly solving for the matrix inverse, assuming one exists, can be avoided by solving for X in $AX = I$. This is usually faster and more accurate because Cholesky or LU factorizations are employed. More advanced factorizations contribute to solving the sparse system problem (A is large and has few nonzero elements) that occurs, for example, in electrical power systems.

All is not lost in terms of inverses in the case of nonsquare matrices $A \in F^{m\times n}$ or rank-deficient square matrices. Define the pseudoinverse $A^+ \in F^{n\times m}$ by:

$$A^+ = (A^T A)^{-1} A^T. \tag{1.19}$$

Note that $A^+A = I$ but AA^+ may not. Hence, A^+ is also termed a **left inverse**. There exists, as one immediately assumes, an analogous derivation for a **right inverse**. An interesting recent study uses pseudoinverses in crptanalysis to prove insecurity.

Example 4

```
Use the same d and e as in example 3.
>> det(d)

    Inf  Inf  Inf
    Inf  Inf  Inf
    Inf  Inf  Inf

>> det(f)

ans =

    0.
```

1.5 The Algebra of Polynomials

Polynomials in the indeterminate λ with coefficients from a field F, usually represented by $F[\lambda]$, form a commutative ring. The set of polynomials of degree less than some integer $m > 0$ with real coefficients along with the standard addition and multiplication of polynomials form a vector space. Such polynomials can be described by:

$$p(\lambda) = a_m\lambda^m + a_{m-1}\lambda^{m-1} + \cdots + a_1\lambda + a_0 = \sum_{k=0}^{m} a_k\lambda^k, \quad (1.20)$$

for $a_i \in \Re$ and $a_m \neq 0$. The **degree** (or **order**) of the polynomial in equation 1.20 is m. Further, if $a_m = 1$, the polynomial is called **monic**.

One of the most important results of classical algebra is that polynomials with real coefficients can be factored into real linear factors and real quadratic factors. Any polynomial $\Re[\lambda]$ has at most m **roots** (or **zeros**). If the same matrix is considered over the field of complex numbers $\mathbb{C}$, then it has exactly m roots. Nonreal complex roots must occur in complex conjugate pairs. Note that there are essentially three problems related to polynomials: **evaluation, root finding**, and **curve fitting**—and MATLAB functions **polyval**, **roots**, and **polyfit** address all three.

Now this section presents at a concrete discussion of **algebras**. An (associative) **algebra** over a field F is a set S, which is both a vector space and a ring over F such that the additive group structures are the same, and for all $s, t \in S$, and $a \in F$, the following axiom holds:

$$a(st) = (as)t = s(at). \quad (1.21)$$

The relationship of equation 1.21 combines the concepts of a ring with those of a vector space. Consider now the ring $F[\lambda]$, which has also a vector space structure. Addition and the additive identity, 0, are the same for both structures. Moreover, for two polynomials $p(\lambda), q(\lambda) \in F[\lambda]$ and $a \in F$, equation 1.21 is satisfied. Thus, polynomials form an associative algebra. The question may arise as to why the terminology **matrix algebra** was used previously. It is easy to show that the set of $n \times n$ matrices over F is an associative algebra by recognizing that multiplication of a matrix A by a scalar r can be written $rA = (rI)A$.

Finally, a ratio of two polynomials is a rational function:

$$f(\lambda) = \frac{n(\lambda)}{d(\lambda)}. \quad (1.22)$$

Rational functions occur most often in control as transfer functions for single-input and single-output systems. Systems with more than one input and more than one output can be described by transfer function matrices. These matrices can be realized as matrix polynomial fractions or as a polynomial matrix "divided" by a polynomial. Much research has been accomplished on this topic, particularly in its relationship to multivariable system analysis and control. Inequalities involving polynomial matrices, "inverses," and optimization problems are also becoming increasingly important.

1.6 Characteristic and Singular Values

1.6.1 Characteristic Values

Characteristic values—also called eigenvalues, characteristic or latent roots, proper or spectral values—describe a square matrix representation of a linear operator that is independent of the basis chosen. The **characteristic polynomial** of $A \in \mathbb{C}^{n\times n}$ is $p(\lambda) = \det(\lambda I - A)$, whose roots are the **characteristic values** of A. Here, matrices are considered over the complex field to admit the possibility of complex roots. The **characteristic equation**, $p(\lambda) = 0$, is of degree n and has n roots. Characteristic values depend on special matrix properties of A. Another important result known as the **Cayley-Hamilton theorem** is that a matrix A satisfies its own characteristic equation; that is, $p(A) = 0$.

The idea behind characteristic values is to describe the action of a matrix on a vector by a single scalar value:

$$Ax = \lambda x, \quad (1.23)$$

where $x \in \mathbb{C}^n$ and $\lambda \in \mathbb{C}$. Equation 1.23 can be written as:

$$(\lambda I - A)x = 0, \quad (1.24)$$

which has nonzero solutions x (**characteristic vectors** or **eigenvectors**) only if λ is a characteristic value of A. Characteristic values are often used in control to determine system stability.

Following what is known about polynomials, complex characteristic values occur in complex conjugate pairs, as do their associated characteristic vectors. Characteristic values are unique although characteristic vectors are not. This makes their actual computation (e.g., using MATLAB) somewhat arbitrary. The function **poly(A)** returns the characteristic polynomial for a matrix A. Then the **roots** command can be utilized to find the characteristic values although this is not a numerically reliable process. Alternatively, one can call the function **eig**, which can also return characteristic vectors as well.

The same function can be used to solve the generalized eigenvector problem in the case where not all eigenvalues are distinct. Eigenvectors associated with distinct eigenvalues are linearly independent; however, eigenvectors associated with repeated eigenvalues may be linearly dependent. The generalized eigenvector problem produces linearly independent eigenvectors by recognizing one can be rather clever in eigenvector choice. The result is that the non-uniqueness of eigenvectors can be used as an advantage. Complete eigenstructure assignment can be approached through the feedback control problem, which has been applied, for example, in active control of structures.

What makes the linear independence of eigenvectors important is that a matrix of such vectors can be used as a **similarity transformation** Q to relate a matrix A to its **normal** or **Jordan canonical form**:

$$\hat{A} = \text{diag}\{J_1, J_2, \ldots, J_k\}, \tag{1.25}$$

where each J_i is a Jordan block of the form:

$$\begin{bmatrix} \lambda & 1 & 0 & \ldots & 0 \\ 0 & \lambda & 1 & \ldots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \ldots & \lambda & 1 \\ 0 & 0 & \ldots & 0 & \lambda \end{bmatrix}. \tag{1.26}$$

For the distinct eigenvalue case, $\hat{A}$ is purely diagonal. For the repeated eigenvalue case, $\hat{A}$ is as close to diagonal as possible. The matrices A and $\hat{A}$ are said to be *similar* and are related by:

$$\hat{A} = Q^{-1}AQ. \tag{1.27}$$

Additional details on eigenvectors and linear transformations in general can be found in Schrader and Sain (2000). Canonical forms such as the companion, controllable, and modal or observable forms are commonly used for control purposes. The key is in always remembering, through the appropriate linear transformation, how a canonical form is related to the original matrix. This is much like dropping breadcrumbs behind you as you move from one place to another so that you can always find your way home.

1.6.2 Singular Values

Unique scalars are associated with nonsquare matrices $A \in F^{m\times n}$, and these are termed **singular values**. In general, a matrix A of rank r can be described by its **singular value decomposition** (SVD):

$$A = U\Sigma V^*, \tag{1.28}$$

where $\Sigma \in F^{m\times n}$ is $\text{diag}\{\sigma_1, \sigma_2, \ldots, \sigma_r, 0, \ldots, 0\}$ and where and $U \in F^{m\times m}$ and $V \in F^{n\times n}$ are **unitary** ($UU^* = U^*U = I$ and $V^*V = VV^* = I$). Here the * notation is used to represent the **complex conjugate** (or **Hermitian**) **transpose**. The elements σ_i are related by:

$$\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r > 0, \tag{1.29}$$

which are the singular values of A; the columns of U are the **left singular vectors**, and the columns of V the **right singular vectors**. Singular values are unique although singular vectors are not. The SVD is quite useful and reliable in determining the rank of a constant matrix or its pseudoinverse and in the realization of transfer function matrices. By construction, singular values are the positive square root of the eigenvalues of A^*A.

Example 5

```

1.7 Nonassociative Algebras

Thus far, this chapter has considered only associative algebras, so now it turns its attention to other algebras for the sake of completeness. Other types of algebras may evolve by generalizing the concept of associative algebras (e.g., alternative algebras) or by redefining the associative product (e.g., Lie algebras). Consider an associative algebra A over a field F and replace the standard associative product of two elements $x, y \in A$, xy, with the *commutator* product $xy - yx$. Note that associativity holds only in specific cases. By redefining the associative product, we obtain a nonassociative algebra called the **Lie algebra**. Similarly, if one chooses the **anticommutator** product, $1/2(xy + yx)$, we obtain the **Jordan algebra**, also nonassociative. Nonassociative algebras are becoming increasingly important in control and quantum computers and in autonomous vehicle motion planning.

The reader is most likely familiar with any number of algebras or classes of algebras such as exterior, multilinear, Lie, Jordan, composition, alternative, differential, nonassociative, Boolean, commutative, or division. Some of these listed algebras may be misnomers according to the strict definition of an **algebra**. Of course, the point is that algebra is much more than operations. It is an axiomatic framework governed by a global view of the whole construct. It is a way of describing how a basic element behaves. And that, after all, is control in its most rudimentary sense.

1.8 Biosystems Applications

Biosystems present many potential applications for the use of algebra, including the areas of biomechanics, tissue engineering, image processing (e.g., CAT and MRI), and biosignal processing (e.g., EMG and EEG). The determination of which variables are dependent and which are independent is important in the design of gait analysis and prostheses. For example, in gait analysis, is the angle between the hip and femur on the opposite side of the body important for proper ankle movement? Is the angle on the same side important? These questions can be answered by taking multiple measurements and solving for dependent and independent variables. Tissue engineering can involve the interaction of materials (e.g., implants, lasers, etc.) with tissues of the body, such as implants using feedback to identify the amount of sugar in the blood for diabetics. The application of control theory to quantum systems, including molecular control, lasing without inversion, NMR spectroscopy, and quantum information systems, has become of great interest in recent years. Medical image analysis can be highly dependent on fundamental algebraic concepts and system theoretic techniques, and bilinear models are widely used for nonlinear biomedical signal and image processing. In medical technology development, the microelectromechanical and nanoelectromechanical phenomena and processes produce new challenges for the control engineer. For noninvasive data systems, such as multisensorial electrophysiology and biomagnetism, sensor array analysis depends on advanced algebraic techniques.

The interested reader should look in the more recent journals and conference proceedings to see other exciting topics that address algebraic notions. For biomedical engineering, the prominent resources are the *IEEE Transactions on Biomedical Engineering*, the *IEEE Transactions on Neural and Rehabilitation*, and the annual *International Conference of the IEEE Engineering in Medicine and Biology Society*. The American Society of Mechanical Engineers (ASME) has a bioengineering division with an active publications and conference schedule.

Stability

Derong Liu
Department of Electrical and Computer Engineering, University of Illinois at Chicago, Chicago, Illinois, USA

2.1 Introduction

For a given control system, stability is usually the most fundamental question to ask. If the system is linear and time-invariant, many stability criteria are available. Among them are the **Routh's stability criterion** and the **Nyquist stability criterion**. If the system is nonlinear or linear but time-varying, however, then such stability criteria do not apply.

Stability is mostly concerned with dynamical systems. It is a fundamental requirement in most engineering applications that the systems designed are stable. In control engineering applications, the design of a control system must first guarantee the stability of the overall system. That is to say, one of the design objectives that must be guaranteed in a controller design for a given system is stability. Stability is always a requirement independent of the technique used in the controller design, be it by **linear control, adaptive control, optimal control, intelligent control**, and the like.

2.2 Stability Concepts

Let $r(t)$, $y(t)$, and $h(t)$ be the input, output, and the impulse responses of a linear time-invariant system, respectively. For an nth order system, its initial conditions are given by:

$$y^{(k)}(0) = \left.\frac{d^k y(t)}{dt^k}\right|_{t=0} \qquad k = 0, 1, \cdots, n-1.$$

Zero initial conditions of an nth order system means that:

$$y^{(k)}(0) = 0,\ k = 0,\ 1, \cdots,\ n-1.$$

Finite initial conditions of an nth order system imply that:

$$\left|y^{(k)}(0)\right| \leq \eta,\ k = 0,\ 1, \cdots,\ n-1,$$

for some positive number $\eta < \infty$.

2.2.1 Bounded-Input Bounded-Output Stability

With zero initial conditions, a linear-time invariant system is said to be **bounded-input bounded-output** (BIBO) stable, or simply stable, if its output $y(t)$ is bounded in response to a bounded input $r(t)$. A system is said to be unstable if it is not BIBO stable.

The stability of a linear system can be determined from the location of the poles of the closed-loop transfer function in the s plane. If any of these poles lie in the right half of the s plane, with increasing time they give rise to the dominant mode, and the transient response increases monotonically or oscillates with increasing amplitude. This represents an unstable system. For such a system, as soon as the power is turned on, the output may increase with time. If no saturation takes place in the system and no mechanical stop is provided, then the system may eventually be subjected to damage and fail since the response of a real physical system cannot increase indefinitely. Hence, closed-loop poles in the right half of the s plane are not permissible in the usual linear control systems. If all closed-loop poles lie to the left of the $j\omega$ axis, any transient response eventually reaches equilibrium. This represents a stable system. Therefore, for BIBO stability, the roots of the characteristic equation, or the poles of the transfer function $H(s)$, must all lie in the left half of the s plane. Note that when a system has roots on the $j\omega$ axis, it is unstable by this definition.

2.2.2 Zero-Input Stability

If the zero-input response $y(t)$, subject to the finite initial conditions, reaches zero as time t approaches infinity, the system is said to be zero-input stable, or stable; otherwise, the system is unstable.

The **zero-input stability** defined here can also be equivalently stated as follows. A linear time-invariant system is zero-input stable if for any set of finite initial conditions, there exists a positive number M that depends on the initial condition, such that:

(1) $|y(t)| \leq M < \infty$ for all $t \geq 0$; and
(2) $\lim_{t \to \infty} |y(t)| = 0$.

Because the second condition requires that the magnitude of $y(t)$ reaches zero as time approaches infinity, the zero-input stability is also known as the **asymptotic stability**.

For linear time-invariant systems, BIBO stability and zero-input stability all have the same requirement: the roots of the characteristic equations must be located in the left half of the s plane. Thus, if a system is BIBO stable, it must also be zero-input or asymptotically stable. For this reason, the present discussion will simply refer to the stability of linear time-invariant systems without mentioning BIBO or zero-input. This chapter also often refers to the situation when the characteristic equation has simple roots on the $j\omega$ axis and none in the right half of the s plane as **marginally stable** or **marginally unstable**.

Example 1

A system with (closed-loop) transfer function is given by:

$$H(s) = \frac{1}{(s+1)(s+2)(s+3)},$$

which will be stable. A system with transfer function is given by:

$$H(s) = \frac{s+1}{(s-1)(s^2+2s+3)},$$

which will be unstable. A system with transfer function is given by:

$$H(s) = \frac{3(s+3)}{(s+2)(s^2+5)},$$

which will be unstable or marginally stable.

2.3 Stability Criteria

Whether a linear system is stable or unstable is a property of the system itself and does not depend on the input or driving function of the system. The poles of the input or driving function do not affect the property of stability of the system, but they contribute only to steady-state response terms in the solution. Thus, the problem of closed-loop stability can be solved readily by choosing no closed-loop poles in the right half of the s plane, including the $j\omega$ axis.

The most common representation of a linear system is given by its closed-loop transfer function in the form of:

$$\frac{B(s)}{A(s)} = \frac{b_0 s^m + b_1 s^{m-1} + \cdots + b_{m-1} s + b_m}{a_0 s^n + a_1 s^{n-1} + \cdots + a_{n-1} s + a_n},$$

where the as and bs are constants and $m \leq n$. A simple criterion, known as Routh's stability criterion, enables the determination of the number of closed-loop poles that lie in the right half of the s plane without having to factor the polynomial $A(s)$.

2.3.1 Routh's Stability Criterion

1) Write the polynomial in s in the following form:

$$a_0 s^n + a_1 s^{n-1} + \cdots + a_{n-1} s + a_n = 0, \tag{2.1}$$

where the coefficients are real quantities. Assume that $a_n \neq 0$; that is, any zero root has been removed.

2) If any of the coefficients are zero or negative in the presence of at least one positive coefficient, there is a root or are roots that are imaginary or have positive real parts. In such a case, the system is not stable.

3) If all coefficients are positive, arrange the coefficients of the polynomial in rows and columns according to the following pattern:

$$\begin{array}{cccccc}
s^n & a_0 & a_2 & a_4 & a_6 & \cdots \\
s^{n-1} & a_1 & a_3 & a_5 & a_7 & \cdots \\
s^{n-2} & b_1 & b_2 & b_3 & b_4 & \cdots \\
s^{n-3} & c_1 & c_2 & c_3 & c_4 & \cdots \\
s^{n-4} & d_1 & d_2 & d_3 & d_4 & \cdots \\
\vdots & \vdots & \vdots & & & \\
s^2 & e_1 & e_2 & & & \\
s^1 & f_1 & & & & \\
s^0 & g_1 & & & &
\end{array}$$

The coefficients b_1, b_2, b_3, and so on, are evaluated as follows:

$$b_1 = \frac{a_1 a_2 - a_0 a_3}{a_1}.$$

$$b_2 = \frac{a_1 a_4 - a_0 a_5}{a_1}.$$

$$b_3 = \frac{a_1 a_6 - a_0 a_7}{a_1}.$$

$$\vdots$$

The evaluation of the *b*s is continued until the remaining ones are all zero. The same pattern of cross-multiplying the coefficients of the two previous rows is followed in evaluating the *c*s, *d*s, and so on. That is:

$$c_1 = \frac{b_1 a_3 - a_1 b_2}{b_1}.$$

$$c_2 = \frac{b_1 a_5 - a_1 b_3}{b_1}.$$

$$c_3 = \frac{b_1 a_7 - a_1 b_4}{b_1}.$$

$$\vdots$$

$$d_1 = \frac{c_1 b_2 - b_1 c_2}{c_1}.$$

$$d_2 = \frac{c_1 b_3 - b_1 c_3}{c_1}.$$

$$\vdots$$

This process is continued until the *n*th row has been completed. The complete array of coefficients is triangular. Note that in developing the array, an entire row may be divided or multiplied by a positive number to simplify the subsequent numerical calculation without altering the stability conclusion.

4) The number of roots in equation 2.1 with positive real parts is equal to the number of changes in the sign of the coefficients of the first column of the array.

It is noted that the exact values of the terms in the first column need not be known; instead, only the signs are needed. The necessary and sufficient conditions that all roots of equations 2.1 lie in the left half of the *s* plane are that all the coefficients of equation 2.1 be positive and all terms in the first column of the array have positive sign.

Example 2

Consider the following polynomial:

$$s^4 + 2s^3 + 3s^2 + 4s + 5 = 0.$$

According to the procedure, the following array can be formed.

$$\begin{array}{lrrr}
s^4 & 1 & 3 & 5 \\
s^3 & 2 & 4 & 0 \\
s^2 & 1 & 5 & \\
s^1 & -6 & & \\
s^0 & 5 & &
\end{array}$$

In this example, the number of changes in the sign of the coefficients in the first column is two. This means that there are two roots with positive real parts. Note that the result is unchanged when the coefficients of any row are multiplied or divided by a positive number to simplify the computation. If the polynomial in the present example is the denominator of a closed-loop transfer function, the corresponding system will be unstable.

Routh's stability criterion is also known as the **Routh-Hurwitz criterion.**

2.3.2 Nyquist Stability Criterion

For a system shown in Figure 2.1, the closed-loop transfer function is given by:

$$\frac{Y(s)}{R(s)} = \frac{G(s)}{1 + G(s)H(s)}.$$

For stability, all roots of the following characteristic equation must lie in the left half of the *s* plane:

$$1 + G(s)H(s) = 0.$$

The Nyquist stability criterion applies to cases when $G(s)H(s)$ has neither poles nor zeros on the $j\omega$ axis. In the system shown in Figure 2.1, if the open-loop transfer function $G(s)H(s)$ has P poles in the right half of the *s* plane and $\lim_{s\to\infty} G(s)H(s) =$ constant, then for stability, the $G(j\omega)H(j\omega)$ locus, as ω varies from $-\infty$ to ∞, must circle the $-1 + j0$ point P times in the counterclockwise direction.

This criterion can be expressed as:

$$Z = N + P,$$

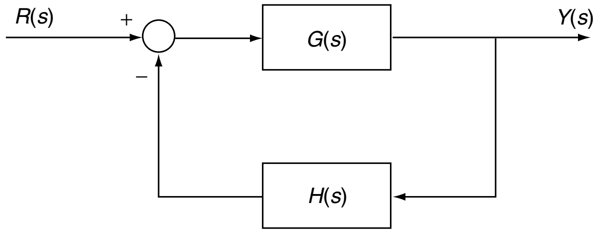

FIGURE 2.1 A Closed-Loop System

where $Z =$ number of zeros of $1 + G(s)H(s)$ in the right half of the s plane, $N =$ number of clockwise encirclements of the $-1 + j0$ point, and $P =$ number of poles of $G(s)H(s)$ in the right half of the s plane. If P is not zero for a stable control system, $Z = 0$ or $N = -P$ must be true, which means that there must be P counterclockwise encirclements of the $-1 + j0$ point.

Example 3

Consider a closed-loop system whose open-loop transfer function is given by:

$$G(s)H(s) = \frac{K}{(T_1 s + 1)(T_2 s + 1)},$$

where $T_1 > 0$ and $T_2 > 0$.

A plot of $G(j\omega)H(j\omega)$ is shown in Figure 2.2. Because $G(s)H(s)$ does not have any poles in the right half of the s plane and the $-1 + j0$ point is not encircled by the $G(j\omega)H(j\omega)$ locus, this system is stable for any positive values of K, T_1, and T_2.

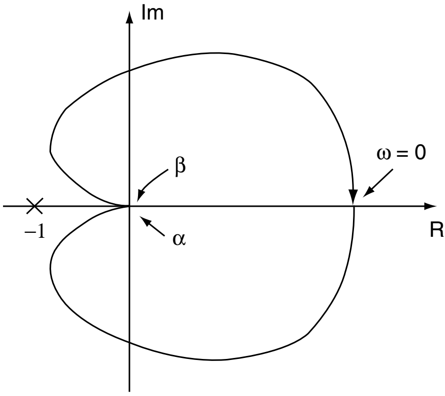

FIGURE 2.2 Polar Plot of $G(j\omega)H(j\omega)$. The α corresponds to $\omega = +\infty$, and β corresponds to $\omega = -\infty$.

Note that in the preceding criterion, it is assumed that $G(s)H(s)$ has neither poles nor zeros on the $j\omega$ axis. In this case, the criterion is derived by considering the Nyquist contour in Figure 2.3(A), which encloses the entire right half of the s plane. When $G(s)H(s)$ has poles and/or zeros on the $j\omega$ axis, the contour must be modified as in Figure 2.3(B).

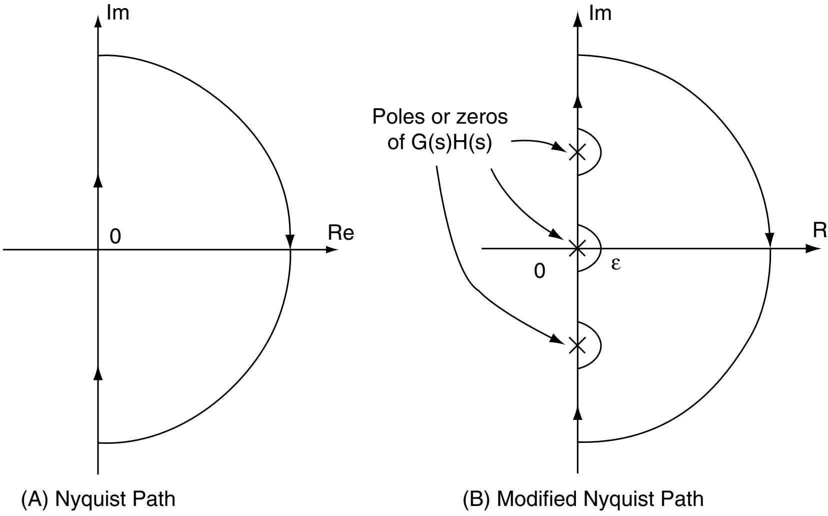
The Nyquist stability criterion also applies to cases when $G(s)H(s)$ has poles and/or zeros on the $j\omega$ axis. In the system shown in Figure 2.1, if the open-loop transfer function $G(s)H(s)$ has P poles in the right half of the s plane, then for stability, the $G(s)H(s)$ locus (as a representative point s traces on the modified Nyquist path in the clockwise direction) must circle the $-1 + j0$ point P times in the counterclockwise direction.

Example 4

A closed-loop system has the following open-loop transfer function:

$$G(s)H(s) = \frac{K(T_2 s + 1)}{s^2(T_1 s + 1)},$$

whose stability depends on the relative magnitude of T_1 and T_2. Plots of the locus $G(s)H(s)$ for three cases, $T_1 < T_2$, $T_1 = T_2$, and $T_1 > T_2$, are shown in Figure 2.4. For $T_1 < T_2$, the locus of $G(s)H(s)$ does not encircle the $-1 + j0$ point, and the closed-loop system is stable. For $T_1 = T_2$, the locus of $G(s)H(s)$ passes through the $-1 + j0$ point, which indicates that the closed-loop poles are located on the $j\omega$ axis. For $T_1 > T_2$, the locus of $G(s)H(s)$ encircles the $-1 + j0$ point twice in the clockwise direction. Thus, the closed-loop system has two closed-loop poles in the right half of the s plane, and the system is unstable.



(A) Nyquist Path

(B) Modified Nyquist Path

FIGURE 2.3 The Nyquist Contour

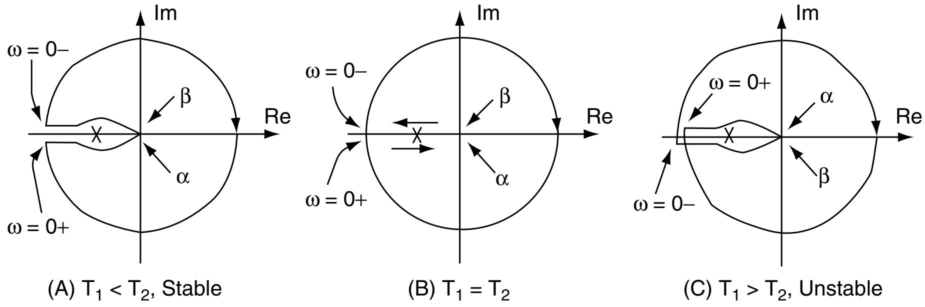


FIGURE 2.4 Polar Plots in the *GH* Plane. For Figure 2.4(B), $G(j\omega)H(j\omega)$ passes through the $-1 + j0$ point. In all of the figures, α corresponds to $\omega = +\infty$ and β corresponds to $\omega = -\infty$.

2.3.3 Phase Margin

The **phase margin** is the amount of additional phase lag at the gain crossover frequency required to bring the system to the verge of instability. The crossover frequency is the frequency at which $|G(j\omega)|$, the magnitude of the open-loop transfer function, is unity. The phase margin γ is 180° plus the phase angle ϕ of the open-loop transfer function at the gain crossover frequency, or:

$$\gamma = 180^\circ + \phi.$$

2.3.4 Gain Margin

The **gain margin** is defined as the reciprocal of the magnitude $|G(j\omega)|$ at the frequency at which the phase angle is -180°. Defining the phase crossover frequency ω_1 to be the frequency at which the phase angle of the open-loop transfer function equals -180° gives the gain margin K_g:

$$K_g = \frac{1}{|G(j\omega_1)|}.$$

In terms of decibels:

$$K_g\mathrm{dB} = 20 \log K_g = -20 \log |G(j\omega_1)|.$$

Phase margin and gain margin are illustrated in Figures 2.5 and 2.6.

For a stable minimum-phase system, the gain margin indicates how much the gain can be increased before the system becomes unstable. For an unstable system, the gain margin indicates how much the gain must be decreased to make the system stable.

2.4 Lyapunov Stability Concepts

When the system in question is nonlinear or linear but time varying, the preceding stability criteria do not apply any more.

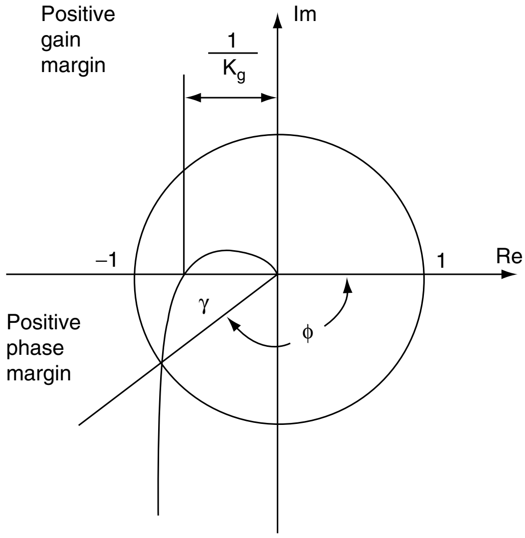

FIGURE 2.5 Phase and Gain Margin of a Stable System

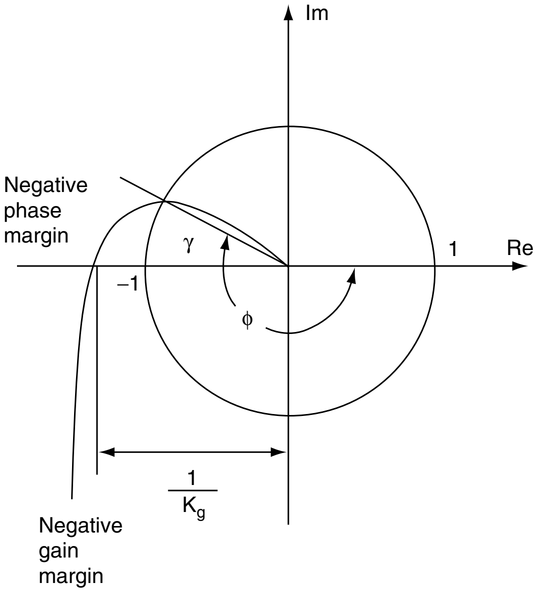

FIGURE 2.6 Phase and Gain Margin of an Unstable System

The alternative, **Lyapunov stability theory**, will be introduced as follows.

Use $\|x\|$ to denote the norm of $x \in R^n$. One example of vector norms is given by:

$$\|x\| = \sqrt{\sum_{i=1}^{n} x_i^2},$$

which is usually called the Euclidean norm or the l_2-norm. A neighborhood of the origin specified by $h > 0$ will be denoted by $B(h) = \{x \in R^n: \|x\| < h\}$. Consider continuous-time dynamical systems described by differential equations of the form:

$$\dot{x} = f(x),\ t \geq 0, \tag{2.2}$$

where $x \in R^n$ and $\dot{x}$ represent the derivative of x with respect to time t. It is assumed that $f: R^n \to R^n$ or $f: B(h) \to R^n$ for some $h > 0$. It is also assumed that $f(x)$ is continuous in x.

2.4.1 Equilibrium Point

The **equilibrium point** is in the state space at which the dynamical system will stay if it starts from that point. For systems described by equation 2.2, an equilibrium point x_e satisfies the condition that $f(x_e) = 0$.

Other terms for equilibrium point include **stationary point, singular point, critical point**, and **rest position**.

Example 5

Consider the simple pendulum system described by the equation:

$$\begin{cases} \dot{x}_1 &= x_2, \\ \dot{x}_2 &= -k \sin x_1, \end{cases} \tag{2.3}$$

where $k > 0$.

Equation 2.3 describes a dynamical system in R^2. The x_1 denotes the angle of the pendulum from the vertical position, and x_2 denotes the angular velocity. This system has two equilibrium points. One of them is located as shown in Figure 2.7(left), and the other is located as shown in Figure 2.7(right). Mathematically, these two equilibrium points can be represented by $(2k\pi, 0)$ and $(2k\pi + \pi, 0)$, respectively, for $k = 0, \pm 1, \pm 2, \ldots, N$.

2.4.2 Isolated Equilibrium Point

An equilibrium point x_e is called isolated if there is an $h > 0$ such that $B(x_e, h) \triangleq \{x \in R^n: \|x - x_e\| < h\}$ contains no equilibrium point other than x_e itself, where $\|\cdot\|$ represents any equivalent vector norm on R^n.

Both equilibrium points in example 5 are isolated equilibrium points in R^2.

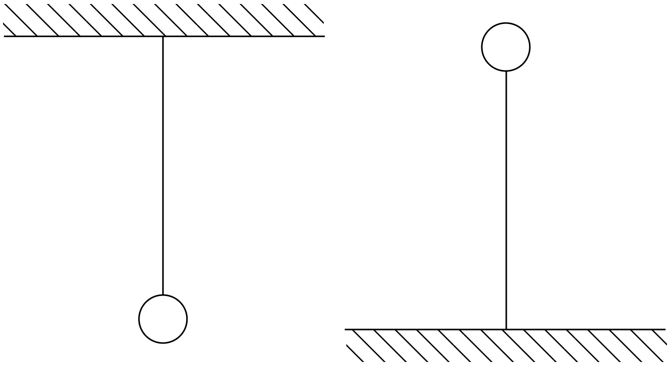

FIGURE 2.7 The Two Equilibrium Points of a Pendulum

Example 6

Consider a system described by equations:

$$\begin{aligned} \dot{x}_1 &= -ax_1 + bx_1x_2. \\ \dot{x}_2 &= -bx_1x_2. \end{aligned} \tag{2.4}$$

The $a > 0$ and $b > 0$ are constants. This example does not have any isolated equilibrium because every point on the x_2 axis (i.e., $x_1 = 0$) is an equilibrium point for equation 2.4.

Example 7

The linear system is described by:

$$\dot{x} = A(t)x,$$

which has a unique equilibrium that is at the origin if $A(t)$ is nonsingular for all $t \geq 0$.

Example 8

Assume that in equation 2.2, f is continuously differentiable with respect to all of its arguments, and let:

$$J(x_e) = \left.\frac{\partial f(x)}{\partial x}\right|_{x=x_e},$$

where $\partial f/\partial x$ is the $n \times n$ **Jacobian matrix** defined by

$$\frac{\partial f}{\partial x} = \left[\frac{\partial f_i}{\partial x_j}\right].$$

If $f(x_e) = 0$, and $J(x_e)$ is nonsingular, then x_e is an isolated equilibrium of system 2.2.

In stability theory, it is usually assumed that a given equilibrium point is an isolated equilibrium.

Stability concepts will be introduced for equilibrium at the origin (i.e., for $x_e = 0$). If the equilibrium x_e of equation 2.2 is not at the origin, one can always transform equation 2.2 by letting $z = x - x_e$. After such a transformation, the new system will have an equilibrium at the origin. Equation 2.2 will then become:

$$\frac{dz}{dt} = F(z),$$

where $F(z) = f(z + x_e)$. Therefore, without loss of generality, one can assume that system 2.2 has an isolated equilibrium point at the origin.

2.4.3 Stability

The equilibrium $x_e = 0$ of equation 2.2 is **stable** if for every $\varepsilon > 0$ there exists a $\delta(\varepsilon) > 0$ such that:

$$\|x(t)\| < \varepsilon \text{ for all } t \geq 0,$$

whenever $\|x(0)\| < \delta(\varepsilon)$.

The behavior of a stable equilibrium point can be depicted in Figure 2.8 for the case $x \in R^2$. By choosing the initial points in a sufficiently small neighborhood of the origin specified by δ, the trajectory of the system can be forced to lie entirely inside a neighborhood of the origin specified by ε.

The equilibrium $x_e = 0$ of equation 2.2 is **asymptotically stable** if the following statements are true:

1) The equilibrium is stable.
2) If there exists an $\eta > 0$ such that $\lim_{t \to \infty} x(t) = 0$ whenever $\|x(0)\| < \eta$.

The set of all $x(0) \in R^n$ such that $x(t) \to 0$ as $t \to \infty$ is called the **domain of attraction** of the equilibrium $x_e = 0$ of equation 2.2.

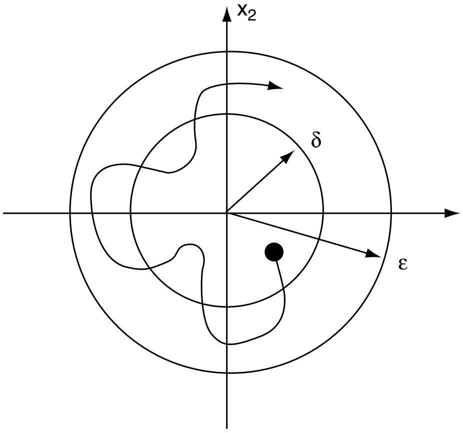

FIGURE 2.8 Typical Behavior of the Trajectory in the Vicinity of a Stable Equilibrium. This is true whenever $x(0) \leq \delta(\varepsilon)$.

The equilibrium $x_e = 0$ of equation 2.2 is **exponentially stable** if there exists an $\alpha > 0$, and for every $\varepsilon > 0$, there exists a $\delta(\varepsilon) > 0$ such that:

$$\|x(t)\| \leq \varepsilon e^{-\alpha t} \text{ for all } t \geq 0,$$

whenever $\|x(0)\| \leq \delta(\varepsilon)$.

The equilibrium $x_e = 0$ of equation 2.2 is **unstable** if the equilibrium is not stable.

The preceeding concepts pertain to local properties of an equilibrium. The following concepts characterize some global properties of an equilibrium.

2.4.4 Global Properties of an Equilibrium

The equilibrium $x_e = 0$ of equation 2.2 is **asymptotically stable in the large** if it is stable and if every solution of the equation tends to zero as $t \to \infty$.

The other term used often for asymptotic stability in the large is **global stability**.

The equilibrium $x_e = 0$ of equation 2.2 is **exponentially stable in the large** (or **globally exponentially stable**) if there exists an $\alpha > 0$ and for any $\beta > 0$, there exists a $k(\beta) > 0$ such that:

$$\|x(t)\| < k(\beta)\|x(0)\|e^{-\alpha t} \text{ for all } t \geq 0,$$

whenever $\|x(0)\| < \beta$.

The preceding concepts are referred to as stability (and instability) **in the sense of Lyapunov**.

2.5 Lyapunov Stability of Linear Time-Invariant Systems

Consider linear systems described by:

$$\dot{x} = Ax, \ t \geq 0 \quad \text{if A is nonsingular.} \tag{2.5}$$

System 2.5 has a unique equilibrium $x_e = 0$.

The equilibrium $x_e = 0$ of equation 2.5 is stable if all eigenvalues of A have nonpositive real parts and if every eigenvalue of A that has a zero real part is a simple zero of the characteristic polynomial of A.

The equilibrium $x_e = 0$ of equation 2.5 is asymptotically stable if and only if all eigenvalues of A have negative real parts.

A real $n \times n$ matrix A is called **stable** or a **Hurwitz matrix** if all of its eigenvalues have negative real parts. If at least one of the eigenvalues has a positive real part, then A is called unstable.

Thus, the equilibrium $x_e = 0$ of equation 2.5 is asymptotically stable if and only if A is stable. If A is unstable, then $x_e = 0$ is unstable.

2.6 Lyapunov Stability Results

The most important fact about the Lyapunov stability theory is to determine the stability properties of an equilibrium of a system 2.2 without having to solve equation 2.2.

2.6.1 Definiteness of a Function

A continuous function $v\colon R^n \to R$ [resp., $v\colon B(h) \to R$] is said to be **positive definite** if:

1) $v(0) = 0$, and
2) $v(x) > 0$ for all $x \neq 0$ [resp., $0 < \|x\| \leq r$ for some $r > 0$].

A continuous function v is said to be **negative definite** if $-v$ is a positive definite function.

Positive semidefinite: A continuous function $v\colon R^n \to R$ [resp., $v\colon B(h) \to R$] is said to be **positive semidefinite** if:

1) $v(0) = 0$, and
2) $v(x) \geq 0$ for all $x \in B(r)$ for some $r > 0$.

A continuous function v is said to be **negative semidefinite** if $-v$ is a positive semidefinite function.

A continuous function $v\colon R^n \to R$ is said to be **radially unbounded** if:

1) $v(0) = 0$,
2) $v(x) > 0$ for all $x \neq 0$, and
3) $v(x) \to \infty$ as $\|x\| \to \infty$.

Example 9

The function $v\colon R^3 \to R$ is given by:

$$v(x) = x_1^2 + x_2^2 + x_3^2,$$

which is positive definite and radially unbounded.

Example 10

The function $v\colon R^3 \to R$ is given by:

$$v(x) = x_1^2 + (x_2 - x_3)^2,$$

which is positive semidefinite. It is not positive definite because it is zero for all $x \in R^3$ such that $x_1 = 0$ and $x_2 = x_3$.

Example 11

The function $v\colon R^3 \to R$ is given by:

$$v(x) = x_1^2 + x_2^2 + x_3^2 - \left(x_1^2 + x_2^2 + x_3^2\right)^3,$$

which is positive definite in the interior of the ball given by $x_1^2 + x_2^2 + x_3^2 < 1$. It is not radially unbounded since $v(x) < 0$ when $x_1^2 + x_2^2 + x_3^2 > 1$.

Example 12

The function $v\colon R^3 \to R$ is given by:

$$v(x) = \frac{x_1^4}{1 + x_1^4} + x_2^4 + x_3^4,$$

which is positive definite but not radially unbounded.

2.6.2 Principle Lyapunov Stability Theorems

- If there exists a continuously differentiable and positive definite function v and its derivative (with respect to t) along the solutions of equation 2.2 given by:

$$\dot{v}_{(2.2)} = \sum_{i=1}^{n} \frac{\partial v}{\partial x_i} f_i(x) = \nabla v(x)^T f(x),$$

is negative semidefinite (or identically zero), then the equilibrium $x_e = 0$ of equation 2.2 is stable.
- If there exists a continuously differentiable and positive definite function v with a negative definite derivative $\dot{v}_{(2.2)}$, then the equilibrium $x_e = 0$ of equation 2.2 is asymptotically stable.
- If there exists a continuously differentiable, positive definite, and radially unbounded function v with a negative definite derivative $\dot{v}_{(2.2)}$, then the equilibrium $x_e = 0$ of equation 2.2 is asymptotically stable in the large.

Example 13

Consider the simple pendulum in example 5. If the following is chosen:

$$v(x) = k(1 - \cos x_1) + \frac{1}{2} x_2^2,$$

then this function is continuously differentiable, $v(0) = 0$, and v is positive definite. Along the solutions of equation 2.3, the following is true:

$$\dot{v}_{(2.3)} = (k \sin x_1)\dot{x}_1 + x_2 \dot{x}_2 = (k \sin x_1)x_2 + x_2(-k \sin x_1) = 0.$$

Therefore, the equilibrium $x_e = 0$ of the simple pendulum system is stable.

Example 14

Consider the system:

$$\begin{aligned} \dot{x}_1 &= (x_1 - c_2 x_2)(x_1^2 + x_2^2 - 1). \\ \dot{x}_2 &= (c_1 x_1 + x_2)(x_1^2 + x_2 - 1). \end{aligned} \tag{2.6}$$

In these equations, $c_1 > 1$ and $c_2 > 0$. If the following is chosen:

$$v(x) = c_1 x_1^2 + c_2 x_2^2,$$

it can be verified that:

$$\dot{v}_{(2.6)} = 2(c_1x_1^2 + c_2x_2^2)(x_1^2 + x_2^2 - 1).$$

Because v is positive definite and $\dot{v}_{(2.6)}$ is negative definite for $x_1^2 + x_2^2 < 1$, the equilibrium $x_e = 0$ of equation 2.6 is asymptotically stable.

Example 15

Consider the system:

$$\begin{aligned}\dot{x}_1 &= x_2 - c_1x_1(x_1^2 + x_2^2).\\ \dot{x}_2 &= -x_1 - cx_2(x_1^2 + x_2).\end{aligned} \tag{2.7}$$

In these equations, $c > 0$. If the following is chosen:

$$v(x) = x_1^2 + x_2^2,$$

it can be verified that:

$$\dot{v}_{(2.7)} = -2c(x_1^2 + x_2^2)^2.$$

Because v is positive definite and radially unbounded and $\dot{v}_{(2.7)}$ is negative definite, the equilibrium $x_e = 0$ of equation 2.7 is asymptotically stable in the large.

Lyapunov instability theorem: The equilibrium $x_e = 0$ of equation 2.2 is unstable if there exists a continuously differentiable function v such that $\dot{v}_{(2.2)}$ is negative definite (positive definite) and if in every neighborhood of the origin there are points x such that $v(x) < 0[v(x) > 0]$.

Example 16

Consider the system:

$$\begin{aligned}\dot{x}_1 &= c_1x_1 + x_1x_2.\\ \dot{x}_2 &= -c_2x_2 + x_1^2.\end{aligned} \tag{2.8}$$

The $c_1 > 0$ and $c_2 > 0$ are constants. If the following is chosen:

$$v(x) = x_2^2 - x_1^2,$$

then the following is true:

$$\dot{v}_{(2.8)} = -2(c_1x_1^2 + c_2x_2^2),$$

Because $\dot{v}_{(2.8)}$ is negative definite and in every neighborhood of the origin $v(x) < 0$ when $|x_1| < |x_2|$, the equilibrium $x_e = 0$ of (2.8) is unstable.

3.1 Introduction

A mathematical model of the physical process that needs to be controlled is needed for control system design and analysis. This model could be derived from first principles, obtained via system identification, or created by one engineer and then given to another. Regardless of the origin of the model, the control engineer needs to completely understand it and its limitations. In some processes, it is possible to consider models with a **single input and output** (SISO) for which a vast amount of literature is available. In many other cases, it is necessary to consider models with **multiple inputs and/or outputs** (MIMO). This chapter presents a selection of modeling, analysis, and design topics for multivariable, finite-dimensional, causal, linear, time-invariant systems that generalize the results for SISO systems. The reader is encouraged to consult the references at the end of this chapter for additional topics in multivariable control systems and for the proofs to the lemmas and theorems presented.

3.2 Modeling

The derivation of a mathematical model for a linear, time-invariant system typically starts by writing differential equations relating the inputs to a standard set of variables, such as loop currents and the configuration variables (e.g., displacements and velocities). In the time domain, the differential equations can be written as follows:

$$P(\mathcal{D})\xi(t) = Q(\mathcal{D})u(t), \tag{3.1}$$

where $\mathcal{D} \overset{\Delta}{=} d/dt$ is a differential operator, $u(t) \in \mathcal{R}^m$ is a vector of inputs, $\xi(t) \in \mathcal{R}^l$ is a vector of the standard variables called the partial state variables, and $P(\mathcal{D})$ and $Q(\mathcal{D})$ are differential operator matrices of compatible dimensions. The vector of output variables is, in general, represented by a linear, differential combination of the partial state variables and the inputs:

$$y(t) = R(\mathcal{D})\xi(t) + W(\mathcal{D})u(t), \tag{3.2}$$

where $y(t) \in \mathcal{R}^p$ is the vector of outputs and where $R(\mathcal{D})$ and $W(\mathcal{D})$ are differential operator matrices of compatible dimensions. The system representation introduced in equations 3.1 and 3.2 is commonly referred to as the **polynomial matrix description** (PMD) and is the most natural representation for many engineering processes. For analysis and design, a state-space representation that is an equivalent representation of proper[1] PMDs is more appropriate. The state-space representation of a system with input $u(t)$ and output $y(t)$ is as follows:

$$\dot{x}(t) = Ax(t) + Bu(t),\ y(t) = Cx(t) + Du(t), \tag{3.3}$$

where $x(t) \in \mathcal{R}^n$ is a vector of state variables, any minimal set of variables at time t_0 that together with the input $u(t)$, $t > t_0$ completely characterizes the response of the system for $t > t_0$. The state-space representation as defined in equation 3.3 will be represented by the four-tuple (A, B, C, D). The study of the fundamental properties of the state-space representation is covered, for example, in a first graduate course in linear systems (Antsaklis and Michel, 1997.) Because any state-space and PMD representation of a given system are equivalent, they have similar properties. For example, the eigenvalues of A are the roots of $|P(\lambda)|$, where $P(\lambda)$ is the polynomial matrix in λ found by replacing $\mathcal{D}$ with λ. Furthermore, the state-space representation is state controllable (observable) if and only if the equivalent PMD is controllable (observable).

The generalization of an SISO transfer function is a transfer function matrix, which is found by taking the Laplace transform of equation 3.3 with zero initial conditions. This operation yields:

$$G(s) = C(sI - A)^{-1}B + D, \tag{3.4}$$

where $G(s) \in \mathcal{R}(s)^{p\times m}$ is a proper rational transfer function matrix consisting of $p \times m$ SISO transfer function entries. The transfer function matrix can also be written in terms of an equivalent PMD. Because a transfer function matrix as in the SISO case represents only the controllable and observable dynamics of a system, consider the following controllable and observable PMD:

$$D_L(s)\xi(s) = N_L(s)u(s),\ y(s) = \xi(s), \tag{3.5}$$

where $D_L(s) \in \mathcal{R}[s]^{p\times p}$ and $N_L(s) \in \mathcal{R}[s]^{p\times m}$ are left coprime polynomial matrices in s. The PMD in equation 3.5 is controllable since $D_L(s)$ and $N_L(s)$ and $N_L(s)$ are left coprime; otherwise, it would only be observable. The PMD is a realization of the transfer function matrix in equation 3.4 since $G(s) = D_L(s)^{-1}N_L(s)$. The poles of a transfer function matrix $G(s)$ are the roots of the pole polynomial of $G(s)$ where the pole polynomial is given by the least common denominator of all nonzero minors of $G(s)$. So, every pole appears as the pole of at least one SISO transfer function entry of $G(s)$. The MIMO poles can also be found as the roots of $|D_L(s)|$. As in SISO systems, the set of poles is a subset of the set of eigenvalues of A *if* A and $G(s)$ satisfy equation 3.4. There are several definitions of multivariable zeros (Schrader and Sain, 1989). The transmission zero definition states that $s = s_z$ is a zero if the rank of $N_L(s_z)$ is less than the rank of $N_L(s)$. An important difference between SISO and transmission zeros is that a transmission zero does not have to be a zero of any SISO transfer function entry of $G(s)$. Another difference is that it is possible for $G(s)$ to have a pole equal to a zero. To understand other properties of poles and transmission zeros, such as multiplicities, the Smith-McMillan form of $G(s)$ can be used.

To understand the effect of the poles of $G(s)$ on a particular output, consider $y_i(s)$, the *i*th response given by:

$$y_i(s) = \sum_{j=1}^{m} G_{ij}(s)u_j(s), \tag{3.6}$$

where $G_{ij}(s)$ is the *ij*th entry of $G(s)$ and where $u_j(s)$ is the Laplace transform of the *j*th input. Equation 3.6 shows that in MIMO systems, the outputs are linear combinations of the inputs where the weights are rational transfer functions. Only the poles of the entries in the *i*th row of $G(s)$ can affect $y_i(s)$, depending on which inputs are nonzero. More insight can be gained by solving for $y_i(s)$ in a state-space representation of the system. Because the poles correspond only to the controllable and observable eigenvalues of A, let equation 3.3 be a minimal, that is, a controllable and observable realization of $G(s)$ with n states. The Laplace transform of the *i*th output is given by:

$$y_i(s) = (C_i(sI - A)^{-1}B + D_i)u(s), \tag{3.7}$$

where C_i and D_i are the *i*th rows of C and D, respectively. If A has distinct eigenvalues, the partial fraction expansion of the response is given by:

$$y_i(s) = \left(\sum_{\ell=1}^{n} \frac{1}{s - \lambda_\ell} C_i v_\ell w_\ell^H B + D_i\right)u(s), \tag{3.8}$$

where v_ℓ, $w_\ell \in C^n$ are right and left eigenvectors of A, respectively, and ^{H} denotes complex-conjugate transpose. The effect of the ℓth pole on the *i*th output is determined by the $1 \times n$ residue matrix $C_i v_\ell w_\ell^H B$ and the product of this residue times the vector of inputs $u(s)$. If each entry in the residue matrix is small, then this pole will have little effect on $y_i(t)$. It is also possible for some entries of the residue matrix not to be small but the product of a residue with the vector of inputs to still be small. This indicates that for some directions of the input vector, a pole may have a more significant effect than in other directions. The concept of input directions is unique to MIMO systems, and it will be discussed again in the next subsection.

Stability is an important system property. This section is mostly interested in two types: **asymptotic** and **bounded-input and bounded-output** (BIBO) stability. Asymptotic stability is a property of an internal representation, such as a state-space. The representation in 3.3 is said to be asymptotically stable if the solutions of $\dot{x}(t) = Ax(t)$ approach the origin

[1] A PMD is proper if $\lim_{\lambda\to\infty} (R(\lambda)P^{-1}(\lambda)Q(\lambda) + W(\lambda))$ exists and is finite. In fact, if the PMD in equations 3.1 and 3.2 is equivalent to the state-space in equation 3.3, then $\lim_{\lambda\to\infty} (R(\lambda)P^{-1}(\lambda)Q(\lambda) + W(\lambda)) = D$.

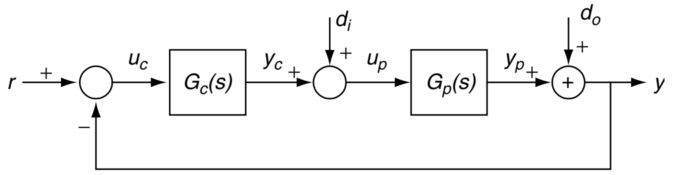

FIGURE 3.1 Classical Unity Feedback Configuration

for all initial conditions $x(0)$. The test for asymptotic stability is that the eigenvalues of A have negative real parts. Asymptotic stability implies BIBO stability, which is a property of an external representation. For BIBO stability, only the poles of a transfer function matrix need to have negative real parts.

Consider now the classical unity feedback configuration in Figure 3.1, where $r(t) \in \mathcal{R}^p$ denotes a vector of reference inputs and where $d_i(t) \in \mathcal{R}^m$ and $d_o(t) \in \mathcal{R}^p$ denote vectors of disturbance inputs at the input and output of the plant, respectively. Assume that the state-space representations (transfer function matrices) of the plant and controller are given by $(A_p, B_p, C_p, D_p)(G_p(s))$ and $(A_c, B_c, C_c, D_c)(G_c(s))$, respectively. The representation of the closed system will be well-formed if the dimensions $(G_p(s) \in \mathcal{R}_p(s)^{p\times m}$ and $G_c(s) \in \mathcal{R}_p(s)^{m\times p})$ are compatible and if $|I + D_pD_c| \neq 0$. The state representation of the closed-loop system is of the form:

$$\dot{x}_{cl}(t) = A_{cl}x_{cl}(t) + B_{cl}w(t), \quad y(t) = C_{cl}x_{cl}(t) + D_{cl}w(t), \tag{3.9}$$

where $x_{cl}(t) = [x_p(t),\, x_c(t)]^T$ and $w(t) = [r(t),\, d_o(t),\, d_i(t)]^T$. The properties of the closed-loop system are determined by analyzing $(A_{cl}(t), B_{cl}(t), C_{cl}(t), D_{cl}(t))$. For example, the closed-loop system is asymptotically stable if the eigenvalues of $A_{cl}(t)$ have negative real parts. The closed-loop system is then said to be internally stable.

The analysis and design of complex feedback configurations is simplified by using the general closed-loop block diagram in Figure 3.2, where $w(t)$ is the vector of all exogenous inputs, $y_K(t)$ is the vector of controller outputs, $z(t)$ is the vector of performance variables, and $u_K(t)$ is the vector of inputs to the controller. The top block is called the two-input and two-output plant, $\boldsymbol{P}$, and the bottom one corresponds to the matrix of controllers denoted by $\boldsymbol{K}$ that is formed after all the controllers have been pulled out of the closed-loop system. As a trivial example, the classical unity feedback is represented in the general block diagram with the following transfer function matrices:

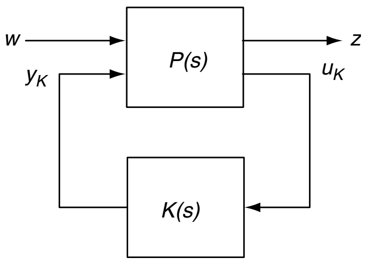

FIGURE 3.2 General Closed-Loop Block Diagram

$$\begin{bmatrix} z(s) \\ u_K(s) \end{bmatrix} = \boldsymbol{P}(s) \begin{bmatrix} w(s) \\ y_K(s) \end{bmatrix}, y_K(s) = \boldsymbol{K}(s)u_K(s),$$

where:

$$\boldsymbol{P}(s) = \left[\begin{array}{c:c} P_{11}(s) & P_{12}(s) \\ \hdashline P_{21}(s) & P_{22}(s) \end{array}\right] = \left[\begin{array}{ccc:c} I & -I & -G_p(s) & -G_p(s) \\ 0 & 0 & 0 & I \\ \hdashline I & -I & -G_p(s) & -G_p(s) \end{array}\right].$$

In this example, $\boldsymbol{K}(s) = G_c(s)$, the exogenous inputs vector is $w(t) = [r(t),\, d_o(t),\, d_i(t)]^T$, the vector of performance variables has been taken to be $z(t) = [r(t) - y(t),\, y_K(t)]^T$, and the vector of controller's inputs and outputs is simply given by $u_K(t) = u_c(t)$ and $y_K(t) = y_c(t)$, respectively. The first performance variable is the tracking error, $e(s) \overset{\Delta}{=} r(s) - y(s)$. A state-space representation of the two-input and two-output plant is the following:

$$\dot{x}_P(t) = A_px_P(t) + \left[\begin{array}{ccc:c} 0 & 0 & B_p & B_p \end{array}\right] \left[\begin{array}{c} w(t) \\ \hdashline y_K(t) \end{array}\right]. \tag{3.10}$$

$$\left[\begin{array}{c} z(t) \\ \hdashline u_K(t) \end{array}\right] = \left[\begin{array}{c} C_p \\ 0 \\ \hdashline -C_p \end{array}\right] x_P(t) + \left[\begin{array}{ccc:c} I & 0 & -D_p & -D_p \\ 0 & 0 & 0 & I \\ \hdashline I & 0 & -D_p & -D_p \end{array}\right] \left[\begin{array}{c} w(t) \\ \hdashline y_K(t) \end{array}\right]. \tag{3.11}$$

The closed-loop transfer function matrix from the exogenous inputs to the performance variables is as follows:

$$z(s) = T_{zw}(s)w(s).$$

The closed-loop transfer function matrix is in fact a lower linear fractional transformation (LFT) of $\boldsymbol{P}(s)$ with respect to $\boldsymbol{K}(s)$ as given by:

$$\begin{aligned} T_{zw}(s) = \mathcal{F}_\ell(\boldsymbol{P}(s), \boldsymbol{K}(s)) = P_{11}(s) \\ + P_{12}(s)\boldsymbol{K}(s)(I - P_{22}(s)\boldsymbol{K}(s))^{-1}P_{21}(s). \end{aligned} \tag{3.12}$$

Based on this LFT, the general closed-loop system is well-formed if $|I - P_{22}(\infty)\boldsymbol{K}(\infty)| \neq 0$. In the trivial example of a classical unity feedback system, this reduces to $|I - P_{22}(\infty)$ $\boldsymbol{K}(\infty)| = |I + D_pD_c| \neq 0$.

3.3 Performance Analysis

The purpose of the controller is to make the closed-loop system meet the desired specifications regardless of the uncertainty present. Examples of specifications are that the closed-loop system should be asymptotically stable, the steady-state error for each output channel should be small, and these stability and performance specifications should be maintained not only for the nominal plant model but also for all models in a specified uncertainty set. In this case, the closed-loop system will be said to have the properties of robust stability and robust performance.

Consider the classical unity feedback configuration in Figure 3.1 with an additional sensor noise vector $\eta(s)$ so that $u_c(s) = r(s) - (\eta(s) + y(s))$. The performance analysis is dependent on the following three types of transfer function matrices:

- **Return ratio:** $L_o(s) = G_p(s)G_c(s)$.
- **Sensitivity:** $S_o(s) = (I + L_o(s))^{-1}$.
- **Complementary sensitivity:** $T_o(s) = L_o(s)(I + L_o(s))^{-1}$.

These transfer function matrices are defined when the loop is broken at the output to the plant. Similar definitions follow when the loop is broken at the plant's input. The input/output and input/error relations can be written as shown next:

$$y(s) = S_o(s)d_o(s) + S_o(s)G_p(s)d_i(s) + T_o(s)r(s) - T_o(s)\eta(s). \quad (3.13)$$

$$e(s) = -S_o(s)d_o(s) - S_o(s)G_p(s)d_i(s) + (I - T_o(s))r(s) + T_o(s)\eta(s). \quad (3.14)$$

Notice that the mapping from the reference inputs, $r(s)$, to the errors contributed by them, $e_r(s)$, is given by $I - T_o(s)$. In this case, if the closed-loop system is internally stable, the steady-state tracking error contributed by a vector of step reference inputs $r(s) = R_0\frac{1}{s}$, $R_0 \in \mathcal{R}^p$ is found using Laplace's final value theorem to be $e_r(\infty) = (I - T_o(0))R_0$. Thus, the error contributions to each output channel will be zero if in addition to internal stability, $T_o(0) = I$. Because the sensitivity and complementary sensitivity transfer function matrices satisfy:

$$S_o(s) + T_o(s) = I, \quad (3.15)$$

then $S_o(0) = 0_{p\times p}$ results in $e_r(\infty) = 0$. A sufficient condition for the dc gain of the sensitivity matrix to vanish is that every entry of $L_o(s)$ must have at least one pole at the origin. This is the generalization of system type to MIMO systems. Furthermore, if $S_o(0) = 0_{p\times p}$, the steady-state error contributed by a vector of step functions at the output disturbances, $d_o(s)$, will also be zero. An additional condition is needed for zero steady-state error contributed by a vector of step functions at the input disturbances, $d_i(s)$. A sufficient condition is that the plant has no entries with poles at the origin.

Making $T(0) = I$ results in the desired zero steady-state errors to vectors of step functions at the reference inputs and at the input and output disturbances. This choice, however, has the undesirable effect of making the error contributed by the dc component of the sensor noise not to be attenuated. This is a common trade-off in control systems, which does not affect the desired performance as long as the signal-to-noise ratio for low frequencies is made sufficiently high.

Zero steady-state error is possible for step inputs by appropriately including an exogenous model of the exosystem in the feedback loop (Gonzalez and Antsaklis, 1991). If zero steady-state error is not needed, then it will be necessary to make the mappings from the four exogenous inputs to the tracking error in equation 3.14 *small.* Three ways to determine the size of a transfer function matrix are presented in the following subsection.

To simplify the presentation, assume from now on that the plant is square with $p = m$. In addition, since the physical units used for input and output signals may lead to errors of different orders of magnitude, it is useful to normalize or scale the magnitudes of the plant's inputs and outputs. Procedures to perform scaling of MIMO systems are presented in, for example, Skogestad and Postlethwaite (1996). One approach is to normalize the plant's inputs and outputs so that the magnitude of each error is less than one. An alternative and common choice is to include the normalization in the frequency-dependent weights to be introduced for control system design.

3.3.1 MIMO Frequency Response and System Gains

To determine the **frequency response** of a BIBO stable transfer function matrix, $G(s)$, let its input be the vector of complex exponentials $u(t) = \underline{u}e^{j\omega t}$, $\underline{u} \in C^p$; then, the steady-state response is a complex exponential vector of the same frequency with amplitudes and phases changed by $G(s)_{|s=j\omega}$. Let the steady-state response be given by $y_{ss}(t) = \underline{y}e^{j\omega t}$, $\underline{y} \in C^p$, then the complex vectors $\underline{u}$ and $\underline{y}$ are related by:

$$\underline{y} = G(j\omega)\underline{u}. \quad (3.16)$$

The complex matrix $G(j\omega) \in C^{p\times p}$ is called the frequency response matrix, and it can be used to determine the size of $G(s)$ at a particular frequency ω.

In general, the size of $G(s)$ is defined as the gain from an input to its corresponding output. If the input is $u(t) = \underline{u}e^{j\omega t}$, the gain of $G(s)$ at ω can be defined at steady-state to be the ratio of the Euclidean vector norms $\|\underline{y}\|/\|\underline{u}\|$. This concept of gain is bounded as follows:

$$\underline{\sigma}(\omega) = \min_{\|\underline{u}\|\neq 0} \frac{\|G(j\omega)\underline{u}\|}{\|\underline{u}\|} \leqslant \frac{\|G(j\omega)\underline{u}\|}{\|\underline{u}\|} \leqslant \max_{\|\underline{u}\|\neq 0} \frac{\|G(j\omega)\underline{u}\|}{\|\underline{u}\|} = \bar{\sigma}(\omega), \quad (3.17)$$

where $\bar{\sigma}(\omega)$ and $\underline{\sigma}(\omega)$ are the largest and smallest singular values of $G(j\omega)$. These bounds are used to define the size of a TFM as follows:

- **Large** $G(s)$ is said to be *large* at ω if $\underline{\sigma}(G(j\omega))$ is large.
- **Small** $G(s)$ is said to be *small* at ω if $\bar{\sigma}(G(j\omega))$ is small.

The application and the scaling of the model determine what is meant by large or small singular values. In general, $\underline{\sigma}(G(j\omega)) \gg 1$ indicates that $G(s)$ is large at ω. Similarly, $\bar{\sigma}(G(j\omega)) \ll 1$ indicates that $G(s)$ is small at ω.

A graphical representation of the frequency response consists of plotting the maximum and minimum singular values of $G(j\omega)$ versus $\log(\omega)$. This is the generalization of Bode's magnitude plot to MIMO systems.

To get a better understanding of the role of singular values, substitute the singular value decomposition (SVD) of $G(j\omega)$ in equation 3.16:

$$\underline{y} = Y(\omega)\Sigma(\omega)U(\omega)^H\underline{u}, \tag{3.18}$$

where $\Sigma(\omega) \in \mathcal{C}^{p\times p}$ is diag $\{\bar{\sigma}(\omega) = \sigma_1(\omega),\ \sigma_2(\omega), \dots, \sigma_p(\omega) = \underline{\sigma}(\omega)\}$ and where $Y(\omega)$ and $U(\omega) \in \mathcal{C}^{p\times p}$ are unitary matrices (see Section 9, Chapter 1). The diagonal entries of $\Sigma(\omega)$ are called the singular values of $G(s)$, and they depend on frequency. They are ordered from the largest to the smallest. Now, rewrite (equation 3.18 in terms of the columns of $Y(\omega)$ and $U(\omega)$, and let $Y(\omega) = [y_1(\omega)\cdots y_p(\omega)]$ and $U(\omega) = [u_1(\omega)\cdots u_p(\omega)]$. Since the columns of $U(\omega)$ form an orthonormal basis of C^p, let $\underline{\alpha}$ be the representation of $\underline{u}$ with respect to $\{u_1(\omega), \dots, u_p(\omega)\}$. Substituting $\underline{u} = U(\omega)\underline{\alpha}$ in equation 3.18 gives the following:

$$\underline{y} = Y(\omega)\Sigma(\omega)\underline{\alpha} = \sum_{i=1}^{p}\sigma_i(\omega)\alpha_i(\omega)y_i(\omega), \tag{3.19}$$

where $\underline{\alpha} = [\alpha_1(\omega)\cdots\alpha_p(\omega)]^T$. This equation shows that the representation of $\underline{y}$ in terms of the columns of $Y(\omega)$ (also an orthonormal basis) is as written here:

$$\Sigma(\omega)\underline{\alpha} = [\bar{\sigma}(\omega)\alpha_1(\omega),\quad \sigma_2(\omega)\alpha_2(\omega)\cdots\underline{\sigma}(\omega)(\omega)\alpha_p(\omega)]^T.$$

The columns of $U(\omega)$ can be called the **principal input directions**, and the columns of $Y(\omega)$ are the **principal output directions**. If the input is parallel to a principal input direction, then the steady-state response will be along the corresponding principal output direction scaled by the corresponding singular value. In this sense, the singular values quantify the size of the effect of a transfer function matrix on particular input directions.

This characterization of size of a TFM will be used to develop quantitative measures of performance when the inputs are sinusoids in a specified frequency band. Two other measures will also be useful, and they can be defined as induced gains when the inputs and outputs belong to specified signal spaces.

Consider first the set of energy signals that are vectors of functions u that map $\mathcal{R}$ into $\mathcal{R}^p$. The signal u is said to have finite energy if:

$$\|u\|_2 = \left(\int_0^\infty \|u(\tau)\|^2 d\tau\right)^{1/2} < \infty, \tag{3.20}$$

where $\|u\|_2$ is the norm of the vector signal and $\|u(\tau)\|$ is the Euclidean norm of a vector in $\mathcal{R}^p$. To pose and solve optimal control problems, it is useful to consider the most general set of energy signals. The desired set is the Lebesgue space of all square integrable functions. This set is denoted by $\mathcal{L}_{2+} \overset{\Delta}{=} \mathcal{L}_2[0, \infty)$. For convenience, the spatial dimension of vectors with entries in $\mathcal{L}_{2+}$ will not be included. A useful measure of the size of the transfer function matrix is the induced system gain. If the system is represented by the mapping $G: \mathcal{L}_2 \to \mathcal{L}_2$, then the induced system gain is as follows:

$$\sup_{u\neq 0}\frac{\|Gu\|_2}{\|u\|_2} = \sup_{\|u\|_2=1}\|Gu\|_2 = \|G\|_\infty, \tag{3.21}$$

where $\|G\|_\infty$ is the induced system norm. This is the $\mathcal{H}_\infty$ norm of the system that gives the maximum gain of the system to a vector of sinusoids in the worst possible direction and worst possible frequency. If $G(s)$ is proper and stable, then $\|G\|_\infty = \sup_\omega \bar{\sigma}\{G(j\omega)\}$ is finite. Another popular measure of a system is the $\mathcal{H}_2$ norm. One interpretation of the $\mathcal{H}_2$ norm is as the gain from a white noise input with unit variance to the power of the output. The power is defined as:

$$\|y\|_{pow} = \left(\lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T}\|y(\tau)\|^2 d\tau\right)^{1/2},$$

where $\|y\|_{pow}$ is only a seminorm.

3.3.2 Performance Measures

Consider again the classical unity feedback configuration in Figure 3.1 with an additional sensor noise vector $\eta(s)$ so that $u_c(s) = r(s) - (\eta(s) + y(s))$. If $r(t)$, $d_i(t)$, and $d_o(t)$ are vectors of sinusoids up to a frequency ω_{low}, then adequate steady-state performance to these inputs requires that $\bar{\sigma}(S_o(j\omega)) \ll 1$ and $\bar{\sigma}(S_o(j\omega)G_p(j\omega)) \ll 1$ for $\omega < \omega_{low}$. The former requirement is met if and only if $\bar{\sigma}(L_o(j\omega)) \gg 1$ for $\omega < \omega_{low}$. If $G_c(s)$ is invertible, the second requirement is met if $\underline{\sigma}(G_c(j\omega)) \gg 1$ for $\omega < \omega_{low}$. If the signal-to-noise ratio becomes poor for $\omega > \omega_{high}$, then acceptable performance at steady-state requires attenuating the high-frequency components of the noise by making $\bar{\sigma}(T_o(j\omega)) \ll 1$ for $\omega > \omega_{high}$. This is accomplished by making $\bar{\sigma}(L_o(j\omega)) \ll 1$ for $\omega > \omega_{high}$. These are just some of the design guidelines that will lead to acceptable designs. There are additional trade-offs and performance limitations that need to be taken into account, including guidelines for roll-offs during the mid-frequencies.

A convenient way to combine the low-, mid-, and high-frequency requirements is to introduce frequency-dependent weights. These weights are included in $\boldsymbol{P}(s)$ when the general block diagram in Figure 3.2 is formed. The weights are typically added on the exogenous input channels and the performance output channels. The former weights serve to include in the model spectral information about the inputs. The latter weights are important in design to emphasize the frequency bands where the performance outputs need to be minimized. A possible design problem that results is to find a proper compensator $G_c(s)$ so that $\|T_{z\omega}\|_\infty < 1$. This and other control problems will be discussed in the following sections.

3.4 Stability Theorems

In this section, a brief introduction will be given to various stability criteria that can be used to determine the stability of a closed-loop control system.

3.4.1 Nyquist Criteria

Consider a negative feedback interconnection of a plant $G_p(s)$ and controller $G_c(s)$ in Figure 3.1. Let n_{Lo+} denote the number of unstable poles of the return ratio $L_o(s)$. Then the Nyquist stability criteria is given by the following theorem:

Stability Theorem: The closed-loop system consisting of the negative feedback interconnection of $G_p(s)$ and $G_c(s)$ is internally stable if and only if $n_{Lo+} = n_{Gp+} + n_{Gc+}$ and the Nyquist plot of $|I + L_o(s)|$ encircles the origin n_{Lo+} times in the anticlockwise direction and does not pass through the origin.

The first condition guarantees that the closed-loop system has no unstable hidden modes. The second condition gives a MIMO generalization of the Nyquist plot in terms of the determinant of $I + L_o(s)$. Because of the determinant, the Nyquist plot of a scalar times $I + L_o(s)$ is not simply a scaled version of the Nyquist plot of $|I + L_o(s)|$.

3.4.2 Small Gain Criteria

Another criteria that is often used to determine internal stability of the feedback interconnection is the **small gain theorem**, which is based on limiting the loop gain of the system. This theorem is central to the analysis of robust stability. The small gain theorem states that if the feedback interconnection of two proper and stable systems has a loop-gain product less than unity, then the closed-loop system is internally stable. There exist several versions of this theorem. One version is given next.

Theorem: Consider the feedback system in Figure 3.1, where systems G_p and G_c are proper and stable. Then, the feedback system is internally stable if:

$$\|G_p\|_\infty \|G_c\|_\infty < 1.$$

The stability theorems already given can be used in the analysis and synthesis of control systems. These theorems are also useful to determine conditions for robust stability and performance of the closed-loop system with the real plant as discussed in the following section.

3.5 Robust Stability

Controller design uses a nominal plant model. The error between the nominal model and the real plant arises primarily from two sources: **unmodeled dynamics** and **parametric uncertainties**. If the controller design does not take these errors into account, it cannot guarantee the performance of the closed-loop system with the real plant nor guarantee that the closed-loop system will be stable. Therefore, it is important to design controllers that will maintain closed-loop stability in spite of erroneous design models and uncertainties in parameter values. Controllers so designed are said to impart stability robustness to the closed-loop system.

To analyze stability robustness, consider the unity feedback system in Figure 3.1. A basic plant uncertainty representation is $G_p(s) = G_{po}(s) + \Delta_a(s)$, where $G_{po}(s)$ is the nominal plant model and where $\Delta_a(s)$ is the additive uncertainty. Other uncertainty representations include the output multiplicative uncertainty, $G_p(s) = (I + \Delta_o(s))G_{po}(s)$, and the input multiplicative one, $G_p(s) = G_{po}(s)(I + \Delta_i(s))$. For design purposes, it helps to normalize the uncertainty representations. For example, consider that the real plant is represented with an output multiplicative uncertainty, and let $\Delta_o(s) = W_o(s)\tilde{\Delta}_o(s)$, where $\tilde{\Delta}_o(s)$ and $W_o(s)$ are proper and stable with $\|\tilde{\Delta}_o(s)\|_\infty \le 1$ and where $W_o(s)$ is a frequency-dependent scaling matrix. In this case, the unity feedback system in Figure 3.1 will be robustly stable if and only if $\|T_o W_o\|_\infty \le 1$.

A more general result is possible that is independent of the particular types of uncertainties needed to represent the real plant. Consider the general block diagram in Figure 3.2: if all the normalized uncertainty blocks are pulled out, it results in a new general block diagram shown in Figure 3.3 that is

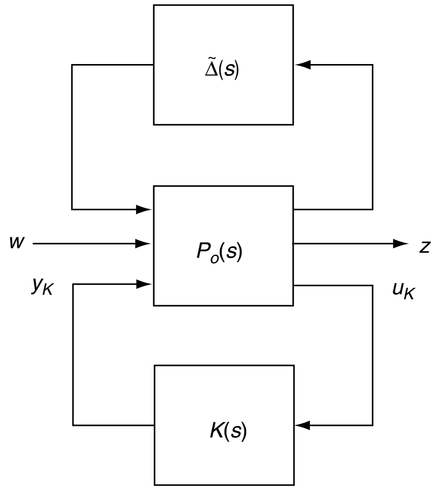

FIGURE 3.3 Closed-Loop System with Uncertainties Pulled Out

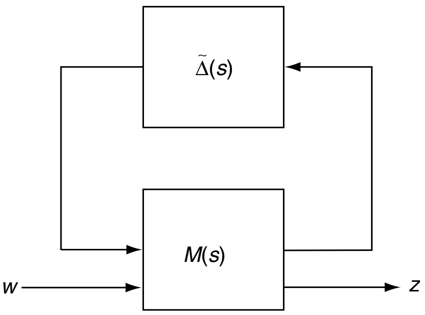

FIGURE 3.4 Simplified Closed-Loop System with Uncertainties Pulled Out

useful for robustness analysis. In Figure 3.3, $\tilde{\Delta}(s)$ is the block diagonal matrix of all the normalized uncertainty blocks ($\|\tilde{\Delta}(s)\|_\infty \leq 1$), and $\boldsymbol{P}_o(s)$ is the augmented nominal plant, including the uncertainty frequency weights. $\boldsymbol{P}_0(s)$ is assumed to be stabilized by $\boldsymbol{K}(s)$. Using a lower LFT, the bottom loop in Figure 3.3 can be closed resulting in Figure 3.4, where $\boldsymbol{M}(s)$ is proper and stable. If $\boldsymbol{M}(s)$ is partitioned corresponding to the two vector inputs and outputs and if $\|M_{11}\|_\infty < 1$, then the closed-loop system is robustly stable. These results that make use of the unstructured uncertainties lead to very conservative results. One way to reduce the conservativeness is to take advantage of the structure in the block diagonal matrix $\tilde{\Delta}(s)$ as done with the structured singular values.

3.6 Linear Quadratic Regulator and Gaussian Control Problems

3.6.1 Linear Quadratic Regulator Formulation

The linear quadratic regulator (LQR) is a classical optimal control problem used by many control engineers. Solutions to LQR are easy to compute and can typically be used to compute a baseline design useful for comparison. A formulation of the LQR problem considers the state equation of the plant:

$$\dot{x}(t) = Ax(t) + Bu(t). \tag{3.22}$$

The formulation also considers the following quadratic cost function of the states and control input:

$$J = \frac{1}{2}x^T(t_f)Sx(t_f) + \frac{1}{2}\int_0^{t_f} x^T(t)Qx(t) + u^T(t)Ru(t)dt, \tag{3.23}$$

where $S = S^T \geq 0$, $Q = Q^T \geq 0$ and $R = R^T > 0$.

To minimize the cost function, consider the Hamiltonian system with state and costate $(p(t))$ dynamics given by:

$$\begin{bmatrix} \dot{x}(t) \\ \dot{p}(t) \end{bmatrix} = \begin{bmatrix} A & -BR^{-1}B^T \\ -Q & -A^T \end{bmatrix} \begin{bmatrix} x(t) \\ p(t) \end{bmatrix}.$$

$$\text{with initial conditions:} \quad x(0) = x_0; \quad p(t_f) = Sx(t_f). \tag{3.24}$$

The optimal controller uses full-state feedback and is given by:

$$u(t) = -R^{-1}B^T P(t)x(t) = -K(t)x(t),$$

where $P(t)$ is the solution of the matrix Riccati equation:

$$\dot{P}(t) = -P(t)A - A^T P(t) + P(t)BR^{-1}B^T P(t) - Q,$$

which is solved backward in time starting at $P(t_f) = S$. The optimal feedback gain matrix $K(t)$ is given by:

$$K = R^{-1}B^T P(t),$$

and the optimal cost is as follows:

$$J_{\text{opt}} = \frac{1}{2}x^T(0)P(0)x(0).$$

3.6.2 Linear Quadratic Gaussian Formulation

The linear quadratic Gaussian (LQG) control problem is an optimal control problem where a quadratic cost function is minimized when the plant has random initial conditions, white noise disturbance input, and white measurement noise. The typical implementation of the LQR solution requires that the plant states be estimated, which can be posed as an LQG problem. The plant is described by the following state and output equations:

$$\begin{aligned} \dot{x}(t) &= Ax(t) + B_u u(t) + B_w w(t). \\ y_m(t) &= C_m x(t) + v(t) \text{ (measurement output).} \\ y_p(t) &= C_p x(t) \text{ (performance output).} \end{aligned} \tag{3.25}$$

The $v(t)$ and $w(t)$ are uncorrelated zero-mean Gaussian noise processes; that is, $w(t)$ and $\upsilon(t)$ are white noise processes with covariances satisfying:

$$E\left\{ \begin{bmatrix} w(t) \\ v(t) \end{bmatrix} [w^T(t+\tau), v^T(t+\tau)] \right\} = \begin{bmatrix} W & 0 \\ 0 & V \end{bmatrix} \delta(\tau).$$

The quadratic cost function that is to be minimized is given by:

$$J = E\left[\frac{1}{2}x^T(t_f)Sx(t_f) + \frac{1}{2}\int_0^{t_f} x^T(t)Qx(t) + u^T(t)Ru(t)dt \right], \tag{3.26}$$

where $S = S^T \geq 0$, $Q = Q^T \geq 0$ and $R = R^T > 0$. The optimal controller is a full-state feedback controller and is given by:

$$u(t) = -K(t)\hat{x}(t),$$

where $\hat{x}(t)$ is the Kalman state estimate. The closed-loop state equation can then be given by:

$$\begin{bmatrix} \dot{x}(t) \\ \dot{e}(t) \end{bmatrix} = A_{cl}(t)\begin{bmatrix} x(t) \\ e(t) \end{bmatrix} + B_{cl}(t)\begin{bmatrix} w(t) \\ v(t) \end{bmatrix},$$

where:

$$A_{cl} = \begin{bmatrix} A - B_u K(t) & B_u K(t) \\ 0 & A - G(t)C_m \end{bmatrix}, \; B_{cl} = \begin{bmatrix} B_w & 0 \\ B_w & -G(t) \end{bmatrix}.$$

The closed-loop state covariance matrix is as follows:

$$\dot{\sum}_{\tilde{x}}(t) = A_{cl}(t)\sum_{\tilde{x}}(t) + \sum_{\tilde{x}}(t)A_{cl}^T(t) + B_{cl}(t)\begin{bmatrix} W & 0 \\ 0 & V \end{bmatrix}B_{cl}^T(t),$$

where $\tilde{x}(t) = [x(t),\, e(t)]^T$, and:

$$\sum_{\tilde{x}}(0) = E\begin{bmatrix} x(0)x^T(0) & x(0)e^T(0) \\ e(0)x^T(0) & e(0)e^T(0) \end{bmatrix}.$$

The performance output covariance is given by:

$$\sum_{y_p}(t) = [\, C_p \quad 0 \,]\sum_{\tilde{x}}(t)\begin{bmatrix} C_p^T \\ 0 \end{bmatrix} = C_p \sum_{\tilde{x}} C_p^T,$$

and the input covariance is given by:

$$\sum_u(t) = [\,-K(t)\;\; K(t)]\sum_{\tilde{x}}(t)\begin{bmatrix} -K^T(t) \\ K^T(t) \end{bmatrix}.$$

The cost is as follows:

$$J = \frac{1}{2}\mathrm{Tr}\left\{\begin{bmatrix} S & 0 \\ 0 & 0 \end{bmatrix}\sum_{\tilde{x}}(t_f) + \int_0^{t_f}\begin{bmatrix} Q + K^T(t)RK(t) & -K^T(t)RK(t) \\ -K^T(t)RK(t) & K^T(t)RK(t) \end{bmatrix}\sum_{\tilde{x}}(t)dt\right\}.$$

Remarks

For convenience of implementation, the steady-state solution obtained in the limit as $t_f \to \infty$ is used. The LQG control design is optimized to reject white noise disturbances; however, it can be modified to handle constant disturbances via feed-forward and integral control. The selection of gains in the feed-forward case can be done in a similar way as in the case of tracking system design. Prior to implementation, the robustness of LQG designs needs to be evaluated since there is no guarantee that any useful robustness will be obtained. For constant disturbance rejection via integral control, one needs to use integral Kalman filter and also integral state feedback. The integral LQG can be used both for disturbance rejection and tracking. Similar modifications are possible to handle tracking of time-varying reference inputs.

3.7 H_∞ Control

The LQR and LQG can also be posed as two-norm optimization problems (referred to as H_2 control problems). If the optimization problem is posed using the H_∞ norm as the cost function, the H_∞ formulation results.

The **$\mathbf{H}_\infty$ control problem** can be defined in terms of the general closed-loop block diagram in Figure 3.2 where the exogenous signals are included in the vector $\omega(s)$ and an appropriate choice of performance variables is given by the vector $z(s)$. The TFM $\boldsymbol{P}(s)$ includes frequency-dependent weights and appropriate normalization as described previously. Consider the following realization of $\boldsymbol{P}(s)$:

$$\dot{x}_P(t) = Ax_P(t) + \left[\, B_1 \vdots B_2 \,\right]\begin{bmatrix} w(t) \\ \cdots\cdots \\ y_K(t) \end{bmatrix} \tag{3.27}$$

$$\begin{bmatrix} z(t) \\ \cdots\cdots \\ u_K(t) \end{bmatrix} = \begin{bmatrix} C_1 \\ \cdots \\ C_2 \end{bmatrix}x_P(t) + \begin{bmatrix} 0 & \vdots & D_{12} \\ \cdots & \cdots & \cdots \\ D_{21} & \vdots & 0 \end{bmatrix}\begin{bmatrix} w(t) \\ \cdots\cdots \\ y_K(t) \end{bmatrix}, \tag{3.28}$$

where:

$$D_{21}B_1^T = 0. \tag{3.29}$$

$$D_{21}D_{21}^T = I. \tag{3.30}$$

$$D_{12}^T C_1 = 0. \tag{3.31}$$

$$D_{12}^T D_{12}^T = I. \tag{3.32}$$

The control objective is to design a feedback controller that internally stabilizes the closed-loop system such that the ∞-norm of the mapping T_{zw} is bounded:

$$\|T_{zw}\|_\infty = \sup_{\|w(t)\|_2 \neq 0} \frac{\|z(t)\|_2}{\|w(t)\|_2} < \gamma. \tag{3.33}$$

A suboptimal controller satisfying the above mentioned objective exists if positive semidefinite solutions to the following two Riccati equations are possible:

$$\dot{P}(t) = P(t)A + A^T P(t) - P(t)(B_2 B_2^T - \gamma^{-2}B_1 B_1^T)P(t) + C_1^T C_1. \tag{3.34}$$

$$\dot{Q}(t) = AQ(t) + Q(t)A^T - Q(t)(C_2^T C_2 - \gamma^{-2}C_1^T C_1)Q(t) + B_1 B_1^T. \tag{3.35}$$

Moreover, the solutions $P(t)$ and $Q(t)$ satisfy the following:

$$\rho(P(t)Q(t)) < \gamma^2. \tag{3.36}$$

The Hamiltonian systems corresponding to the two Riccati equations can be obtained similarly to how they were obtained for the LQG case. The H_∞ controller, which satisfies the mentioned bound, is given by:

$$\begin{aligned}\dot{x}_c &= A_c(t)x_c(t) + B_c(t)u_K(t).\\ y_K(t) &= C_c(t)x_c(t).\end{aligned}\tag{3.37}$$

The matrices $A_c(t)$, $B_c(t)$, and $C_c(t)$ are given as follows:

$$\begin{aligned}A_c(t) &= A + \gamma^{-2}B_1B_1^TP(t) - B_2B_2^TP(t)\\ &\quad - [I - \gamma^{-2}Q(t)P(t)]^{-1}Q(t)C_2^TC_2.\\ B_c(t) &= [I - \gamma^{-2}Q(t)P(t)]^{-1}Q(t)C_2^T.\\ C_c(t) &= -B_1^TP(t).\end{aligned}\tag{3.38}$$

In practice, the steady-state solution of the H_∞ control problem is often desired. The steady-state solution not only simplifies the controller implementation but also renders a closed-loop system time-invariant, simplifying the robustness and performance analysis. For the steady-state H_∞ control problem, a suboptimal solution exists *if* and only if the following conditions are satisfied. The first condition is that the algebraic Riccati equation:

$$0 = PA + A^TP - P(B_2B_2^T - \gamma^{-2}B_1B_1^T)P + C_1^TC_1,$$

has a positive semidefinite solution P such that $[A - (B_2B_2^T - \gamma^{-2}B_1B_1^T)P]$ is stable. The second condition is that the algebraic Riccati equation:

$$0 = AQ + QA^T - Q(C_2^TC_2 - \gamma^{-2}C_1^TC_1)Q + B_1B_1^T,$$

has a positive semidefinite solution Q such that $[A - Q(C_2^TC_2 - \gamma^{-2}C_1^TC_1)]$ is stable. The third condition is $\rho(PQ) < \gamma^2$.

3.8 Passivity-Based Control

Passivity is an important property of dynamic systems. A large class of physical systems, such as flexible space structures with collocated and compatible actuators and sensors, can be classified as being naturally passive. A passive system can be robustly stabilized by any strictly passive controller despite unmodeled dynamics and parametric uncertainties. This important stability characteristic has attracted much attention of researchers in the control of passive systems. This section presents selected definitions and stability theorems for passive linear systems.

3.8.1 Passivity of Linear Systems

For finite-dimensional linear, time-invariant (LTI) systems, passivity is equivalent to **positive realness** of the transfer function (Newcomb, 1966; Desoer and Vidyasagar, 1975). The concept of strict positive realness has also been defined in the literature and is closely related to strict passivity.

Let $G(s)$ denote a $p \times p$ matrix whose elements are proper rational functions of the complex variable s. The $G(s)$ is said to be stable if all its elements are analytic in $Re(s) \geq 0$. Let the conjugate-transpose of a complex matrix H be denoted by H^H.

Definition 1

A $p \times p$ rational matrix $G(s)$ is said to be positive real (PR) if:

- All elements of $G(s)$ are analytic in $Re(s) > 0$
- $G(s) + G^H(s) \geq 0$ in $Re(s) > 0$, or equivalently:
  - Poles on the imaginary axis are simple and have non-negative-definite residues
  - $G(j\omega) + G^H(j\omega) \geq 0$ for $\omega \in (-\infty, \infty)$

Various definitions of **strictly positive real** (SPR) systems are found in the literature (Kelkar and Joshi, 1996). Given below is the definition of a class of SPR systems: marginally, strictly, and positive-real (MSPR) systems.

Definition 2

A $p \times p$ rational matrix $G(s)$ is said to be **marginally strictly positive real** (MSPR) if it is positive real and the following is true:

$$G(j\omega) + G^H(j\omega) > 0 \; for \; \omega \in (-\infty, \infty).$$

Definition 2 (Joshi and Gupta, 1996) gives the least restrictive class of SPR systems. If $G(s)$ is MSPR, it can be expressed as $G(s) = G_1(s) + G_2(s)$, where $G_2(s)$ is weak SPR (Kelkar and Joshi, 1996) and where all the poles of $G_1(s)$ are purely imaginary (Joshi and Gupta, 1996).

3.8.2 State-Space Characterization of PR Systems

For LTI systems, the state-space characterization of positive real (PR) conditions results in the Kalman-Yakubovich-Popov (KYP) lemma. In Lozano-Leal and Joshi (1990), the KYP lemma was extended to WSPR systems, in Joshi and Gupta (1996), it was extended to MSPR systems. These extensions are given next.

Let (A, B, C, D) denote an nth-order minimal realization of the $p \times p$ transfer function matrix $G(s)$. The following lemma then gives the state-space characterization of WSPR system.

The Lozano-Leal and Joshi (1990) Lemma: The $G(s)$ is WSPR if and only if there exist real matrices: $P = P^T > 0$, $P \in R^{n \times n}$, $L \in R^{p \times n}$, and $W \in R^{p \times p}$, such that:

$$\begin{aligned}A^TP + PA &= -L^TL.\\ C &= B^TP + W^TL.\\ W^TW &= D + D^T.\end{aligned}\tag{3.39}$$

In these equations, (A, B, L, W) is controllable and observable or minimal, and $F(s) = W + L(sI - A)^{-1}B$ is minimum phase. If $G(s)$ is MSPR, it can be expressed as $G(s) = G_1(s) + G_2(s)$, where $G_2(s)$ is WSPR and all the poles of $G_1(s)$ are purely imaginary (Josh and Gupta, 1996). Let (A_2, B_2, C_2, D) denote an n_2^{th}-order minimal realization of $G_2(s)$, the stable part of $G(s)$. The following lemma is an extension of the KYP lemma to the MSPR case.

The Josh and Gupta (1996) Lemma: If $G(s)$ is MSPR, there exist real matrices: $P = P^T > 0$, $P \in R^{n \times n}$, $\mathfrak{L} \in R^{p \times n_2}$ and $W \in R^{p \times p}$, such that equation 3.39 holds with:

$$L = [0_{p \times n_1}, \mathfrak{L}_{p \times n2}], \tag{3.40}$$

where $(A_2, B_2, \mathfrak{L}, W)$ is minimal and $F(s) = W + L(sI - A)^{-1}B = W + \mathfrak{L}(sI - A_2)^{-1}B_2$ is minimum phase.

3.8.3 Stability of PR Systems

The stability theorem for a feedback interconnection of a PR and a MSPR system is given next.

LMI form of PR Lemma: An alternate form of KYP Lemma can be given in terms of the following Linear Matrix Inequality (LMI). A system (A, B, C, D) is said to be PR if it satisfies:

$$\begin{bmatrix} A^TP + PA & PB \\ B^TP & 0 \end{bmatrix} + \begin{bmatrix} C & D \\ 0 & I \end{bmatrix}^T \begin{bmatrix} U & W \\ W^T & V \end{bmatrix} \begin{bmatrix} C & D \\ 0 & I \end{bmatrix} < 0 \tag{3.41}$$

$$P = P_T > 0, \tag{3.42}$$

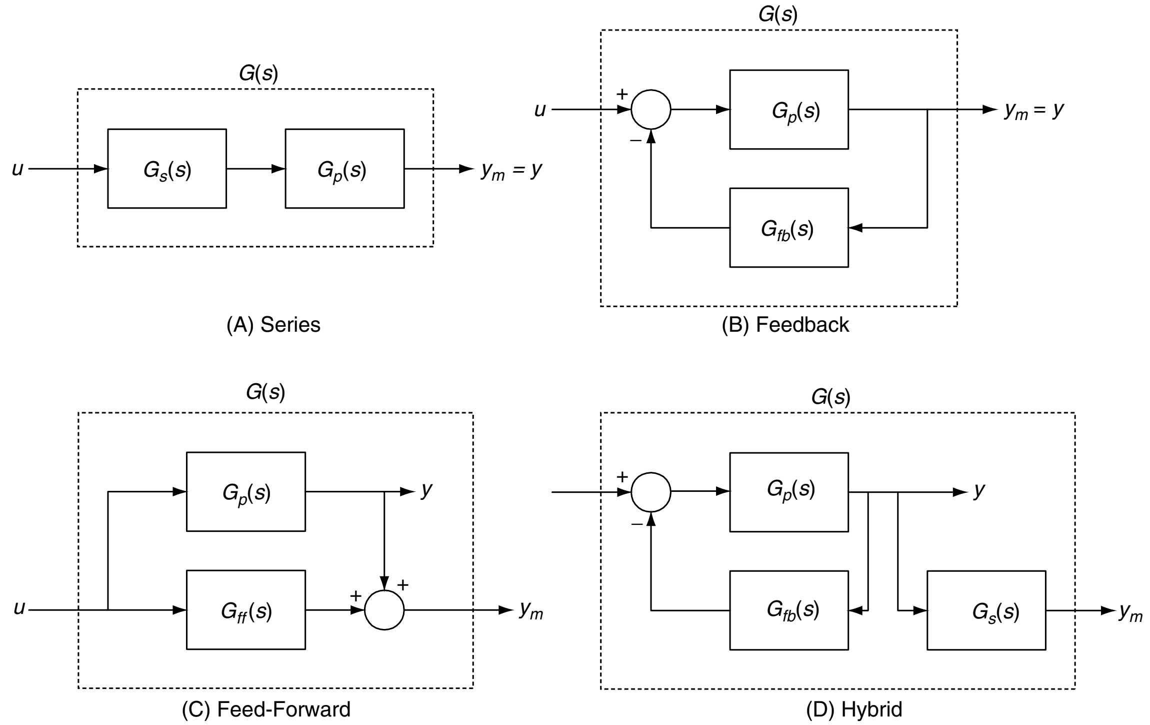
where $U = 0$, $V = 0$, and $W = -I$. This LMI condition is convenient to use in the case of checking PR-ness of MIMO systems. This LMI is a special case of dissipativity LMI (Kelkar and Joshi, 1996).

Stability Theorem

The closed-loop system consisting of negative feedback interconnection of $G_p(s)$ and $G_c(s)$ (Figure 3.1) is globally asymptotically stable if $G_p(s)$ is PR, $G_c(s)$ is MSPR, and none of the purely imaginary poles of $G_c(s)$ is a transmission zero of $G_p(s)$ (Joshi and Gupta, 1996).

Note that in the theorem systems $G_p(s)$ and $G_c(s)$ can be interchanged. Some nonlinear extensions of these results are also obtained in Isidori *et al.* (1999). Passivity-based controllers based on these fundamental stability results have proven to be highly effective in robustly controlling inherently passive linear and nonlinear systems.

Most physical systems, however, are not inherently passive, and passivity-based control methods cannot extend directly to such systems. For example, unstable systems and acoustic systems are not passive. One possible method of making these nonpassive systems amenable to passivity-based control is to *passify* them using suitable compensation. If the compensated system is ensured to be *robustly passive* despite plant uncertainties, it can be robustly stabilized by any MSPR controller. In Kelkar and Joshi (1997), various passification tech-



(A) Series

(B) Feedback

(C) Feed-Forward

(D) Hybrid

FIGURE 3.5 Methods of Passification

niques are presented, and some numerical examples are given, demonstrating the use of such techniques. A brief review of these methods is given next.

3.8.4 Passification Methods

The four passification methods in Figure 3.5 **series**, **feedback**, **feed-forward**, and **hybrid passification** are given in Kelkar and Joshi (1997) for finite-dimensional linear time-invariant nonpassive systems as shown. Once passified, the system can be controlled by any MSPR or weakly SPR (WSPR) controller (Isidori *et al*., 1999). In Figure 3.5, the system with input $u(t)$ and output $y_m(t)$ $(G(s))$ represents the passified system. The type of passification to be used depends on the dynamic characteristics of the unpassified plant. For example, the system having unstable poles will require feedback passification, whereas the system having nonminimum phase zeros (i.e., having unstable zero dynamics) will require feed-forward passification. Some systems may require a combination of the basic passification methods. For SISO systems, the passification process is easier than for MIMO systems. The reason is that for SISO systems, only the phase plot needs to be checked to determine passivity, whereas in the case of MIMO systems, the KYP lemma conditions have to be checked. One numerical technique that can be used to check the KYP lemma is linear matrix inequality (LMI)-based PR conditions. The solution of the LMI can be done using the LMI tool box in MATLAB or another semidefinite programming package.

One important thing to be noted here is that, in the case of inherently passive systems, the use of an MSPR controller guarantees stability robustness to unmodeled dynamics and parametric uncertainties; however, in the case of nonpassive systems that are rendered passive using passifying compensation, stability robustness depends on the robustness of the passification. That is, the problem of **robust stability** is transformed into the problem of **robust passification**. In Kelkar and Joshi (1998) a number of sufficient conditions are derived to check the robustness of the passification.

3.9 Conclusion

This chapter has presented some of the fundamental tools in the analysis and design of linear, time-invariant, continuous-time, robust, multivariable control systems. The chapter starts with an introduction to modeling. The analysis tools include basic measures of performance, frequency response, and stability theorems. Linear quadratic, H_∞ and passivity-based control synthesis techniques were also introduced.

State Estimation

Jay Farrell
Department of Electrical Engineering,
University of California,
Riverside, California, USA

4.1 Introduction

The **state of a system** is the *minimal* set of information required to *completely* summarize the status of the system at an initial time t_0. Because the state is a complete summary of the status of the system, it is immaterial how the system managed to get to its state at t_0. In addition, knowledge of the state at t_0, of the inputs to the system for $t > t_0$, and of the dynamics of the system allows the state to be determined for all $t > t_0$. Therefore, the concept of **state** allows time to be divided into past ($t < t_0$), present ($t = t_0$), and future ($t > t_0$), with the state at t_0 summarizing the information from the past that is necessary (together with knowledge of the system inputs) to predict the future evolution of the system.

The goal of the control system designer is to specify the inputs to a dynamic system to force the system to perform some useful purpose. This task can be interpreted as forcing the system from its state at t_0 to a desired state at a future time $t_1 > t_0$. Obtaining accurate knowledge of the state at t_0 and for all t between t_0 and t_1 is often critical to the completion of this control objective. This process is referred to as state estimation.

4.2 State-Space Representations

For dynamic systems described by a finite number of ordinary differential equations, the state of the dynamic system can be represented as a vector $\boldsymbol{x}(t)$ in **continuous-time**. For dynamic systems described by a finite number of ordinary difference equations, the state of the dynamic system can be represented as a vector $\boldsymbol{x}(k)$ in **discrete-time**. In either case, $\boldsymbol{x} \in \Re^n$. The vector representation of the state allows numerous tools from linear algebra to be applied to the analysis and design of state estimation and control systems. The state-space model in continuous-time representation is the following:

$$\begin{aligned}\dot{\boldsymbol{x}}(t) &= \boldsymbol{F}(t)\boldsymbol{x}(t) + \boldsymbol{G}_u\boldsymbol{u}(t) + \boldsymbol{G}_\omega\omega(t).\\ \boldsymbol{y}(t) &= \boldsymbol{H}(t)\boldsymbol{x}(t) + \nu(t).\end{aligned} \tag{4.1}$$

The $\boldsymbol{u} \in \Re^m$ is the deterministic control input, $\omega \in \Re^q$ is a stochastic (process noise) vector, $\boldsymbol{y} \in \Re^p$ is the measured output, and $\nu \in \Re^p$ is a stochastic (measurement noise) vector. The process and measurement noise vectors are each assumed to be Gaussian white noise processes:

$$\begin{aligned} E\langle \omega(t)\rangle = 0 \quad & E\langle \omega(t_1), \omega(t_2)\rangle = \boldsymbol{Q}(t_1)\delta(t_1 - t_2). \\ E\langle \nu(t)\rangle = 0 \quad & E\langle \nu(t_1), \nu(t_2)\rangle = \boldsymbol{R}(t_1)\delta(t_1 - t_2). \end{aligned} \tag{4.2}$$

The $\delta(t)$ is the Dirac delta function. The power spectral density matrices $\boldsymbol{Q}(t)$ and $\boldsymbol{R}(t)$ are symmetric positive definite for all t.

State estimation may be desired for two reasons. First, when the measurement matrix $\boldsymbol{H} \neq \boldsymbol{I}$, then the state is not directly measured; however, knowledge of the full state may be desirable (e.g., for control). Second, even if $\boldsymbol{H} = \boldsymbol{I}$, it may be beneficial to filter the measurements to decrease the effects of the measurement noise. Filtering can be considered as a state estimation process.

State estimation and control processes are often implemented via a computer. Therefore, for implementation purposes, it is usually convenient to work with the discrete-time state-space representation:

$$\begin{aligned} \boldsymbol{x}(k+1) &= \boldsymbol{\Phi}_x(k)\boldsymbol{x}(k) + \boldsymbol{\Gamma}_u \boldsymbol{u}(k) + \boldsymbol{\Gamma}_\omega \omega_d(k) \\ \boldsymbol{y}(k) &= \boldsymbol{H}(k)\boldsymbol{x}(k) + \nu(k). \end{aligned} \tag{4.3}$$

In equation 4.3, $\boldsymbol{x}(k) = \boldsymbol{x}(kT)$, k is an integer, and T is a fixed sample period. If $\boldsymbol{F}$, $\boldsymbol{G}_u$, and $\boldsymbol{G}_\omega$ are time invariant over the interval $(kT, (k+1)T]$, then $\boldsymbol{\Phi}_x(k)$, $\boldsymbol{\Gamma}_u$, $\boldsymbol{\Gamma}_\omega$, and the statistics of the discrete-time Gaussian white noise process $\omega_d(k)$ can be determined so that the solutions to equation 4.1 at the sample times $t = kT$ have the same first- and second-order statistics as the solution of equation 4.3. Both $\nu(k)$ and $\omega_d(k)$ are discrete-time Gaussian white noise sequences with covariance matrices defined by:

$$E\langle \nu(k)\nu(j)^T\rangle = \begin{cases} \boldsymbol{R}(k) & \text{if } k = j, \\ 0 & \text{otherwise;} \end{cases} \text{ and,}$$

$$E\langle \omega_d(k)\omega_d(j)^T\rangle = \begin{cases} \boldsymbol{Q}_d(k) & \text{if } k = j, \\ 0 & \text{otherwise.} \end{cases}$$

The fact that linear operations on Gaussian random variables yields Gaussian random variables and the assumptions that $\boldsymbol{u}(k)$ is deterministic and $\omega_d(k)$ and $\nu(k)$ are Gaussian random variables allow $\boldsymbol{x}(k)$ and $\boldsymbol{y}(k)$ to be modeled as Gaussian random variables. Therefore, the distributions of $\boldsymbol{x}(k)$ and $\boldsymbol{y}(k)$ are completely characterized by their first- and second-order statistics, which may be time varying.

The mean and variance of the state [i.e., $\bar{\boldsymbol{x}}(k) = E\langle \mathbf{x}(k)\rangle$ and $\boldsymbol{P}(k) = E\langle (\mathbf{x}(k) - \bar{\mathbf{x}}(k))(\boldsymbol{x}(k) - \bar{\boldsymbol{x}}(k))^T\rangle$] can be propagated through time using the model of equation 4.3 as:

$$\bar{\boldsymbol{x}}(k+1) = \boldsymbol{\Phi}(k)\bar{\boldsymbol{x}}(k) + \boldsymbol{\Gamma}_u \boldsymbol{u}(k). \tag{4.4}$$

$$\boldsymbol{P}(k+1) = \boldsymbol{\Phi}(k)\boldsymbol{P}(k)\boldsymbol{\Phi}^T(k) + \boldsymbol{\Gamma}_\omega \boldsymbol{Q}_d(k)\boldsymbol{\Gamma}_\omega^T. \tag{4.5}$$

The superscript T denotes a transpose. Note that when initial conditions $\bar{\boldsymbol{x}}(k_o)$, $\boldsymbol{P}(k_o)$; signal $\boldsymbol{u}(k)$; noise statistics $\boldsymbol{Q}_d(k)$; and the state-space model $\boldsymbol{\Phi}(k)$, $\boldsymbol{\Gamma}_u$, $\boldsymbol{\Gamma}_\omega$ are known for $k \in [k_o, k_f]$, these equations allow propagation of the mean and variance of the state for all $k \in [k_o, k_f]$. At any time instant of interest, the mean and variance of the output (i.e., $\bar{\boldsymbol{y}}$ and $\boldsymbol{P}_y$), can be computed as:

$$\bar{\boldsymbol{y}}(k) = \boldsymbol{H}(k)\bar{\boldsymbol{x}}(k) \tag{4.6}$$

$$\boldsymbol{P}_y(k) = \boldsymbol{H}(k)\boldsymbol{P}(k)\boldsymbol{H}^T(k) + \boldsymbol{R}(k). \tag{4.7}$$

4.3 Recursive State Estimation

Equations 4.4 through 4.5 provide the mean and the covariance of the state through time based only on the initial mean state vector and its error covariance matrix. When measurements $y(k)$ are available, the measurements can be used to improve the accuracy of an estimate of the state vector at time k. The symbols $\hat{\boldsymbol{x}}^-(k)$ and $\hat{\boldsymbol{x}}^+(k)$ are used to denote the estimate of $\boldsymbol{x}(k)$ before and after incorporating the measurement, respectively.

Similarly, the symbols $\boldsymbol{P}_{\hat{x}}^-(k)$ and $\boldsymbol{P}_{\hat{x}}^+(k)$ are used to denote the error covariance matrices corresponding to $\hat{\boldsymbol{x}}^-(k)$ and $\hat{\boldsymbol{x}}^+(k)$, respectively. This section presents the time propagation and measurement update equations for both the state estimate and its error covariance. The equations are presented in a form that is valid for any linear unbiased measurement correction. These equations contain a gain matrix $\boldsymbol{K}$ that determines the estimator performance. The choice of $\boldsymbol{K}$ to minimize the error covariance $\boldsymbol{P}_{\hat{x}}^+(k)$ will be of interest.

For an unbiased linear measurement, the update will have the form:

$$\hat{\boldsymbol{x}}^+(k) = \hat{\boldsymbol{x}}^-(k) + \boldsymbol{K}(k)(\boldsymbol{y}(k) - \hat{\boldsymbol{y}}^-(k)), \tag{4.8}$$

where $\hat{\boldsymbol{y}}^-(k) = \boldsymbol{H}(k)\hat{\boldsymbol{x}}^-(k)$. The error covariance of $\hat{\boldsymbol{x}}^+(k)$ is the following:

$$\begin{aligned} \boldsymbol{P}_{\hat{x}}^+(k) = {} & (\boldsymbol{I} - \boldsymbol{K}(k)\boldsymbol{H}(k))\boldsymbol{P}_{\hat{x}}^-(k)(\boldsymbol{I} - \boldsymbol{K}(k)\boldsymbol{H}(k))^T \\ & + \boldsymbol{K}(k)\boldsymbol{R}(k)\boldsymbol{K}^T(k). \end{aligned} \tag{4.9}$$

$\boldsymbol{K}(k)$ is a possibly time-varying state estimation gain vector to be designed. If no measurement is available at time k, then $\boldsymbol{K}(k) = 0$, which yields $\hat{\boldsymbol{x}}^+(k) = \hat{\boldsymbol{x}}^-(k)$ and $\boldsymbol{P}_{\hat{x}}^+(k) = \boldsymbol{P}_{\hat{x}}^-(k)$. If a measurement is available, and the state estimator is designed well, then $\boldsymbol{P}_{\hat{x}}^+(k) \leq \boldsymbol{P}_{\hat{x}}^-(k)$. In either case, the time propagation of the state estimate and its error covariance matrix is achieved by:

$$\hat{\boldsymbol{x}}^-(k+1) = \boldsymbol{\Phi}(k)\hat{\boldsymbol{x}}^+(k) + \hat{\boldsymbol{\Gamma}}_u \boldsymbol{u}(k) \tag{4.10}$$

$$\boldsymbol{P}_{\hat{x}}^-(k+1) = \boldsymbol{\Phi}(k)\boldsymbol{P}_{\hat{x}}^+(k)\boldsymbol{\Phi}^T(k) + \boldsymbol{\Gamma}_\omega \boldsymbol{Q}_d(k)\boldsymbol{\Gamma}_\omega^T. \tag{4.11}$$

At least two issues are of interest relative to the state estimation problem. First, does there exist a state estimation gain vector $\boldsymbol{K}(k)$ such that $\hat{\boldsymbol{x}}$ is guaranteed to converge to $\boldsymbol{x}$ regardless of initial condition and the sequence $\boldsymbol{u}(k)$? Second, how should the designer select the gain vector $\boldsymbol{K}(k)$?

The first issue raises the question of observability. A linear time-invariant system is observable if the following matrix has rank n:

$$\left[\boldsymbol{H}^T, \boldsymbol{\Phi}^T\boldsymbol{H}^T, \ldots, (\boldsymbol{\Phi}^T)^n\boldsymbol{H}^T\right].$$

When a system is observable, then it is guaranteed that a stabilizing gain vector $\boldsymbol{K}$ exists. Assuming that the system of interest is observable, the remainder of this chapter discusses the design and analysis of state estimators.

Figure 4.1 portrays the state estimator in conjunction with the system of interest. The system of interest is depicted in the upper left. The state estimator is superimposed on a gray background in the lower right.

This interconnected system will be referred to as the **state estimation system**. The figure motivates several important comments. First, although the state estimator has only n states, the state estimation system has $2n$ states. Second, the inputs to the state estimation system are the deterministic input u and the stochastic inputs ω and ν. Third, the inputs to the state estimator are the deterministic input u and the measured plant output y. The state space model for the state estimation system is the following:

$$\begin{bmatrix} \boldsymbol{x}(k+1) \\ \hat{\boldsymbol{x}}^-(k+1) \end{bmatrix} = \begin{bmatrix} \boldsymbol{\Phi}_x & 0 \\ \boldsymbol{LH}_x & \boldsymbol{\Phi} - \boldsymbol{LH} \end{bmatrix} \begin{bmatrix} \boldsymbol{x}(k) \\ \hat{\boldsymbol{x}}^-(k) \end{bmatrix} + \begin{bmatrix} \boldsymbol{\Gamma}_u & \boldsymbol{\Gamma}_\omega & \boldsymbol{0} \\ \hat{\boldsymbol{\Gamma}}_u & \boldsymbol{0} & \boldsymbol{L} \end{bmatrix} \begin{bmatrix} u(k) \\ \omega(k) \\ \nu(k) \end{bmatrix}, \quad (4.12)$$

where $\boldsymbol{L} = \boldsymbol{\Phi K}$.

Based on this state-space model, with the assumption that the system is time invariant, the transfer function from ν to $\hat{y}$ is as written here:

$$\boldsymbol{G}_\nu(z) = \boldsymbol{H}[z\boldsymbol{I} - (\boldsymbol{\Phi} - \boldsymbol{LH})]^{-1}\boldsymbol{L}, \quad (4.13)$$

where z is the discrete-time unit advance operator. Assuming that $\boldsymbol{H} = \boldsymbol{H}_x$, the transfer function from u to r is as follows:

$$\boldsymbol{G}_u(z) = \boldsymbol{H}[z\boldsymbol{I} - (\boldsymbol{\Phi} - \boldsymbol{LH})]^{-1} \left[(z\boldsymbol{I} - \boldsymbol{\Phi})(z\boldsymbol{I} - \boldsymbol{\Phi}_x)^{-1}\boldsymbol{\Gamma}_u - (z\boldsymbol{I} - \boldsymbol{\Phi}_x)(z\boldsymbol{I} - \boldsymbol{\Phi}_x)^{-1}\hat{\boldsymbol{\Gamma}}_u\right]. \quad (4.14)$$

Therefore, if $\boldsymbol{\Gamma}_u = \hat{\boldsymbol{\Gamma}}_u$ and $\boldsymbol{\Phi}_x = \boldsymbol{\Phi}$, then this transfer function is identically zero. Assuming again that $\boldsymbol{H} = \boldsymbol{H}_x$, the transfer function from ω to r is the following:

$$\boldsymbol{G}_\omega(z) = \boldsymbol{H}[z\boldsymbol{I} - (\boldsymbol{\Phi} - \boldsymbol{LH})]^{-1}[z\boldsymbol{I} - \boldsymbol{\Phi}][z\boldsymbol{I} - \boldsymbol{\Phi}_x]^{-1}\boldsymbol{\Gamma}_\omega. \quad (4.15)$$

In the special case where, in addition, $\boldsymbol{\Phi}_x = \boldsymbol{\Phi}$, the transfer function $\boldsymbol{G}_\omega(z)$ has n identical poles and zeros. This transfer functions is often stated as:

$$\boldsymbol{G}_\omega(z) = \boldsymbol{H}[z\boldsymbol{I} - (\boldsymbol{\Phi} - \boldsymbol{LH})]^{-1}\boldsymbol{\Gamma}_\omega, \quad (4.16)$$

where n pole and zero cancellations have occurred. These pole-zero cancellations and therefore the validity of equation 4.16 are dependent on the exact modeling assumption and the stability of the canceled poles.

4.4 State Estimator Design Approaches

Two categories of design approaches are commonly discussed: **Luenberger observers** and **Kalman filters**.

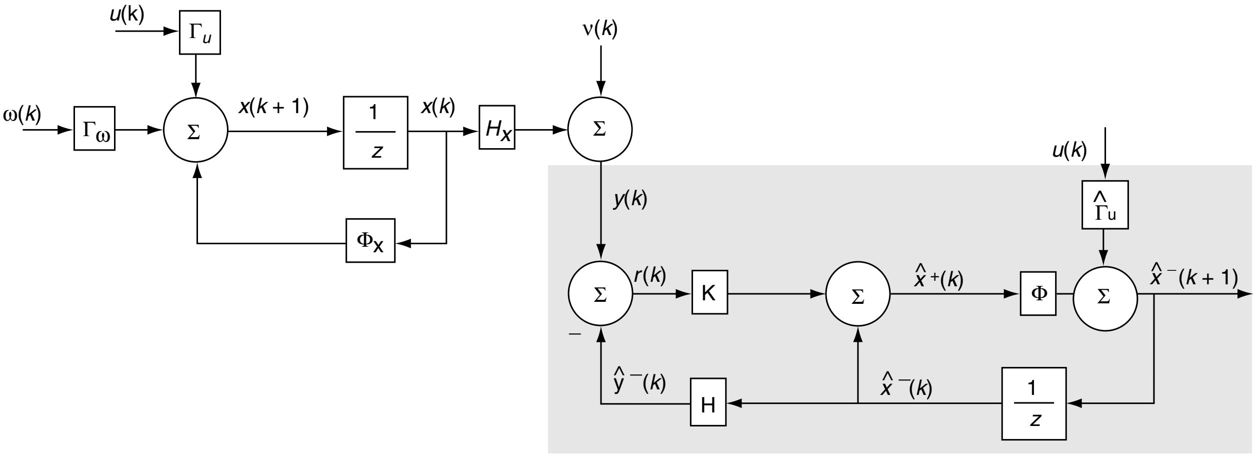

FIGURE 4.1 State Estimation System Block Diagram

4.4.1 Luenberger Observer

The time propagation and measurement update equations 4.8 through 4.11 can be combined. The combined equation for the estimate and its error covariance *prior* to the measurement correction at time $k+1$ are as follows:

$$\hat{\boldsymbol{x}}^-(k+1) = \boldsymbol{\Phi}(\boldsymbol{I} - \boldsymbol{KH})\hat{\boldsymbol{x}}^-(k) + \boldsymbol{\Gamma}_u \boldsymbol{u}(k) + \boldsymbol{\Phi K y}(k). \quad (4.17)$$

$$\boldsymbol{P}^-_{\hat{x}}(k+1) = \boldsymbol{\Phi}\left[(\boldsymbol{I} - \boldsymbol{KH})\boldsymbol{P}^-_{\hat{x}}(k)(\boldsymbol{I} - \boldsymbol{KH})^T + \boldsymbol{KRK}^T\right]\boldsymbol{\Phi}^T + \boldsymbol{\Gamma}_\omega \boldsymbol{Q}_d \boldsymbol{\Gamma}^T_\omega. \quad (4.18)$$

The time indices have been dropped for convenience of notation. The combined equation for the estimate and its error covariance *posterior* to the measurement update are the following:

$$\hat{\boldsymbol{x}}^+(k+1) = (\boldsymbol{I} - \boldsymbol{KH})\boldsymbol{\Phi}\hat{\mathbf{x}}^+(k) + (\boldsymbol{I} - \boldsymbol{KH})\boldsymbol{\Gamma}_u \mathbf{u}(k) + \boldsymbol{K y}(k+1). \quad (4.19)$$

$$\boldsymbol{P}^+_{\hat{x}}(k+1) = (\boldsymbol{I} - \boldsymbol{KH})[\boldsymbol{\Phi}\boldsymbol{P}^+_{\hat{x}}(k)\boldsymbol{\Phi}^T + \boldsymbol{\Gamma}_\omega \boldsymbol{Q}_d \boldsymbol{\Gamma}^T_\omega](\boldsymbol{I} - \boldsymbol{KH})^T + \boldsymbol{KRK}^T. \quad (4.20)$$

Note that even if the system is time invariant (i.e., $\boldsymbol{\Phi}$, $\boldsymbol{K}$, $\boldsymbol{H}$, $\boldsymbol{\Gamma}_u$, $\boldsymbol{\Gamma}_\omega$ all constant), both the state estimate and its error covariance matrix still change with time.

Assuming perfect modeling (i.e., $\boldsymbol{\Phi} = \boldsymbol{\Phi}_x$, etc.) and a time-invariant system, the discrete-time dynamics of the state estimation error $\tilde{\boldsymbol{x}}^- = \boldsymbol{x} - \hat{\boldsymbol{x}}^-$ can be computed using equations 4.3 and 4.17:

$$\tilde{\boldsymbol{x}}^-(k+1) = \boldsymbol{\Phi}\tilde{\boldsymbol{x}}^-(k) + \boldsymbol{\Gamma}_\omega \omega(k) + \boldsymbol{\Phi K}(y(k) - \hat{y}(k)). \quad (4.21)$$

$$= \boldsymbol{\Phi}(\boldsymbol{I} - \boldsymbol{KH})\tilde{\mathbf{x}}^-(k) + \boldsymbol{\Gamma}_\omega \omega(k) - \boldsymbol{\Phi K}\nu(k). \quad (4.22)$$

Equation 4.22 shows that stability of the state estimate requires that the eigenvalues of $(\boldsymbol{\Phi} - \boldsymbol{LH})$ have a magnitude less than one, where $\boldsymbol{L} = \boldsymbol{\Phi K}$.

The **Luenberger observer** uses a time-invariant gain vector $\boldsymbol{L}$ to place the eigenvalues of the observer state transition matrix $(\boldsymbol{\Phi} - \boldsymbol{LH})$ at specified locations in the unit circle $|z| < 1$. When the output y is a scalar, there exists a unique $\boldsymbol{L}$ that will place the n eigenvalues at their specified locations. When $\boldsymbol{y}$ is a vector of measurements, then portions of the eigenvectors of $(\boldsymbol{\Phi} - \boldsymbol{LH})$ can also be specified by the designer. The observer pole placement problem is dual to the controller pole placement problem.

4.4.2 Kalman Filter

Equations 4.8 and 4.9 illustrate the trade-offs that are implicit in the selection of the gain matrix $\boldsymbol{K}$. The state estimation error after the measurement has two contributions. The first is the state estimation error propagated from the previous time instant:

$$(\boldsymbol{I} - \boldsymbol{K}(k)\boldsymbol{H}(k))\boldsymbol{P}^-_{\hat{x}}(k)(\boldsymbol{I} - \mathrm{K}(k)\boldsymbol{H}(k))^T.$$

The second is the state estimation error due to measurement noise at the current time:

$$\boldsymbol{K}(k)\boldsymbol{R}\boldsymbol{K}^T(k).$$

The **Kalman filter algorithm** produces the time varying gain sequence $\boldsymbol{K}(k)$ that minimizes[1] *trace* $(\boldsymbol{P}^+_{\hat{x}}(k))$ at every measurement instant *k*.

The Kalman filter gain sequence is computed as:

$$\boldsymbol{K}(k) = \boldsymbol{P}^-_{\hat{x}}(k)\boldsymbol{H}(k)^T[\boldsymbol{H}(k)\boldsymbol{P}^-_{\hat{x}}(k)\boldsymbol{H}(k)^T + \boldsymbol{R}(k)]^{-1}. \quad (4.23)$$

For a time-varying linear system driven by Gaussian white noise, the Kalman filter gain sequence can be derived as the optimal estimator from the least-squares, maximum-likelihood, and mean-squares perspectives. The estimator discussion of this chapter was initiated with the assumed "linear update" of equation 4.8. This assumption is not restrictive in the sense that it can be shown for linear systems with additive noise Gaussian white measurement and process noise that a linear measurement update is optimal (i.e., a nonlinear estimator will not achieve better performance). The Kalman filter also has the property that the measurement residual $\boldsymbol{r}(k)$ is a white noise sequence.

For the Kalman filter, even if the system is time invariant (i.e., $\boldsymbol{\Phi}$, $\boldsymbol{\Gamma}_{\mathbf{u}}$, $\boldsymbol{\Gamma}_\omega$, $\boldsymbol{H}$, $\boldsymbol{R}$, and $\boldsymbol{Q}$ constant), the Kalman filter may be time varying. When a steady-state Kalman filter exists, the steady-state Kalman filter gain is:

$$\boldsymbol{K} = \boldsymbol{P}^-_{ss}\boldsymbol{H}^T[\boldsymbol{H}\boldsymbol{P}^-_{ss}\boldsymbol{H}^T + \boldsymbol{R}]^{-1}, \quad (4.24)$$

where $\boldsymbol{P}^-_{ss}$ is the steady-state solution of equation 4.18, which is the discrete-time algebraic Riccati equation:

$$\boldsymbol{P}^-_{ss} = \boldsymbol{\Phi}\left[\boldsymbol{P}^-_{ss} - \boldsymbol{P}^-_{ss}\boldsymbol{H}^T[\boldsymbol{H}\boldsymbol{P}^-_{ss}\boldsymbol{H}^T + \boldsymbol{R}]^{-1}\boldsymbol{H}\boldsymbol{P}^-_{ss}\right]\boldsymbol{\Phi}^T + \boldsymbol{\Gamma}_\omega \boldsymbol{Q}_d \boldsymbol{\Gamma}^T_\omega. \quad (4.25)$$

This form of the equation is particular to the Kalman filter and does not hold for general estimators. In steady-state, $\boldsymbol{P}^-_{\hat{x}}$ is constant with value $\boldsymbol{P}^-_{ss}$. In steady-state, $\boldsymbol{P}^+_{\hat{x}}$ is also constant with value $(\boldsymbol{I} - \boldsymbol{KH})\boldsymbol{P}^-_{ss}$. Note that $\boldsymbol{P}^-_{\hat{x}}$ and $\boldsymbol{P}^+_{\hat{x}}$ are *not* equal in steady-state.

Let $\hat{\boldsymbol{z}}(k) = \boldsymbol{C}\hat{x}(k)$ be a linear combination of the states that is of interest. When the steady-state Kalman filter exists, the transfer function from $\boldsymbol{y}$ to $\hat{\boldsymbol{z}}$ is the following:

$$\boldsymbol{C}[z\boldsymbol{I} - \boldsymbol{\Phi}(\boldsymbol{I} - \boldsymbol{KH})]^{-1}\boldsymbol{K}. \quad (4.26)$$

[1] If $\boldsymbol{D} = [d_{ij}]$ is an $n \times n$ matrix, then *trace* $(D) = \sum_{i=1}^n d_{ii}$.

Equation 4.26 is the infinite impulse response Weiner filter for estimating $\boldsymbol{z}$ from $\boldsymbol{y}$. Finite impulse response Weiner filters could be constructed from the Markov parameters of this steady-state Kalman filter.

4.5 Performance Analysis

This chapter has presented two methods for the design of state estimators; however, the task is not complete. For example, the Kalman filter methodology would require the designer to develop and use a full stochastic model of the system, process noise, actuators, and sensors. Because the Kalman filter approach assumes a linear model driven by white noise, any colored noise process will necessitate the augmentation of additional states to the model so that the colored noise process is represented as a linear system with white noise inputs.

The construction of such models is not straightforward. Often due to data and experimental limitations, the modeling process does not yield a single exact model but a range of possible models. The full model may also be too complex to allow a full Kalman filter implementation with online covariance propagation. Even when the full implementation is possible, additional analysis may show that nearly equivalent and possibly more robust performance can be achieved with fewer computations for an implementation using a reduced order model.

The goal of this section is to present methods for the analysis of suboptimal or reduced order filters. The idea of the analysis approach is not difficult, but the implementation of computationally efficient algorithms can be time consuming. The interested reader should consult the references at the end of this chapter.

4.5.1 Error Budgeting

Error budgeting is a methodology for determining how much each error source contributes to the overall estimation error. The methodology uses covariance propagation equations 4.9 and 4.11 that are repeated below for convenience:

$$\boldsymbol{P}_{\hat{x}}^{+}(k) = (\boldsymbol{I} - \boldsymbol{K}(k)\boldsymbol{H}(k))\boldsymbol{P}_{\hat{x}}^{-}(k)(\boldsymbol{I} - \boldsymbol{K}(k)\boldsymbol{H}(k))^{T} + \boldsymbol{K}(k)\boldsymbol{R}\boldsymbol{K}^{T}(k). \tag{4.27}$$

$$\boldsymbol{P}_{\hat{x}}^{-}(k+1) = \boldsymbol{\Phi}(k)\boldsymbol{P}_{\hat{x}}^{+}(k)\boldsymbol{\Phi}^{T}(k) + \boldsymbol{\Gamma}_{\omega}\boldsymbol{Q}_{d}(k)\boldsymbol{\Gamma}_{\omega}^{T}. \tag{4.28}$$

Note that if the gain sequence $\boldsymbol{K}(k)$ is known, then equations 4.27 and 4.28 are linear in $\boldsymbol{P}$, $\boldsymbol{Q}_d$, and $\boldsymbol{R}$. Therefore, the superposition principle can be applied. The error budgeting procedure can therefore be divided into three steps, where the second step has several subparts. The error budgeting approach is presented here assuming that the Kalman filtering approach is used and that the system model is known and correct. Suboptimal filtering is discussed in the next subsection.

Assuming that $\boldsymbol{\Phi}$, $\boldsymbol{P}_{\hat{x}}(0)$, $\boldsymbol{\Gamma}_{\omega}$, $\boldsymbol{Q}_d$, $\boldsymbol{H}$ and $\boldsymbol{R}$ are known for each k, the procedure is as follows.

- **Step 1**: Iterate equations 4.27 and 4.28 for the time duration of interest. Compute $\boldsymbol{K}(k)$ over the time interval using equation 4.23. This gain sequence is stored and used in each repetition of step 2. It is critical that the same gain sequence be used throughout step 2.
- **Step 2**: Divide the error sources into q mutually exclusive subgroups. For simplicity of this discussion, let $q = 3$ and the subgroups be (1) $\boldsymbol{P}_{\hat{x}}(0)$, (2) $\boldsymbol{Q}_d$, and (3) $\boldsymbol{R}$. In general, each component of $\boldsymbol{P}_{\hat{x}}(0)$, $\boldsymbol{Q}_d$, and $\boldsymbol{R}$ could be in its own subgroup. The main constraint is that each error component must be in exactly one subgroup.
  Equations 4.27 and 4.28 are now iterated over the time duration of interest, for q repetitions. Each repetition uses the estimator gain sequence determined in step 1. For the ith repetition $(q-1)$, error sources are set to zero, with only the ith subgroup of error sources being nonzero. Denote the sequence of covariance matrices that results from the ith repetition as $\boldsymbol{P}_{\hat{x}}^{-}(k,i)$ and $\boldsymbol{P}_{\hat{x}}^{+}(k,i)$.
- **Step 3**: The covariance matrices $\boldsymbol{P}_{\hat{x}}^{-}(k,i)$ and $\boldsymbol{P}_{\hat{x}}^{+}(k,i)$ (usually just the diagonal elements) are compared to identify which of the q error sources is dominant at any time k. Identification of the dominant sources allows the sensor or model development efforts to focus on the most effective directions. Identification of insignificant error sources motivates areas of possible cost savings through either the elimination of sensors or the purchase of lower cost sensors.

In step 1, it is useful as a check to also save the covariance matrices. The check is that the sum of the covariance matrices from each iteration of step 2 should equal the corresponding covariance matrix from step 1:

$$\boldsymbol{P}_{\hat{x}}^{-}(k) = \sum_{i=1}^{q} \boldsymbol{P}_{\hat{x}}^{-}(k,i) \text{ and } \boldsymbol{P}_{\hat{x}}^{+}(k) = \sum_{i=1}^{q} \boldsymbol{P}_{\hat{x}}^{+}(k,i), \tag{4.29}$$

for all k in the time span of interest.

4.5.2 Covariance Analysis

Covariance analysis is concerned with the iteration of equations 4.27 and 4.28 to characterize the expected filter performance. These equations are applicable for any estimator gain sequence. The error budgeting analysis of the previous section is a form of covariance analysis.

A second form of covariance analysis is the iteration of the same equations for suboptimal gain sequences. **Suboptimal gain sequences** are often of interest to avoid the need for online computation of the error covariance equations, which are typically the most computationally expensive portion of the Kalman algorithm. Examples of suboptimal gain sequences are the Luenberger gain, the steady-state Kalman filter gain, or a curve fit to the time-varying Kalman gain sequence. Iteration of equations 4.27 and 4.28 once for the optimal gain sequence and once for a suboptimal gain sequence allows analysis of the amount of performance degradation expected from the suboptimal approach. Note that this paragraph has only considered the case where the design model matches the actual system, but a suboptimal gain sequence is used. The case where the filter model is distinct from the system model is discussed in the remainder of this section.

Consider a system described by:

$$\left.\begin{aligned} \boldsymbol{x}(k+1) &= \boldsymbol{\Phi}_x \mathbf{x}(k) + \boldsymbol{\Gamma}_\omega \omega_d(k) \\ \boldsymbol{y}(k) &= \boldsymbol{H}_x(k)\mathbf{x}(k) + \nu(k) \end{aligned}\right\}, \tag{4.30}$$

and an estimator design model described by:

$$\left.\begin{aligned} \hat{\boldsymbol{x}}(k+1) &= \boldsymbol{\Phi}\hat{\boldsymbol{x}}(k) + \boldsymbol{\Gamma}\hat{\omega}_d(k) \\ \hat{\boldsymbol{y}}(k) &= \boldsymbol{H}(k)\hat{\boldsymbol{x}}(k) + \hat{\nu}(k). \end{aligned}\right\}. \tag{4.31}$$

The time propagation and measurement update of the state estimate are as follows:

$$\left.\begin{aligned} \hat{\boldsymbol{x}}^-(k+1) &= \boldsymbol{\Phi}\hat{\boldsymbol{x}}^+(k) \\ \hat{\boldsymbol{x}}^+(k) &= \hat{\boldsymbol{x}}^-(k) + \hat{\boldsymbol{K}}(\mathbf{y}(k) - \hat{\boldsymbol{y}}^-(k)) \end{aligned}\right\}, \tag{4.32}$$

where $P(0)$ and the properties of $\hat{\nu}$ and $\hat{\omega}_d$ are accounted for in the design of the estimator gain sequence $\hat{\boldsymbol{K}}(k)$.

The remainder of this section is concerned with calculation of the error variance of $\boldsymbol{z} = (\boldsymbol{V}\boldsymbol{x} - \hat{\boldsymbol{x}})$ in the actual implemented system where the design model of the estimator does not match the "truth model" for the actual system. In this model structure, $dim(\boldsymbol{x})$ is usually larger than $dim(\hat{\boldsymbol{x}})$. The matrix $\boldsymbol{V}$ is defined to select the appropriate linear combination of the actual system states that correspond to the estimator states.

To analyze the performance of the coupled system, the joint state space representation for the system 4.30 and the implemented estimator 4.32 will be required:

$$\begin{bmatrix} \boldsymbol{x}^-(k+1) \\ \hat{\boldsymbol{x}}^-(k+1) \end{bmatrix} = \begin{bmatrix} \boldsymbol{\Phi}_x(k) & 0 \\ 0 & \boldsymbol{\Phi}(k) \end{bmatrix} \begin{bmatrix} \boldsymbol{x}^+(k) \\ \hat{\boldsymbol{x}}^+(k) \end{bmatrix} + \begin{bmatrix} \boldsymbol{\Gamma}_\omega(k) \\ 0 \end{bmatrix} \omega_d(k) \tag{4.33}$$

$$\boldsymbol{z}(k) = [\boldsymbol{V} - \mathbf{I}] \begin{bmatrix} \boldsymbol{x}(k) \\ \hat{\boldsymbol{x}}(k) \end{bmatrix} \tag{4.34}$$

$$\boldsymbol{y}^-(k) = [\boldsymbol{H}_x(k), 0] \begin{bmatrix} \boldsymbol{x}^-(k) \\ \hat{\boldsymbol{x}}^-(k) \end{bmatrix} + \nu(k) \tag{4.35}$$

$$\hat{\boldsymbol{y}}^-(k) = [0, \mathbf{H}(k)] \begin{bmatrix} \boldsymbol{x}^-(k) \\ \hat{\boldsymbol{x}}^-(k) \end{bmatrix} \tag{4.36}$$

$$\mathbf{K}(k) = \begin{bmatrix} 0 \\ \hat{\boldsymbol{K}}(k) \end{bmatrix} \tag{4.37}$$

$$\begin{bmatrix} \mathbf{x}^+(k) \\ \hat{\mathbf{x}}^+(k) \end{bmatrix} = \begin{bmatrix} \boldsymbol{x}^-(k) \\ \hat{\boldsymbol{x}}^-(k) \end{bmatrix} + \boldsymbol{K}(\mathrm{y}^-(k) - \hat{y}^-(k)) \tag{4.38}$$

This expression represents the actual time propagation of the real system and the estimate. Since the estimate is calculated exactly,[2] no process driving noise is represented in the corresponding rows of equation 4.33. In addition, the zeros concatenated into the estimation gain vector account for the fact that the estimator corrections do not affect the state of the actual system. For this coupled system, the covariance propagates between sampling times according to:

$$\boldsymbol{P}_{11}^-(k+1) = \boldsymbol{\Phi}_x \boldsymbol{P}_{11}^+ \boldsymbol{\Phi}_x^T + \boldsymbol{\Gamma}_\omega \boldsymbol{Q}_d \boldsymbol{\Gamma}_\omega^T. \tag{4.39}$$

$$\boldsymbol{P}_{12}^-(k+1) = \boldsymbol{\Phi}_x \boldsymbol{P}_{12}^+ \boldsymbol{\Phi}^T. \tag{4.40}$$

$$\boldsymbol{P}_{22}^-(k+1) = \boldsymbol{\Phi}\boldsymbol{P}_{22}^+ \boldsymbol{\Phi}^T. \tag{4.41}$$

The system is altered by measurement updates according to:

$$\boldsymbol{P}_{11}^+(k) = \boldsymbol{P}_{11}^-. \tag{4.42}$$

$$\boldsymbol{P}_{12}^+(k) = \boldsymbol{P}_{12}^-\left(\boldsymbol{I} - \boldsymbol{H}^T\hat{\boldsymbol{K}}^T\right) + \boldsymbol{P}_{11}^- \boldsymbol{H}_x^T \hat{\boldsymbol{K}}^T. \tag{4.43}$$

$$\begin{aligned} \boldsymbol{P}_{22}^+(k) = {} & \left(\boldsymbol{I} - \hat{\boldsymbol{K}}\boldsymbol{H}\right)\boldsymbol{P}_{22}^-\left(\boldsymbol{I} - \boldsymbol{H}^T\hat{\boldsymbol{K}}^T\right) + \hat{\boldsymbol{K}}\boldsymbol{H}_x\boldsymbol{P}_{11}^-\boldsymbol{H}_x^T\hat{\boldsymbol{K}}^T \\ & + \hat{\boldsymbol{K}}\boldsymbol{R}\hat{\boldsymbol{K}}^T + \hat{\boldsymbol{K}}\boldsymbol{H}_x\boldsymbol{P}_{12}^-\left(\boldsymbol{I} - \boldsymbol{H}^T\hat{\boldsymbol{K}}^T\right) \\ & + \left(\boldsymbol{I} - \hat{\boldsymbol{K}}\boldsymbol{H}\right)\boldsymbol{P}_{21}^-\boldsymbol{H}_x^T\hat{\boldsymbol{K}}^T. \end{aligned} \tag{4.44}$$

In equations 4.39 through 4.44, $\boldsymbol{P}_{11} = cov(\boldsymbol{x}, \boldsymbol{x})$, $\boldsymbol{P}_{21}^T = \boldsymbol{P}_{12} = cov(\boldsymbol{x}, \hat{\boldsymbol{x}})$, $\boldsymbol{P}_{22} = cov(\hat{\boldsymbol{x}}, \hat{\boldsymbol{x}})$. The error variance of the variable of interest, $\boldsymbol{z}$, is defined at any instant by:

$$cov(\boldsymbol{z}) = \boldsymbol{P}_z = \boldsymbol{V}\boldsymbol{P}_{11}\boldsymbol{V}^T + \boldsymbol{P}_{22} - \boldsymbol{V}\boldsymbol{P}_{12} - \boldsymbol{P}_{21}\boldsymbol{V}^T. \tag{4.45}$$

Because the matrix $\boldsymbol{P}_z$ depends on $\boldsymbol{K}$, the covariance analysis can be repeated for different gain sequences to compare the predicted performance of the alternative implementations. For given gain sequences, the covariance analysis can be repeated for different values of $\boldsymbol{\Phi}_x$, $\boldsymbol{Q}_d$, and $\boldsymbol{R}$ to determine the sensitivity of the performance to the design assumptions.

4.6 Implementation Issues

4.6.1 Minimizing Latency Due to Computation

Because the Kalman filter covariance equations and gain computation do not depend on the data, the equations can be reorganized to minimize the latency between the time that

[2] Quantization error can be modeled by a second additive noise source affecting the estimate but is dropped in this analysis for convenience. In floating point processors, the effect is small.

the measurements become available and the time that the measurement-corrected state estimates are generated.

Assume that $\boldsymbol{\Phi}(k), \boldsymbol{H}(k+1), \boldsymbol{Q}_d(k)$, and $\boldsymbol{R}(k+1)$ are known at time k. Also, assume that $\hat{\boldsymbol{x}}^+(k)$ has just been computed and posted at time k:

1. Compute the error covariance corresponding to $\hat{\boldsymbol{x}}^+(k)$ using equation 4.9:
$$\boldsymbol{P}^+(k) = [\boldsymbol{I} - \boldsymbol{K}(k)\boldsymbol{H}(k)]\boldsymbol{P}^-(k)[\boldsymbol{I} - \boldsymbol{K}(k)\boldsymbol{H}(k)]^T + \boldsymbol{K}(k)\boldsymbol{R}(k)\boldsymbol{K}(k)^T.$$
2. Propagate the state estimate covariance to the next time instant using equation 4.11:
$$\boldsymbol{P}^-(k+1) = \boldsymbol{\Phi}(k)\boldsymbol{P}^+(k)\boldsymbol{\Phi}(k)^T + \boldsymbol{\Gamma}_\omega \boldsymbol{Q}_d(k)\boldsymbol{\Gamma}_\omega^T.$$
3. Precompute the Kalman gain vector for the upcoming measurement using equation 4.23:
$$\boldsymbol{K}(k+1) = \boldsymbol{P}^-(k+1)\boldsymbol{H}(k+1)^T (\boldsymbol{H}(k+1)\boldsymbol{P}^-(k+1)\boldsymbol{H}(k+1)^T + \boldsymbol{R}(k+1))^{-1}.$$
4. As soon as $\boldsymbol{u}(k)$ is available, propagate the state estimate to the next time instant using equation 4.10:
$$\hat{\boldsymbol{x}}^-(k+1) = \boldsymbol{\Phi}(k)\hat{\boldsymbol{x}}^+(k) + \boldsymbol{\Gamma}_u \boldsymbol{u}(k).$$
5. When $\boldsymbol{y}(k+1)$ becomes available, the only computation required for the corrected state estimate is as follows:
$$\hat{\boldsymbol{x}}^+(k+1) = \hat{\boldsymbol{x}}^-(k+1) + \boldsymbol{K}(k+1)[\boldsymbol{y}(k+1) - \boldsymbol{H}(k+1)\hat{\boldsymbol{x}}^-(k+1)].$$

Step 5 is completed with high priority. Immediately after completion of step 5, $\hat{\boldsymbol{x}}^+(k+1)$ is posted for use by other systems. Then, k is incremented by 1 and as CPU time becomes available, steps 1 through 4 are completed as low priority processes as long as they are complete before $\boldsymbol{y}(k+1)$ becomes available (again). In step 1, equation 4.9 is used because the equation is applicable to any estimation gain vector, while the alternative form $\boldsymbol{P}^+(k) = [\boldsymbol{I} - \boldsymbol{K}(k)\mathbf{H}(k)]\mathbf{P}^-(k)$ is applicable only for the Kalman gain vector. Also, equation 4.9 has better numeric properties. Note that the portions of step 5 involving $\hat{\boldsymbol{x}}^-(k+1)$ could also be precomputed to allow additional latency reduction. If $\boldsymbol{\Phi}(k)$, $\boldsymbol{H}(k)$, $\boldsymbol{Q}_d(k)$, and $\boldsymbol{R}(k)$ can be determined off-line, then steps 1 through 3 can be computed off-line, so that only steps 4 and 5 occur online. If a Luenberger estimator is used, steps 1 and 2 are eliminated, and $\boldsymbol{K} = \boldsymbol{L}$ is fixed; therefore, only the time propagation and measurement updates of steps 4 and 5 are required online.

4.6.2 Scalar Processing

The Kalman filter algorithms have been presented, for notational convenience, in a vector form with m measurements. The portion of the measurement update that requires the most computing operations (i.e., flops) is the covariance update and gain vector calculation. For example, the following standard algorithms can be programmed to require $(\frac{3}{2}n^2m + \frac{3}{2}nm^2 + nm + m^3 + \frac{1}{2}m^2 + \frac{1}{2}m)$ flops:

$$\boldsymbol{K} = \boldsymbol{P}^-\boldsymbol{H}^T(\boldsymbol{R} + \boldsymbol{H}\boldsymbol{P}^-\boldsymbol{H}^T). \tag{4.46}$$

$$\mathbf{P}^+ = (\boldsymbol{I} - \boldsymbol{K}\boldsymbol{H})\boldsymbol{P}^-. \tag{4.47}$$

Alternatively, when the measurements are independent, the measurements can be equivalently treated as m sequential measurements with a zero width time interval between measurements.

Define the following as:

$$\boldsymbol{P}_1 = \boldsymbol{P}^-(k) \quad \hat{\boldsymbol{x}}_1 = \hat{\boldsymbol{x}}^-(k)$$
$$\boldsymbol{H} = \begin{bmatrix} \boldsymbol{H}_1 \\ \vdots \\ \boldsymbol{H}_m \end{bmatrix} \quad \boldsymbol{R} = \begin{bmatrix} R_1 & \dots & 0 \\ \vdots & & \vdots \\ 0 & \dots & R_m \end{bmatrix}. \tag{4.48}$$

Then, the equivalent scalar measurement processing algorithm is for $i = 1$ to m:

$$\boldsymbol{K}_i = \frac{\boldsymbol{P}_i\boldsymbol{H}_i^T}{R_i + \boldsymbol{H}_i\boldsymbol{P}_i\boldsymbol{H}_i^T}. \tag{4.49}$$

$$\hat{\boldsymbol{x}}_{i+1} = \hat{\boldsymbol{x}}_i + \boldsymbol{K}_i(\bar{y}_i - \boldsymbol{H}_i\hat{\boldsymbol{x}}_i). \tag{4.50}$$

$$\boldsymbol{P}_{i+1} = (\boldsymbol{I} - \boldsymbol{K}_i\boldsymbol{H}_i)\boldsymbol{P}_i. \tag{4.51}$$

In addition, the state and error covariance matrix posterior to the set of m measurements are defined by:

$$\hat{\boldsymbol{x}}^+(k) = \hat{\boldsymbol{x}}_{m+1} \tag{4.52}$$

$$\boldsymbol{P}^+(k) = \boldsymbol{P}_{m+1}. \tag{4.53}$$

The total number of computations for the m scalar measurement updates is $m(\frac{3}{2}n^2 + \frac{5}{2}n)$ plus m scalar divisions. Thus, it can be seen that m scalar updates are computationally cheaper for any m.

At the completion of the m scalar measurements, $\hat{\boldsymbol{x}}^+(k)$ and $\boldsymbol{P}^+(k)$ will be identical to the values that would have been computed by the corresponding vector measurement update. The state feedback measurement vectors $\boldsymbol{K}_i$ corresponding to the scalar updates are *not* equal to the columns of the state feedback gain matrix that would result from the corresponding vector update. This is due to the different ordering of the updates affecting the error covariance matrix $\boldsymbol{P}_i$ at the intermediate steps during the scalar updates.

4.6.3 Complementary Filtering

In applications, it often happens that multiple noisy measurements of a signal are available, and it is of interest to

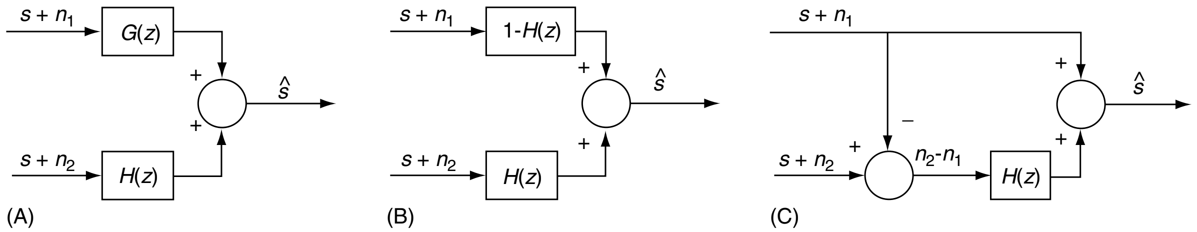

FIGURE 4.2 Block diagrams for the Estimation of a Signal s from Noisy Measurements. (A) Generic Filter Structure. (B) Complementary Filter Constrained to Not Distort s. (C) Feed-forward Complementary Filter.

combine the measurements to obtain an improved or even optimal estimate of the signal. Such a situation is illustrated in Figure 4.2(A), where two measurements of the signal s are available:

$$s_1 = s + n_1 \text{ and } s_2 = s + n_2 \tag{4.54}$$

The measurement noise processes n_1 and n_2 are random independent processes with known spectral densities, and s can be either random or deterministic; however, the signal s is not known, so it cannot be interpreted as the u term in equation 4.54. The objective is to design filters $G(z)$ and $H(z)$ such that $\hat{s} = G(z)s_1 + H(z)s_2$. If the estimator is designed with the constraint that the signal s cannot be distorted by the estimation process, then $G(z) = 1 - H(z)$. This constrained estimator, referred to as a complementary filter, is shown in Figure 4.2(B). Restructuring the complementary filter block diagram as shown in Figure 4.2(C) has two advantages. First, only a single filter is required. Second, the input to $H(z)$ is a random signal with known spectral density. Therefore, the filter design problem is properly structured for the Kalman or Weiner filter design techniques. The objective of the filter is to accurately estimate $-\hat{n}_1$. Additional computational advantages result that will be stated in the following example.

4.7 Example: Inertial Navigation System Error Estimation

As an illustrative example of the estimation concepts presented in this chapter, consider the following example of the calibration of a simplified inertial navigation system (INS) using an independent measurement of position:

$$p_m = p + \nu,$$

where ν is assumed to be Gaussian white noise with $cov(\nu) = \sigma_\nu^2 = (0.01\, m)^2$ and where p is the true position.

The inertial navigation system computations, which are depicted by the left block diagram in Figure 4.3, are the following:

$$\dot{p}_c = v_c, \quad \dot{v}_c = a_m, \tag{4.55}$$

where a_m is the measured acceleration that is corrupted by a bias plus Gaussian white noise, v_c is the computed velocity, and p_c is the computed position. The bias is assumed to be a random walk:

$$\dot{b} = \omega,$$

where ω is a Gaussian white noise process. Note that the INS computation block diagram can be decomposed into signal

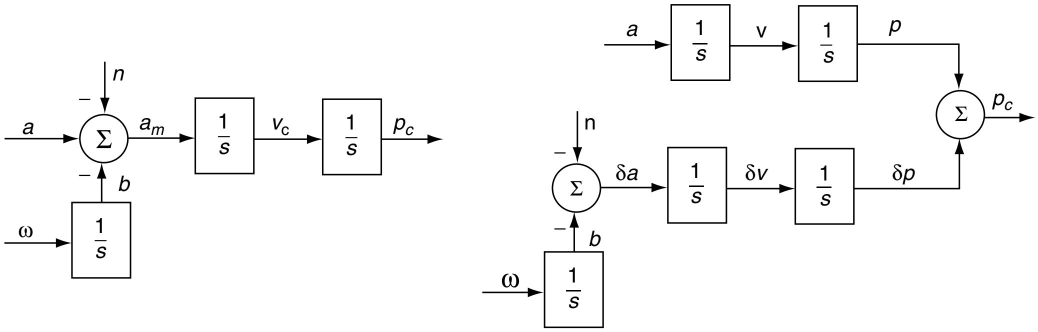

FIGURE 4.3 Inertial Navigation System Block Diagrams. (A) Block Diagram of the Actual INS Computations (B) Block Diagram Decomposing the INS into Signal and Error Channels

and noise channels as illustrated in Figure 4.3(B). This block diagram illustrates that the position p_c computed by the INS can be considered as the sum of the true position p and a colored noise process δp. The state-space model for δp is as seen here:

$$\begin{bmatrix} \delta\dot{p} \\ \delta\dot{v} \\ \dot{b} \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \delta p \\ \delta v \\ b \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & 1 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} \omega \\ n \end{bmatrix}. \qquad (4.56)$$

$$\delta p = [\,1 \quad 0 \quad 0\,] \begin{bmatrix} \delta p \\ \delta v \\ b \end{bmatrix}. \qquad (4.57)$$

The model specifies the $\boldsymbol{F}$, $\boldsymbol{H}$, and Γ_w matrices. Note that $\Gamma_u = 0$. The spectral density of w and n are denoted $\sigma_w^2 = 4 \times 10^{-10} \frac{m^2}{s^5}$ and $\sigma_n^2 = 10^{-4} \frac{m^2}{s^3}$, which correspond to an inexpensive solid-state device.

The feed-forward complementary filter to combine p_c and p_m to estimate p is shown in Figure 4.4. In this figure, all signals are illustrated in continuous time to clearly show the integrals involved. Both the INS and the filter would typically be implemented via computer in discrete-time representation. The analysis that follows will also be performed in discrete time. This feed-forward complementary filter implementation has several useful features in addition to those previously noted. First, the inputs to the filter $H(s)$ are stationary stochastic quantities unaffected by p, v, or a. In typical INS applications, this independence is not true. Second, in the discrete-time implementation, the INS update rate can be much higher that the rate at which the position measurements are made. For Kalman filter implementations, this fact significantly reduces the computational load because the time propagation and measurement updates of the estimation error covariance matrices, which are the most computationally expensive portion of the algorithm, occur at the lower rate of the position measurement.

Consider the design of the complementary filter as a Kalman filter, where $\boldsymbol{H} = [1,\ 0,\ 0]$, $\boldsymbol{R} = \sigma_v^2$, and:

$$\Phi = \begin{bmatrix} 1 & T & \frac{1}{2}T^2 \\ 0 & 1 & T \\ 0 & 0 & 1 \end{bmatrix} \text{ and}$$

$$\boldsymbol{Q}_d = \begin{bmatrix} \frac{\sigma_n^2 T^3}{3} + \frac{\sigma_\omega^2 T^5}{20} & \frac{\sigma_n^2 T^2}{2} + \frac{\sigma_\omega^2 T^4}{8} & \frac{\sigma_\omega^2 T^3}{6} \\ \frac{\sigma_n^2 T^2}{2} + \frac{\sigma_\omega^2 T^4}{8} & \sigma_n^2 T + \frac{\sigma_\omega^2 T^3}{3} & \frac{\sigma_\omega^2 T^2}{2} \\ \frac{\sigma_\omega^2 T^3}{6} & \frac{\sigma_\omega^2 T^2}{2} & \sigma_\omega^2 T \end{bmatrix}. \qquad (4.58)$$

The left column of Figure 4.5 shows the covariance analysis using the method of Section 4.5.2 for a scenario where the position aiding is available at 1 Hz for the first 60 sec but not available for the subsequent 15 sec. In the first 60 sec the position and velocity error standard deviations (STDs) have effectively reached their steady-state accuracy. These plots clearly show that error accumulates during each 1 sec of INS integration and is reduced by each 1 Hz position update. The accelerometer bias error is still being slowly corrected at the end of the 60 sec of position corrections.

Two natural questions relevant to the system design are what are the dominant error sources causing the growth of the INS errors between the 1-Hz corrections during the first 60 sec, and what are the dominant error sources that cause the INS error growth during the period when the position aiding is no longer available. Both of these question are answerable by the error budgeting analysis described in Section 4.5.1. The error budget analysis plot for the position estimate is shown in Figure 4.5(D). This figure shows the error contributions from ω, n, v, and the total error from all sources. The plot for the error contribution from $P(0)$ has not been included because it is insignificant for the time period shown. Note that the figure plots the standard deviations (STDs). To perform the superposition check that the errors from the individual sources add up to the total error at every time instant, the plotted

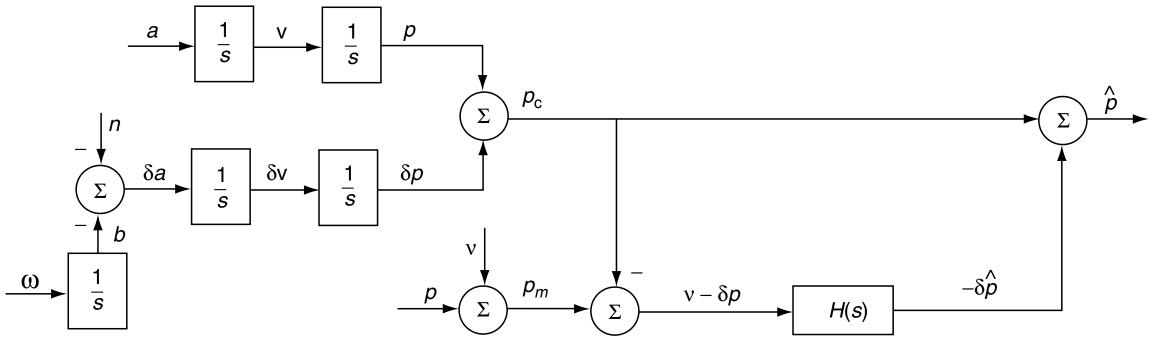

FIGURE 4.4 Feed-Forward Complementary Filter Implementation of the Simplified Position-Aided Inertial Navigation System

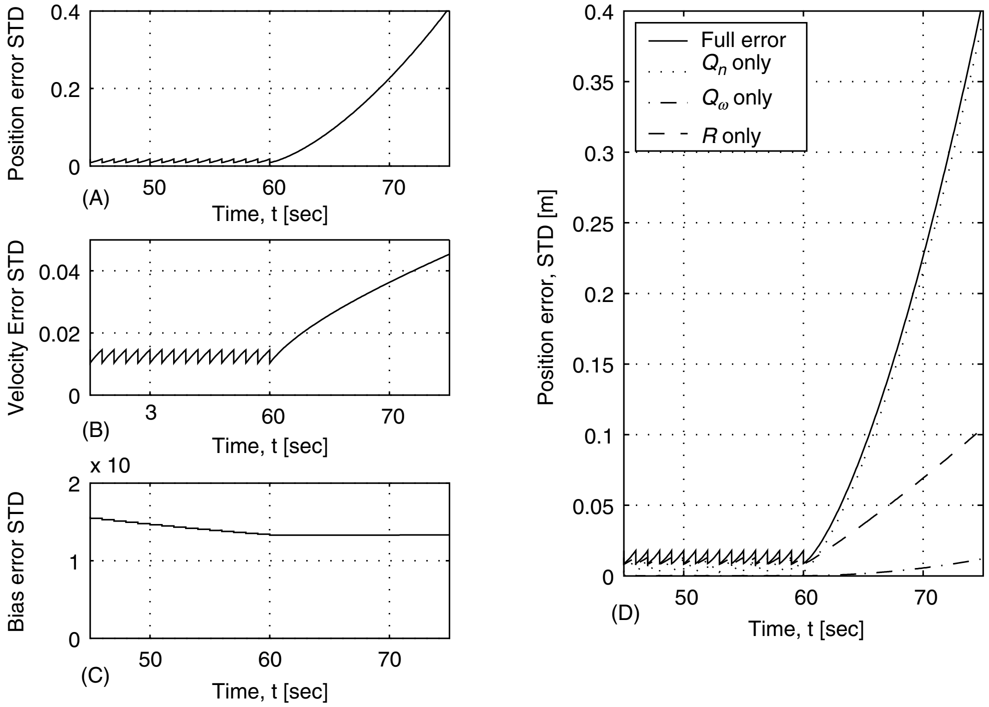

FIGURE 4.5 Covariance and Error Budget Analysis for the Position-Aided INS Example (A) Position Error in m/s Versus Time (B) Velocity Error in m/s Versus Time. (C) Accelerometer Bias Error in m/s Versus Time (D) Position Error Budget Analysis

quantities must be squared prior to the addition. The figure clearly shows that by 62 sec, 2 sec after the position aiding has been removed, the acceleration measurement noise n has become the dominant error source. The accelerometer bias drift term is rather insignificant. Therefore, if the design objective were to maintain position accuracy less than 0.3 m for a longer period of time, then either an independent velocity aiding measurement or an accelerometer with less measurement noise would be required.

This example has been designed as a simplified analysis of a carrier phase differential global positioning system-aided INS. A full error analysis is significantly more complicated for a few reasons. First, the INS equations are nonlinear. The implementation therefore requires a more advanced estimator implementation, such as an extended Kalman filter. Second, the INS error equations are functions of the acceleration and angular rate of the inertial measurement unit. In addition, the linearized measurement matrix is a function of the satellite positions and is therefore time varying. Therefore, the state-space model is time varying, and the full error analysis would be dependent on assumed vehicle maneuvers and satellite configurations.

4.8 Further Reading

Various aspects of linear algebra and the state-space methodology are discussed in Brogan (1991). The Luenberger observer is presented in Luenberger (1966). The Kalman filter is presented in Kalman (1960, 1961). Estimation theory and estimator design are discussed in several texts (Brown and Hwang, 1992; Gelb *et al.*, 1974; Maybeck, 1979). Practical aspects of estimation theory including state augmentation, suboptimal filter analysis, and applications are discussed in Farrell and Barth (1999), Gelb et al. (1974), and Maybeck (year). Markov parameters and FIR approximations to IIR filters are discussed in Mendel (1995) and Moore (1981). Efficient computation of the discrete-time state transition matrix and process noise covariance matrix are discussed in Van Loan (1978). The full implementation of the GPS/INS system corresponding to the example is described in Farrell (2000).

Cost-Cumulants and Risk-Sensitive Control

Chang-Hee Won
*Department of Electrical Engineering,
University of North Dakota,
Grand Forks,
North Dakota, USA*

5.1 Introduction

Cost-cumulant control, also known as statistical control, is an optimal control method that minimizes a linear combination of quadratic cost cumulants. **Risk-sensitive control** is an optimal control method that minimizes the exponential of the quadratic cost criterion. This is equivalent to optimizing a denumerable sum of all the cost cumulants.

Optimal control theory deals with the optimization, either minimization or maximization, of a given cost criterion. **Linear-quadratic-Gaussian control**, **minimum cost-variance control**, and **risk-sensitive control** are discussed in terms of cost cumulants. Figure 5.1 presents an overview of the optimal control and the relationships among different optimal control methods.

5.2 Linear-Quadratic-Gaussian Control

The **linear quadratic Gaussian (LQG) control** method optimizes the mean, which is the first cumulant, of a quadratic cost criterion (Anderson and Moore, 1989; Davis, 1977; Kwarkernaak and Sivan, 1972).

Typical system dynamics for LQG control are given by the stochastic equation:

$$\begin{aligned} dx(t) &= Ax(t)dt + Bk(t, x)dt + E(t)dw(t). \\ y(t)dt &= Cx(t)dt + dv(t). \end{aligned} \tag{5.1}$$

Here $w(t)$ and $v(t)$ are vector Brownian motions. The meaning of a **Brownian motion**, such as $w(t)$, can be given directly or in terms of its differential $dw(t)$. In the latter case, the $dw(t)$ is a Gaussian random process with zero mean, covariance matrix $W\,dt$, and independent increments. A similar description applies to $dv(t)$, with covariance $V\,dt$. It is assumed that $dw(t)$ and $dv(t)$ are independent. The matrices A, B, C, and E are of compatible size. It should be remarked that the formalism of equation 5.1 is that of a stochastic differential equation. Intuitively, one thinks of dividing both sides of this equation by dt to obtain the more colloquial form. But the formal derivative of a Brownian motion—which is known as white noise—is not a well-defined random process, and this motivates an alternate way of thinking.

The quadratic cost criterion is given by:

$$J(k) = \int_0^{t_F} (x'Qx + k'Rk)dt. \tag{5.2}$$

The weighting matrix Q is a symmetric and positive semidefinite matrix, and R is a symmetric and positive definite matrix.

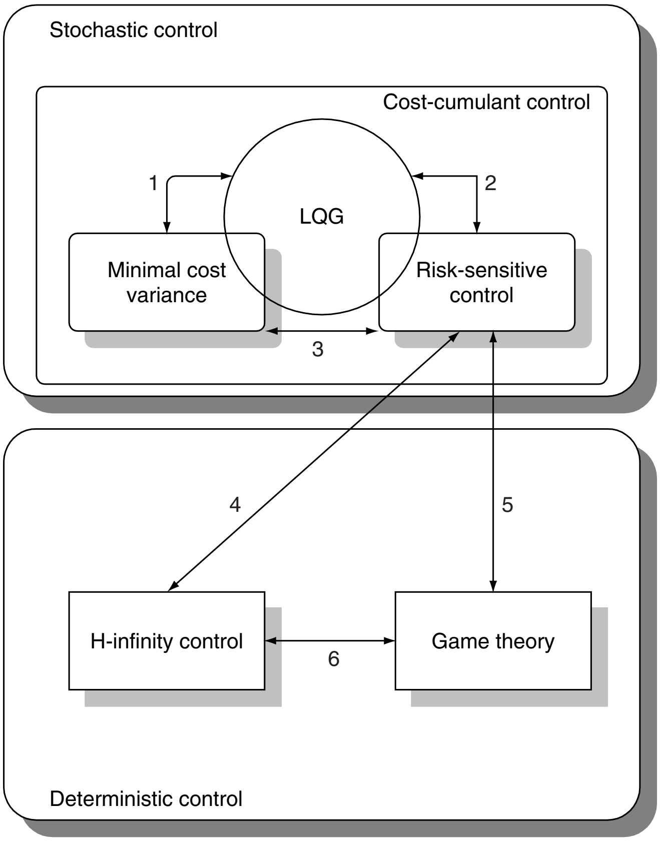

FIGURE 5.1 Relationship Between Various Optimal and Robust Control Methods. (Sain *et al.*, 2000; Jacobson, 1973; Won and Sain, 1995; Glover and Doyle, 1988; Whittle, 1990; Rhee and Speyer, 1992; Jacobson, 1973; Runolfsson, 1994; Uchida, 1989; Basar and Bernhard, 1991.)

The LQG control problem then becomes a minimization of the mean quadratic cost over feedback controller k:

$$J^* = \min_k E\{J(k)\}. \tag{5.3}$$

The full-state feedback control problem is to choose the control k as a function of the state x so that the cost criterion of equation 5.3 is minimized. The general partial observation or output feedback control problem is to choose the control k as a function of the observation y so that the cost of equation 5.3 is minimized.

Assume now that the problem has a solution of the quadratic form $\frac{1}{2}x'\Pi x$. The matrix Π can be found from the **Riccati equation**:

$$0 = \dot{\Pi}(t) + Q + A'\Pi(t) + \Pi(t)A - \Pi(t)BR^{-1}B'\Pi(t), \tag{5.4}$$

where $\Pi(t_F) = 0$.

Then the **full-state feedback optimal controller** is given by (Davis, 1977):

$$k(t, x) = -R^{-1}B'\Pi(t)x(t). \tag{5.5}$$

The solution of the output feedback LQG problem is found using the **certainty equivalence principle**. The optimal control is found using a Kalman filter, where an optimal estimate $\hat{x}$ is obtained such that $E\{(x-\hat{x})'(x-\hat{x})\}$ is minimum. Then this estimate is used as if it were an exact measurement of the state to solve the deterministic LQG control.

For the output feedback case, the estimated states are given by:

$$\frac{d\hat{x}}{dt} = Ax + Bk + PCV^{-1}(y - C\hat{x}), \tag{5.6}$$

where P satisfies the **forward Riccati equation**:

$$\dot{P}(t) = W + AP(t) + P(t)A' - P(t)C'V^{-1}CP(t). \tag{5.7}$$

In equation 5.7, the initial condition is $P(0) = \mathrm{cov}(x_0)$. Finally the **optimal output feedback controller** is given as:

$$k(t, x) = -R^{-1}B'\Pi(t)\hat{x}(t). \tag{5.8}$$

5.3 Cost-Cumulant Control

5.3.1 Minimal Cost Variance Control

Minimum cost variance (MCV) control is a special case of cost-cumulant or statistical control where the second cumulant, variance, is minimized, whereas the first cumulant, mean, is kept at a prespecified level.

Here, open-loop MCV and full-state feedback MCV control laws are discussed. An **open-loop control law** is a function u: $[0, t_F] \rightarrow u$ where u is some specified allowable set of control values. A **closed-loop or feedback control law** is a function that depends on time and the past evolution of the process [i.e., $u(t, x(s); 0 \leq s \leq t)$].

Open-Loop MCV Control

Consider a linear system (Sain and Liberty, 1971):

$$dx(t) = A(t)x(t)dt + B(t)u(t)dt + E(t)dw(t), \tag{5.9}$$

and the performance measure:

$$J = \int_0^{t_F} [x'(t)Qx(t) + u'(t)Ru(t)]dt + x'(t_F)Q_F x(t_F), \tag{5.10}$$

where $w(t)$ is zero mean with white characteristics relative to the system, t_F is the fixed final time, $x(t) \in \mathbb{R}^n$ is the state of the system, and $u(t) \in \mathbb{R}^m$ is the control action. Note that:

$$E\{dw(t)dw'(t)\} = W\ dt. \tag{5.11}$$

The fundamental idea behind minimal cost-variance control is to minimize the variance of the cost criterion J:

$$J_{MV} = VAR_k\{J\}, \tag{5.12}$$

while satisfying a constraint:

$$E_k\{J\} = M, \tag{5.13}$$

where J is the cost criterion and where the subscript k on E denotes the expectation based on a control law k generating the control action $u(t)$ from the state $x(t)$ or from a measurement history arising from that state. By means of a Lagrange multiplier μ corresponding to the constraint of equation 5.13, one can form the function:

$$J_{MV} = \mu(E_k\{J\} - M) + VAR_k\{J\}, \tag{5.14}$$

which is equivalent to minimizing:

$$\hat{J}_{MV} = \mu E_k\{J\} + VAR_k\{J\}. \tag{5.15}$$

A Riccati solution to $\hat{J}_{MV}$ minimization is developed for the open-loop case:

$$u(t) = k(t, x(0)). \tag{5.16}$$

The solution is based on the differential equations:

$$\dot{z}(t) = A(t)z(t) - \frac{1}{2}B(t)R^{-1}B'(t)\hat{\rho}(t). \tag{5.17}$$

$$\dot{\hat{\rho}}(t) = -A'(t)\hat{\rho}(t) - 2Qz(t) - 8\mu Q\nu(t). \tag{5.18}$$

$$\dot{\nu}(t) = A(t)\nu(t) + E(t)WE'(t)y(t). \tag{5.19}$$

$$\dot{y}(t) = -A'(t)y(t) - Qz(t). \tag{5.20}$$

These equations have the boundary conditions:

$$z(0) = x(0). \tag{5.21}$$

$$\hat{\rho}(t_F) = 2Q_F\ z(t_F) + 8\mu Q_F\nu(t_F). \tag{5.22}$$

$$\nu(0) = 0. \tag{5.23}$$

$$y(t_F) = Q_F z(t_F). \tag{5.24}$$

The equations also have the control action relationship:

$$\nu(t) = -\frac{1}{2}R^{-1}B(t)\rho(t). \tag{5.25}$$

The variable $z(t)$ is the mathematical expectation of $x(t)$. The variable $\rho(t)$ corresponds to the costate variable of optimal control theory because it is the variable that enforces the differential equation constraint between $z(t)$ and $\nu(t)$. The variable $\nu(t)$ and $y(t)$ are introduced to reduce the integro-differential equation.

Full-State Feedback Minimal Cost-Variance Control

Consider the Ito sense stochastic differential equation (SDE) with control (Sain *et al.*, 2000):

$$dx(t) = [A(t)x(t) + B(t)k(t, x)]\ dt + E(t)\ dw(t).$$

The equation also has the cost criterion:

$$J(t, x(t), k) = \int_t^{t_F} [x(t)'Qx(t) + k'(t, x)R(t)k(t, x)]ds + x'(t_F)Q_F x(t_F). \tag{5.26}$$

In MCV control, we define a class of admissible controllers, and then the cost variance is minimized within that class of controllers. Define $V_1(t, x; k) = E\{J(t, x(t), k)|x(t) = x\}$ and $V_2(t, x; k) = E\{J^2(t, x(t), k)|x(t) = x\}$. A function M is an admissible mean cost criterion if there exists an admissible control law k such that:

$$V_1(t, x; k) = M(t, x), \tag{5.27}$$

for all $t \in [0, t_F]$ and $x \in \mathbb{R}^n$.

A minimal mean cost-control law k_M^* satisfies $V_1(t, x; k_M^*) = V_1^*(t, x) \leq V_1(t, x; k)$ for $t \in T, x \in \mathbb{R}^n$ and for k, an admissible control law. An MCV control law $k_{V|M}^*$ satisfies $V_2(t, x; k_{V|M}^*) = V_2^*(t, x) \leq V_2(t, x; k)$ for $t \in T$, $x \in \mathbb{R}^n$ whenever k is admissible. The corresponding minimal cost variance is given by $V^*(t, x) = V_2^*(t, x) - M^2(t, x)$ for $t \in T$, $x \in \mathbb{R}^n$. Here the full-state feedback solution of the MCV control problem is presented for a linear system and a quadratic cost criterion.

Then the linear optimal MCV controller is given by (Sain *et al.*, 2000):

$$K_{V|M}^*(t, x) = -R^{-1}(t)B'(t)[\mathcal{M}(t) + \gamma(t)V(t)]x,$$

where $\mathcal{M}$ and $\mathcal{V}$ are the solutions of the **coupled Riccati-type equations** (suppressing the time argument):

$$0 = \dot{\mathcal{M}} + A'\mathcal{M} + \mathcal{M}A + Q - \mathcal{M}BR^{-1}B'\mathcal{M} + \gamma^2\mathcal{M}BR^{-1}B'\mathcal{V}. \tag{5.28}$$

$$0 = \dot{V} + 4\mathcal{M}EWE'\mathcal{M} + A'\mathcal{V} + \mathcal{V}A - \mathcal{M}BR^{-1}B'\mathcal{V} - \mathcal{V}BR^{-1}B'\mathcal{M} - 2\gamma\mathcal{V}BR^{-1}B'\mathcal{V}, \tag{5.29}$$

with boundary conditions $\mathcal{M}(t_F) = Q_F$ and $\mathcal{V}(t_F) = 0$. Once again, if γ approaches zero, classic LQG results are obtained.

This MCV idea can be generalized to minimize any cost cumulants. Viewing the cost function as a random variable and optimizing any cost cumulant is called cost-cumulant or statistical control.

5.4 Risk-Sensitive Control

A large class of control systems can be described in state-variable form by the stochastic equations (Anderson and Moore, 1989; Whittle, 1996):

$$\begin{aligned} dx(t) &= Ax(t)dt + Bk(t,\, x)dt + dw(t). \\ y(t)dt &= Cx(t)dt + dv(t). \end{aligned} \tag{5.30}$$

Here, $x(t)$ is a $2n$-dimensional state vector, $k(t{,}x)$ is an m-dimensional input vector, $w(t)$ is a q-dimensional disturbance vector of Brownian motions, $y(t)$ is a p-dimensional vector of output measurements, and $v(t)$ is an r-dimensional output noise vector of Brownian motions that affect the measurements being taken.

The risk-sensitive cost criterion is given by:

$$J_{RS}(\theta) = -\theta^{-1}\log E_k\{e^{-\theta J}\}, \tag{5.31}$$

where J is the classical quadratic cost criterion:

$$J = \int_0^{t_F} (x'Qx + k'Rk)dt. \tag{5.32}$$

The RS control problem then becomes a minimization of the cost $J_{RS}(\theta)$ over feedback controller k:

$$J^*_{RS}(\theta) = \min_u J_{RS}(\theta). \tag{5.33}$$

Assume a solution of the quadratic form $\frac{1}{2}x'\Pi x - \sigma' x +$ (terms independent of x). The matrix Π can be found from the Riccati-type equation:

$$0 = \dot{\Pi}(t) + Q + A'\Pi(t) + \Pi(t)A - \Pi(t)\big(BR^{-1}B' + \theta W\big)\Pi(t), \tag{5.34}$$

where $\Pi(t_F) = 0$.

Then, the full-state feedback optimal controller is given by (Whittle, 1996):

$$k(t,\, x) = -R^{-1}B'\Pi(t)x(t) + R^{-1}B'\sigma(t), \tag{5.35}$$

where $\dot{\sigma}(t) + (A - \Pi(B'R^{-1}B' + \theta W))'\,\sigma(t) = 0$ is a backward linear equation. The matrix P satisfies the forward Riccati-type equation:

$$\dot{P}(t) = W + AP(t) + P(t)A' - P(t)\big(C'V^{-1}C + \theta Q\big)P(t), \tag{5.36}$$

where $P(0) = (x_0)$. The updating equation for the risk-sensitive Kalman filter is given by:

$$\frac{d\mathring{x}}{dt} = Ax + Bk + PCV^{-1}(y - C\mathring{x}) - \theta PQ\mathring{x}, \tag{5.37}$$

where $\mathring{x}(0) = 0$. $\mathring{x}$ denotes the mean of x conditional on the initial information, current observation history, and previous control history. Finally, the optimal output feedback controller is given as (Whittle, 1996):

$$k(t,\, x) = -R^{-1}B'\Pi(t)\hat{x}(t) + R^{-1}B'\sigma(t), \tag{5.38}$$

where $\hat{x}$ is the minimal-stress estimate of x, given by:

$$\hat{x}(t) = (I + \theta P(t)\Pi(t))^{-1}(\mathring{x}(t) + \theta P(t)\sigma(t)). \tag{5.39}$$

As θ approaches zero, the cost criterion of equation 5.31 becomes $E_k\{J\}$, and the matrices Π and P are obtained from the Riccati equations:

$$O = \dot{\Pi}(t) + Q + A'\Pi(t) + \Pi(t)A - \Pi(t)BR^{-1}B'\Pi(t). \tag{5.40}$$

$$\dot{P}(t) = W + AP(t) + P(t)A' - P(t)C'V^{-1}CP(t). \tag{5.41}$$

Thus, the classic LQG result is obtained as θ approaches zero:

5.5 Relationship Between Risk-Sensitive and Cost-Cumulant Control

To see the relationship between RS and cost-cumulant control, consider a cost criterion:

$$J = \int_0^{t_F} [x(t)'Qx(t) + k'(t,x)R(t)k(t,x)]ds + x'(t_F)Q_F x(t_F). \tag{5.42}$$

Classical LQG control minimizes the first cumulant or the mean of the cost criterion of equation 5.42. In MCV control, the second cumulant of equation 5.42 is minimized while the mean is kept at a prespecified level. Furthermore, RS control minimizes an infinite linear combination of the cost cumulants. To see this, consider an RS cost criterion:

$$J_{RS} = -\theta^{-1}\log\,(E\{\exp\,(-\theta J)\}), \tag{5.43}$$

where θ is a real parameter and E denotes expectation. Then, the moment-generating function or the first characteristic function is given by:

$$\phi(s) = E\exp\,(-sJ). \tag{5.44}$$

The cumulant generating function $\psi(s)$ is defined by:

$$\psi(s) = \log\phi(s) = \sum_{i=1}^{\infty}\frac{(-1)^i}{i!}\beta_i s^i, \tag{5.45}$$

in which the $\{\beta_i\}$ are known as the **cumulants** or sometimes as the **semi-invariants** of J. Now by comparing equations 5.43, 5.44, and 5.45, it is noted that:

$$J_{RS} = \left(-\theta^{-1}\right)\left\{\sum_{i=1}^{\infty}\frac{(-1)^i}{i!}\beta_i(J)(\theta)^i\right\}, \tag{5.46}$$

where $\beta_i(J)$ denotes the ith cumulant of J with respect to the control law k. Thus, it is important to note that the RS cost criterion is an infinite linear combination of the cost cumulants. Moreover, approximating to the second order:

$$\begin{aligned} J_{RS} &= \beta_1(J) - \frac{\theta}{2}\beta_2(J) + O(\theta^2) \\ &= E\{J\} - \frac{\theta}{2} VAR\{J\} + O(\theta^2). \end{aligned} \tag{5.47}$$

Therefore, the minimal cost mean and minimal cost variance problems can be viewed as first- and second-order approximations of the RS control problem respectively. Minimizing the $VAR\{J\}$ under the restriction that the first cumulant $E\{J\}$ exists is called the **minimal cost variance** (MCV) **problem**. Moreover, minimizing any linear combination of cost cumulants under certain restrictions would be called cost-cumulant or statistical control. Thus, classical LQG control (optimization of the first cumulant), MCV control (optimization of the second cumulant), and RS control (optimization of the infinite number of cumulants) are all special cases of the cost-cumulant control problem.

5.6 Applications

An application of risk-sensitive control to satellite attitude maneuver is given in this section. An application of minimal cost variance control to an earthquake structure control is also given here. For linear quadratic Gaussian applications, see Anderson and Moore (1989), Fleming and Rishel (1975) and Kwarkernaak and Sivan (1972). For more risk-sensitive control examples, refer to Bensoussan (1992) and Whittle (1996).

5.6.1 Risk-Sensitive Control Applied to Satellite Attitude Maneuver

This subsection shows the simulation results associated with the model of a geostationary satellite equipped with a bias momentum wheel on the third axis of body frame. This model assumes that the disturbance torque is Gaussian white noise. A stochastic RS controller is then applied. For this model, small attitude angle and roll/yaw dynamics are assumed to be decoupled from the pitch dynamics.

A roll/yaw attitude model of the geostationary satellite is simplified as the following linear differential equation of $h_w \gg \max\{I_i, \omega_c\}$:

$$\begin{aligned} dx(t) &= \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -\frac{h_w\omega_c}{I_{11}} & 0 & 0 & -\frac{h_w}{I_{11}} \\ 0 & -\frac{h_w\omega_c}{I_{22}} & \frac{h_w}{I_{22}} & 0 \end{bmatrix} x(t)dt \\ &+ \begin{bmatrix} 0 \\ 0 \\ \frac{B_e}{I_{11}}\cos(\alpha) \\ \frac{B_e}{I_{22}}\sin(\alpha) \end{bmatrix} m(t)dt + \begin{bmatrix} 0 \\ 0 \\ \frac{1}{I_{11}} \\ \frac{1}{I_{22}} \end{bmatrix} dw(t) \end{aligned} \tag{5.48}$$

$$dy(t) = I_{4\times4}x(t)dt + dv(t) \tag{5.49}$$

The dw/dt is Gaussian white noise representing the disturbance torque, dv/dt is Gaussian white noise representing the measurement noise, h_w is the wheel momentum, α is the angle that the positive roll axis makes with the magnetic torquer, ω_c is the orbital rate, I_{ii} is the moment of inertia of the ith axis, $x = [\gamma, r, \dot{\gamma}, \dot{r}]$ is the state with yaw (γ), roll (r), m is a dipole moment of the magnetic torquer (control), $B_e = 1.07 \times 10^{-7}$ telsa is the nominal magnetic field strength, and $I_{4\times4}$ is an identity matrix with dimension four. The expected value of dw/dt is zero with $E\{dw/dt \times dw/dt\} = 0.7B_e$, and the expected value of dv/dt is zero with $E\{dv/dt \times dv/dt'\} = 1 \times 10^{-7}$. Here $\theta = 5 \times 10^{-2}$ was chosen for the demonstration purpose, but this risk-sensitivity parameter, θ should be viewed as another design parameter just like the weighting matrices Q and R. By varying this θ, different performance and stability results can be obtained. Theoretically, all θ that give a solution to the Riccati equation 5.36 are possible. The next example shows how to choose this risk-sensitivity parameter to obtain larger stability margin. The constants for the operational mode are given as $I_{11} = 1988\,\text{kg}{\cdot}\text{m}^2$, $I_{22} = 1876\,\text{kg}{\cdot}\text{m}^2$, $I_{12} = I_{21} = 0$, $h_w = 55\ \text{kg}{\cdot}\text{m}^2/s$, $\omega_c = 0.00418\,\text{deg}/s$, and $\theta = 60$ deg. These values are actual parameters of the geostationary satellite. The initial condition is [0.5 deg, 0, 0, 0.007 deg/sec]. Finally, the weighting matrices are chosen to be $Q = I_{4\times4}$ and $R = 1 \times 10^{-10}$.

In this model, the states are measured with the sensor noise, dv/dt. A Kalman filter is then used to estimate the states. The following simulations are performed using MATLAB, a software package. The RS controller is found using equation 5.35. Note that both yaw and roll angles reduce to a value close to the origin. Figure 5.2 shows the roll and yaw angles with respect to time variation. After about 3 hours, both roll and yaw angles stay below 0.1 degree. Initially, large control action is needed, but after 3 hours or so, less than 300 Atm^2 magnetic

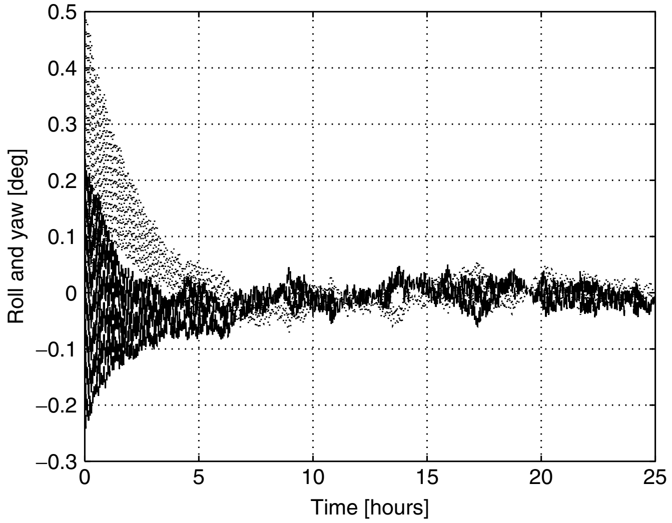

FIGURE 5.2 Roll (Dark) and Yaw (Light) Versus Time, RS Control

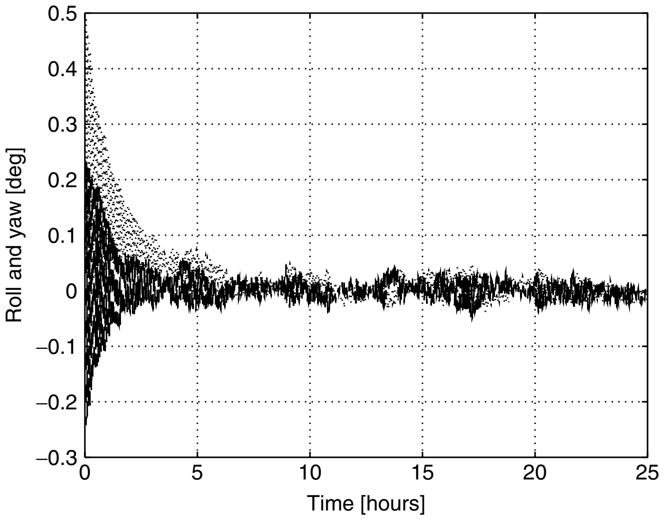

FIGURE 5.3 Roll (Dark) and Yaw (Light) Versus Time, LQG Control

torque is required. It is important to note that despite the external disturbances, RS control law produces good performance.

To compare the results with the well-known LQG controller, the system was simulated with an LQG controller. The θ approached infinity in equation 5.36. Note that equation 5.36 becomes a classical Riccati equation as θ goes to infinity. This is shown in Figure 5.3. Note that in LQG case, it takes longer for yaw and roll angles to fall below 0.1 degree, and the variation in the angles are larger than the RS case. Thus, in this sense, RS controller outperforms the LQG controller.

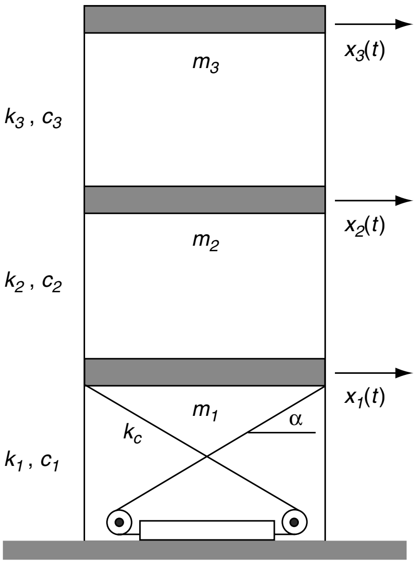

FIGURE 5.4 Schematic Diagram for Three Degree-of-Freedom Structure

5.6.2 MCV Control Applied to Seismic Protection of Structures

A 3DOF, single-bay structure with an active tendon controller as shown in Figure 5.4 is considered here. The structure is subject to a one-dimensional earthquake excitation. If a simple shear frame model for the structure is assumed, the governing equations of motion in state space form can be written as:

$$dx(t) = \begin{bmatrix} 0 & I \\ -M_s^{-1}K_s & -M_s^{-1}C_s \end{bmatrix} x(t)dt + \begin{bmatrix} 0 \\ M_s^{-1}B_s \end{bmatrix} u(t)dt + \begin{bmatrix} 0 \\ -\Gamma_s \end{bmatrix} dw(t),$$

where the following apply:

$$M_s = \begin{bmatrix} m_1 & 0 & 0 \\ 0 & m_2 & 0 \\ 0 & 0 & m_3 \end{bmatrix}, \; B_s = \begin{bmatrix} -4k_c \cos\alpha \\ 0 \\ 0 \end{bmatrix}.$$

$$C_s = \begin{bmatrix} c_1 + c_2 & -c_2 & 0 \\ -c_2 & c_2 + c_3 & -c_3 \\ 0 & -c_3 & c_3 \end{bmatrix}, \; \Gamma_s = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}.$$

$$K_s = \begin{bmatrix} k_1 + k_2 & -k_2 & 0 \\ -k_2 & k_2 + k_3 & -k_3 \\ 0 & -k_3 & k_3 \end{bmatrix}.$$

The m_i, c_i, k_i are the mass, damping, and stiffness, respectively, associated with the ith floor of the building. The k_c is the stiffness of the tendon. The Brownian motion $w(t)$ with $E\{dw(t)\} = 0$ and $E\{dw(t)dw'(t)\} = Wdt$; in this example, $W = 1.00 \times 2\pi$ in^2/sec^3. The parameters were chosen to

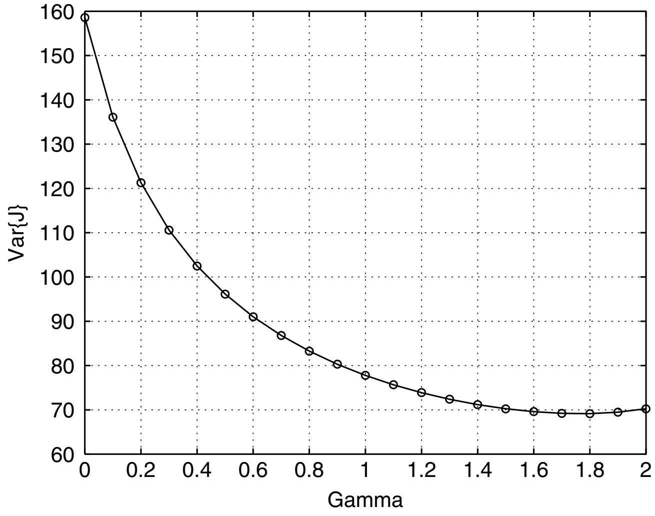

FIGURE 5.5 Optimal Variance: Full-State Feedback, MCV, 3DOF

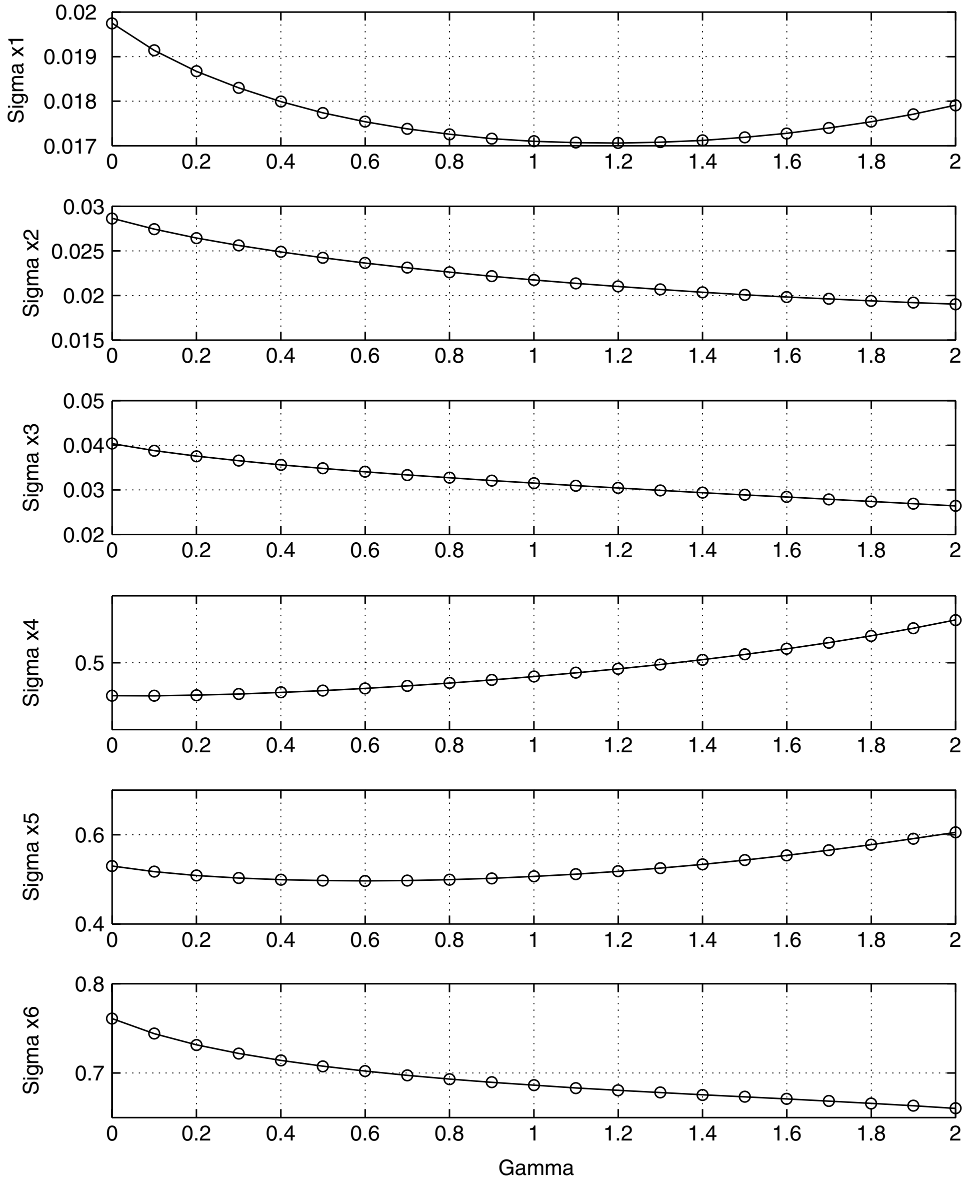

FIGURE 5.6 Displacements and Velocities. Full-State Feedback, MCV, 3DOF

match modal frequencies and dampings of an experimental structure. The cost criterion is given by:

$$J = \int_0^{t_F} \left(z'(t) K_s z(t) + k_c u^2(t)\right) dt,$$

together with $R = k_c$, where z is a vector of floor displacements and $x = [z\ \dot{z}]'$.

Figure 5.5 shows that the variance of the cost criterion decreases as γ increases. Note that the $\gamma = 0$ point corresponds to the classical LQG case.

Figure 5.6 shows the RMS displacement responses of first (σ_{x_1}), second (σ_{x_2}), and third (σ_{x_3}) floor and the RMS velocity responses of first (σ_{x_4}), second (σ_{x_5}), and third (σ_{x_6}) floor, respectively, versus the MCV parameter γ. It is important to note that both third floor RMS displacement and velocity responses can be decreased by choosing large γ.

5.7 Conclusions

This chapter describes linear-quadratic-Gaussian (LQG), minimal cost variance (MCV), and risk-sensitive (RS) controls in terms of the cost cumulants. Cost cumulant control, which is also called statistical control, views the optimization criterion as a random variable and minimizes any cumulant of the optimization criterion. Then LQG, MCV, and RS are all special cases of cost cumulant control where in LQG the mean, in MCV the variance, and in RS all cumulants of the cost function are optimized. This chapter provides the optimal controllers for the LQG, MCV, and RS methods. Finally, satellite attitude control application using RS controller and building control application using MCV controller are described.

Frequency Domain System Identification

Gang Jin
*Ford Motor Company,
Dearborn, Michigan, USA*

6.1 Introduction

A general procedure for the frequency domain identification of multiple inputs/multiple outputs (MIMO) linear time invariant systems is illustrated in Figure 6.1. Typically, one starts with the experimental frequency response function (FRF) of the test system. These FRF data may either be computed from the saved input/output measurement data or measured directly online by a spectrum analyzer. Based on these data, the matrix fraction (MF) or the polynomial matrix (PM) curve-fitting technique is applied to find a transfer function matrix (TFM) that closely fits into the FRF data. Detailed algorithms for the curve-fitting are introduced in Section 6.2. Frequently, for the purposes of simulation and control, one needs a state-space realization of the system. This may be achieved by various linear system realization algorithms. In particular, the eigensystem realization algorithm (ERA) is presented in Section 6.3 for this purpose, thanks to its many successes in previous application studies. The Markov parameters, based on the parameters from which the state-space model will be derived, can be easily generated from the identified transfer function matrix. Finally, as a measure of performance, the model FRF is computed and is compared to the experimental FRF. This is illustrated in Section 6.4 by means of two experimental application examples.

6.2 Frequency Domain Curve-Fitting

Frequency domain curve-fitting is a technique to fit a TFM closely into the observed FRF data. Like other system identification techniques, this is a two-step procedure: **model structure selection** and **model parameter optimization**. In this context, the first step is to parameterize the TFM in some special forms. Two such forms are introduced in the following: the matrix fraction (MF) parameterization and the polynomial matrix (PM) parameterization. This is always a critical step in the identification because it will generally lead to quite different parameter optimization algorithms and resulting model properties. In particular, this section shows that for the MF form, the parameters can be optimized by means of linear least squares (LLS) solutions. As for the PM parameterization, one has to resort to some nonlinear techniques; specifically, this section introduces the celebrated Gauss-Newton (GN) method. On the other hand, the PM parameterization offers more flexibility in the sense that it allows the designer to specify certain properties of the identified model (e.g., fixed zeros in any input/output channels). This feature may be quite desirable as shown by the application studies in Section 6.4.

Before starting the discussion, it is important to make clear the notations that will be used throughout this section. Assume the test system has r input excitation channels and

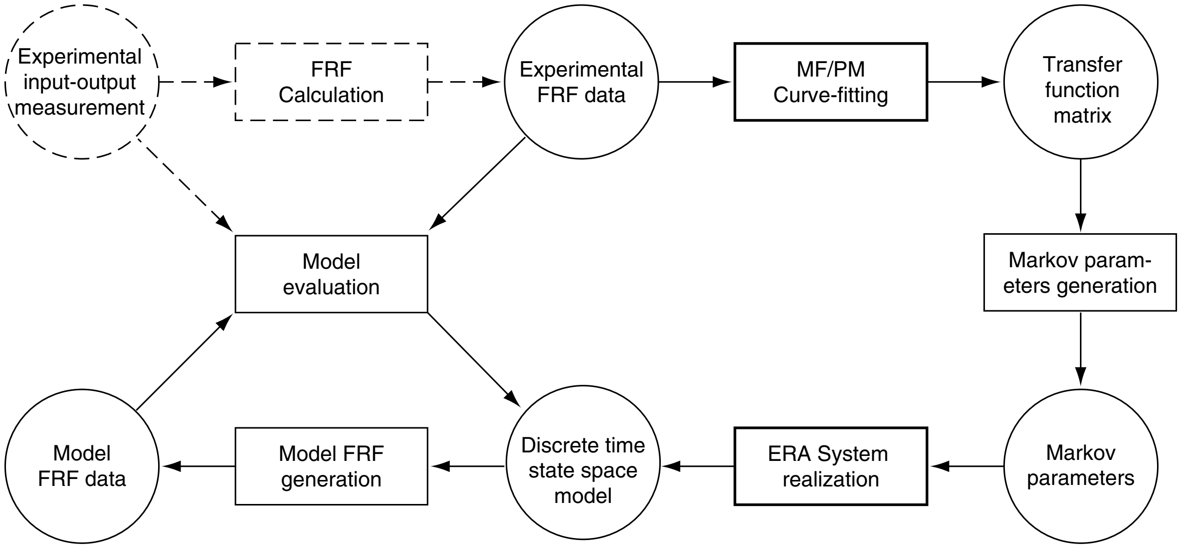

FIGURE 6.1 General Procedure of Frequency Domain System Identification. Bolded components imply critical steps; dashed components imply steps may be excluded.

m output measurement channels. Use $\{\mathcal{G}(\omega_i)\}_{i=1,...l}$ to denote the observed FRF data based on which the TFM $G(z^{-1})$ will be estimated. To evaluate $G(z^{-1})$ at discrete frequencies ω_i, use the map $z(\omega_i) = e^{j2\pi\omega_i/w_s}$, with w_s being the sampling frequency. The curve-fitting error is measured by Frobenius norm $\|\cdot\|_F$ for matrices and by 2-norm $\|\cdot\|_2$ for vectors. Use I_n to denote an identity matrix of dimensions $n \times n$.

6.2.1 Matrix Fraction Parameterization

The **matrix fraction** (MF) **parameterization** of a TFM takes the following form:

$$G(z^{-1}) = Q^{-1}(z^{-1})R(z^{-1}), \tag{6.1}$$

where:

$$Q(z^{-1}) = I_m + Q_1 z^{-1} + Q_2 z^{-2} + \cdots + Q_q z^{-q}, \tag{6.2}$$

$$R(z^{-1}) = R_0 + R_1 z^{-1} + R_2 z^{-2} + \cdots + R_p z^{-p}. \tag{6.3}$$

The constant matrices $Q_1, \ldots, Q_q$ and $R_0, R_1, \ldots, R_p$ are referred to as **observer Markov parameters** in Juang (1994). From the same reference, the reader may find more detailed material for the MF curve-fitting discussed here and the ERA realization algorithm discussed in a later section. To simplify the notation, without loss of generality, assume $p = q$.

To fit the TFM $G(z^{-1})$ as in equation 6.1 into the observed FRF data $\{\mathcal{G}(\omega_i)\}_{i=1,\ldots,l}$, one may solve the following parameter optimization problem:

$$G^*(z^{-1}) = \arg \min_{G=Q^{-1}R} \sum_{i=1}^{l} \|Q(z^{-1}(\omega_i))\mathcal{G}(\omega_i) - R(z^{-1}(\omega_i))\|_F^2. \tag{6.4}$$

Substituting the $Q(z^{-1})$ and $R(z^{-1})$ polynomials in equations 6.2 and 6.3 and vectorizing the summation, equation 6.4 is changed into the form:

$$G^*(z^{-1}) = \arg \min_{G=Q^{-1}R} \|\Phi\Theta + \Psi\|_F, \tag{6.5}$$

where:

$$\Phi = \begin{bmatrix} z^{-1}(\omega_1)\mathcal{G}^T(\omega_1) & \ldots & z^{-p}(\omega_1)\mathcal{G}^T(\omega_1) & -I_r & -z^{-1}(\omega_1)I_r & \ldots & -z^{-p}(\omega_1)I_r \\ \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ z^{-1}(\omega_i)\mathcal{G}^T(\omega_l) & \ldots & z^{-p}(\omega_l)\mathcal{G}^T(\omega_l) & -I_r & -z^{-1}(\omega_l)I_r & \ldots & -z^{-p}(\omega_l)I_r \end{bmatrix}. \tag{6.6}$$

$$\Psi^T = [\mathcal{G}(\omega_1) \cdots \mathcal{G}(\omega_l)]. \tag{6.7}$$

$$\Theta^T = \left[Q_1 \cdots Q_p \, R_0 \, R_1 \cdots R_p\right]. \tag{6.8}$$

Thus, the MF curve-fitting has been reduced to a standard LLS problem, which can be solved by various efficient algorithms (e.g., the QR factorization approach quoted in algorithm of equations 6.29 through 6.31).

6.2.2 Polynomial Matrix Parameterization

The **polynomial matrix** (PM) **parameterization** of a TFM has the form:

$$G(z^{-1}) = \frac{B(z^{-1})}{\alpha(z^{-1})}, \tag{6.9}$$

where:

$$B(z^{-1}) = B_0 + B_1 z^{-1} + B_2 z^{-2} + \cdots + B_p z^{-p}. \tag{6.10}$$

$$\alpha(z^{-1}) = 1 + a_1 z^{-1} + a_2 z^{-2} + \cdots + a_q z^{-q}. \tag{6.11}$$

These equations are the numerator polynomial matrix and the minimal polynomial of the TFM, respectively. Assume that the orders of the numerator and denominator are equal (i.e., $p = q$). The goal of parameter optimization is to find $G^*(z^{-1})$ with a prespecified order p such that the estimation error is minimized:

$$G^*(z^{-1}) = \arg\min_G \sum_{i=1}^{l} w^2(\omega_i) \| \mathcal{G}(\omega_i) - G(z^{-1}(\omega_i)) \|_F^2 \quad (6.12)$$

Here, an additional term $w(\cdot)$ is included to allow desirable frequency weighting on the estimation error. In the following, $G(z^{-1})$ in equation 6.12 will be parametized in a way that allows the inclusion of the fixed zeros. This is done first for the single input/single output (SISO) case; then, it is generalized to the MIMO case.

Let the numerator polynomial of the SISO system be the following:

$$B(z^{-1}) = \bar{B}(z^{-1}) \cdot \tilde{B}(z^{-1}) \quad (6.13)$$

$$= \bar{\psi}^T \bar{b} \cdot \tilde{\psi}^T \tilde{b}, \quad (6.14)$$

where $\bar{b} = [\bar{b}_0, \bar{b}_1, \ldots, \bar{b}_{p_s}]^T$ is the numerator parameter vector corresponding to the fixed zeros; $\tilde{b} = [\tilde{b}_0, \tilde{b}_1, \ldots, \tilde{b}_{p-p_s}]^T$ is the to-be-estimated numerator parameter vector; and $\bar{\psi} = [1, z^{-1}, \ldots, z^{-p_s}]^T$ and $\tilde{\psi} = [1, z^{-1}, \ldots, z^{-(p-p_s)}]^T$ are the corresponding z-vectors. Similarly, the denominator polynomial is as follows:

$$\alpha(z^{-1}) = 1 + \phi^T a, \quad (6.15)$$

where $a = [a_1, \ldots, a_p]^T$ and $\phi = [z^{-1}, \ldots, z^{-p}]^T$. The estimation error to be minimized is then:

$$F = \sum_{i=1}^{l} \left| w(\omega_i) \left(\mathcal{G}(\omega_i) - \frac{\bar{\psi}^T(\omega_i)\bar{b} \cdot \tilde{\psi}^T(\omega_i)\tilde{b}}{1 + \phi^T(\omega_i)a} \right) \right|^2 \quad (6.16)$$

$$= \sum_{i=1}^{l} \left| \frac{w(\omega_i)}{1 + \phi^T(\omega_i)a} \left(\mathcal{G}(\omega_i) - [\bar{\psi}^T(\omega_i)\bar{b} \cdot \tilde{\psi}^T(\omega_i) - \mathcal{G}(\omega_i) \cdot \phi^T(\omega_i)] \begin{bmatrix} \tilde{b} \\ a \end{bmatrix} \right) \right|^2, \quad (6.17)$$

where for simplicity $\bar{\psi}$ and $\tilde{\psi}$ are written as functions of ω_i.

For the MIMO case, equation 6.17 is generalized to (recall that m and r denote the numbers of output and input channels respectively):

$$F = \sum_{j=1}^{m} \sum_{k=1}^{r} \sum_{i=1}^{l} \left| \frac{w(\omega_i)}{1 + \phi^T(\omega_i)a} \left(\mathcal{G}_{jk}(\omega_i) - [\bar{\psi}_{jk}^T(\omega_i)\bar{b}_{jk} \cdot \tilde{\psi}_{jk}^T(\omega_i) - \mathcal{G}_{jk}(\omega_i) \cdot \phi^T(\omega_i)] \begin{bmatrix} \tilde{b}_{jk} \\ a \end{bmatrix} \right) \right|^2. \quad (6.18)$$

Finally, the right-hand side of equation 6.18 is vectorized for standard optimizations:

$$F(\theta) = \| \boldsymbol{W}(a)(\boldsymbol{y} - \boldsymbol{H}\theta) \|_2^2, \quad (6.19)$$

where $\theta = [\tilde{b}_{11}^T, \tilde{b}_{12}^T, \ldots, \tilde{b}_{mr}^T, a^T]^T$, $\boldsymbol{y}$ is a vector containing the measured FRF data, and $\boldsymbol{W}(a)$ is a weighting function with variate a.

Readers should have no difficulties to derive the detailed expressions of $\boldsymbol{W}(a)$ and $\boldsymbol{H}$. For the special case when there is no fixed zeros (i.e., $\bar{\psi}^T \bar{b} = 1$ in equation 6.14), the results are given in Bayard (1992). It is important to point out that $\boldsymbol{W}(a)$ and $\boldsymbol{H}$ have the following structure:

$$\boldsymbol{W}(a) = \begin{bmatrix} W(a) & 0 & \cdots & 0 \\ 0 & W(a) & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & W(a) \end{bmatrix}. \quad (6.20)$$

$$\boldsymbol{H} = \begin{bmatrix} \Psi_{11} & 0 & \cdots & 0 & \Phi_{11} \\ 0 & \Psi_{12} & \ddots & \vdots & \Phi_{12} \\ \vdots & \ddots & \ddots & 0 & \vdots \\ 0 & \ldots & 0 & \Psi_{mr} & \Phi_{mr} \end{bmatrix}. \quad (6.21)$$

These structures enable the design of an efficient optimization algorithm. This will be discussed in the next section.

6.2.3 Least Squares Optimization Algorithms

This section serves two purposes. First, it gives a brief (but general) account on a few of the most important parameter optimization algorithms, namely the **linear least squares** (LLS) method, the Newton's method, and the Gauss-Newton's (GN) method. Second, the discussion applies some of the methods to the parameter optimization problems arising from the curve-fitting process. In particular, this section presents a fast algorithm based on the GN method to the minimization of equation 6.19. Excellent textbooks in this field are abundant, and this discussion only refers the reader to a few of them: Gill *et al.*, (1981), Dennis and Schnabel (1996), and Stewart (1973).

General Algorithm Development

Let $F(\theta)$ be the scalar-valued multivariate objective function to be minimized. If the first and second derivatives of F are available, a local quadratic model of the objective function may be obtained by taking the first three terms of the Taylor-series expansion about a point θ_k in the parameter vector space:

$$F(\theta_k + p) \approx F_k + g_k^T p + \frac{1}{2} p^T G_k p, \tag{6.22}$$

where p denotes a step in the parameter space and where F_k, g_k, and G_k denote the value, gradient, and Hessian of the objective function at θ_k. Equation 6.22 indicates that to find a local minimum of the objective function, an iterative searching procedure is required. The celebrated **Newton's method** is defined by choosing the step $p = p_k$ so that $\theta_k + p_k$ is a stationary point of the quadratic model in 6.22. This amounts to solving the following linear equation:

$$G_k p_k = -g_k. \tag{6.23}$$

In the system identification case, the objective function $F(\theta)$ is often in the **sums of squares** form, as in equation 6.19:

$$F(\theta) = \frac{1}{2}\sum_{i=1}^{n} f_i(\theta)^2 = \frac{1}{2}\|f(\theta)\|_2^2, \tag{6.24}$$

where f_i is the ith component of the vector f. To implement the Newton's method, the gradient and Hessian of F are calculated as:

$$g(\theta) = J(\theta)^T f(\theta) \tag{6.25}$$

$$G(\theta) = J(\theta)^T J(\theta) + Q(\theta), \tag{6.26}$$

where $J(\theta)$ is the Jacobian matrix of f and where $Q(\theta) = \sum_{i=1}^{n} f_i(\theta) G_i(\theta)$, with $G_i(\theta)$ being the Hessian of $f_i(\theta)$. The Newton's equation 6.23 thus becomes as follows:

$$(J(\theta_k))^T J(\theta_k) + Q(\theta_k))p_k = -J(\theta_k)^T f(\theta_k). \tag{6.27}$$

When $\|f(\theta_k)\|$ is small, $\|Q(\theta_k)\|$ is usually small and is often omitted from equation 6.27. If this is the case, then solving p_k from 6.27 is equivalent to solving the following linear least squares (LLS) problem:

$$p_k = \arg\min_p \frac{1}{2}\|J(\theta_k)p + f(\theta_k)\|_2^2. \tag{6.28}$$

Equation 6.28 gives the **Gauss-Newton method**. The LLS problem is often solved by the QR factorization method given in the following algorithm.

Algorithm 1 (QR Factorization and LLS Solution)

Let $A \in R^{m\times n}$ have full column rank. Then A can be uniquely factorized into the form:

$$A = QR, \tag{6.29}$$

where Q has orthonormal columns and where R is upper triangular with positive diagonal elements. The unique solution of the LLS problem:

$$\min_{x\in R^n} \|Ax - y\|_2^2, \tag{6.30}$$

is given by:

$$x^* = R^{-1}Q^T y. \tag{6.31}$$

Application to the Curve-Fitting Problems

This discussion now returns to the PM curve-fitting problem in equation 6.19. By letting $f = \boldsymbol{W}(a)(\boldsymbol{y} - \boldsymbol{H}\theta)$, the Gauss-Newton method in equation 6.28 may be applied. It turns

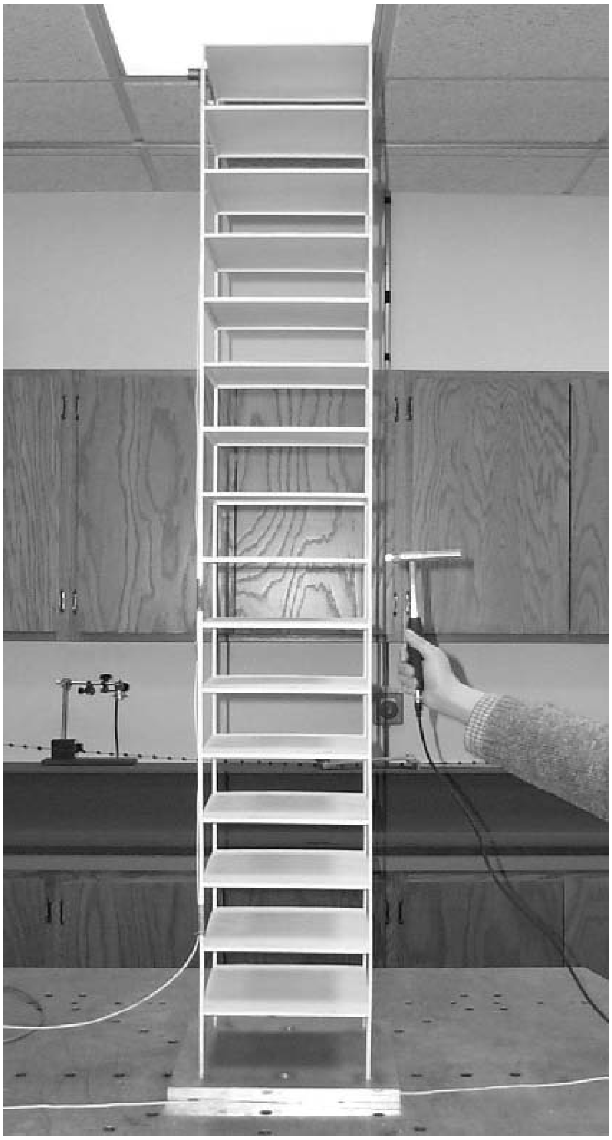

FIGURE 6.2 Picture of the 16-Story Structure

TABLE 6.1 Key Identification Parameters

	Curve-fitting			System realization		
Test structure	Type	p	q	α	β	n
16-Story	MF	16	16	32	32	10
Benchmark	PM	8	8	12	30	8

out that the Jacobian matrix $J(\theta_k)$ of f has an identical structure as H in equation 6.21. Thus, instead of solving equation 6.28 directly, the following decomposition of LLS problems may be applied.

Algorithm 2 (Decomposition of LLS Problem)

Let $A \in R^{m\times n}$ have full column rank. Decompose A into $A = [A_1, A_2]$, with $A_1 \in R^{m\times p}$ and $A_2 \in R^{m\times q}$. Let the unique QR factorization of A_1 be $A_1 = Q_1R_1$. Then the unique solution x^* of the LLS problem of equation 6.30 has the form $x^* = [x_1^{*T}, x_2^{*T}]^T$, with x_2^* and x_1^* being the unique solutions of the following LLS problems:

$$\min_{x_2\in R^q} \quad \|\tilde{A}_2x_2 - y\|_2^2. \qquad (6.32)$$

$$\min_{x_1\in R^p} \quad \|A_1x_1 - (y - A_2x_2^*)\|_2^2. \qquad (6.33)$$

In these equations, $\tilde{A}_2 = (I - Q_1Q_1^T)A_2$.

In practice, $J(\theta_k)$ is divided into $J(\theta_k) = [J_1(\theta_k), J_2(\theta_k)]$, with $J_1(\theta_k)$ corresponding to the block-diagonal terms and $J_2(\theta_k)$ the last block matrix column in $J(\theta_k)$. Solving the LLS problems with $J_2(\theta_k)$ and $J_1(\theta_k)$ thus corresponds to updating the denominator a and the numerators b_{jk} estimations. Moreover, due to its block-diagonal structure, the LLS problem with $J_1(\theta_k)$ should be further decomposed (i.e., the LLS solutions of b_{jk} are independently solved for each j and k). Thus, the computational cost of the optimization algorithm is significantly reduced.

To complete the discussion of the algorithm, note that the initial values for the Gauss-Newton iteration may be generated by the classical Sanathanan-Koerner (SK) iteration composed of a sequence of reweighted LLS problems:

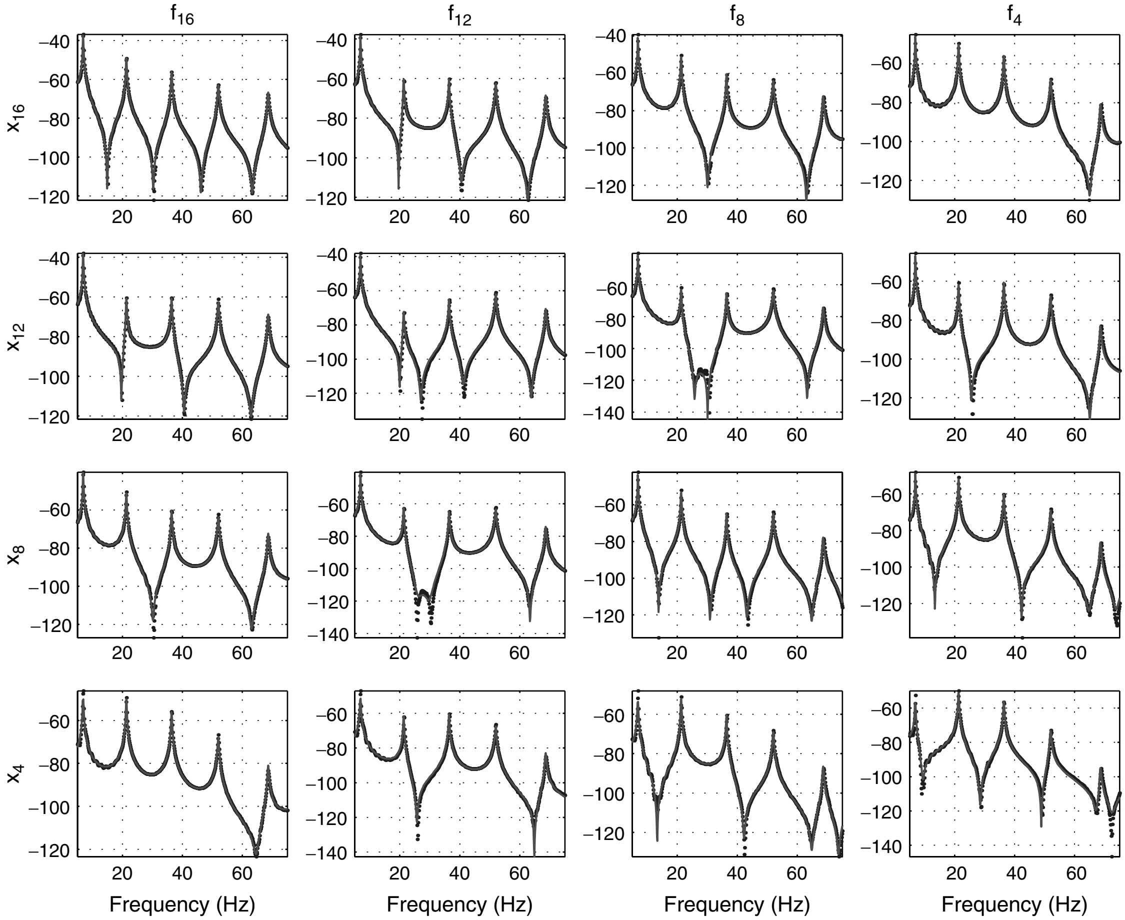

FIGURE 6.3 Comparison of Experimental and Model FRF for the 16-Story Structure: Magnitude Plot. f_j denotes the input force on the jth floor; x_j denotes the output displacement of the jth floor; dotted lines are for measurement data; solid lines are for model output.

$$\theta_{k+1} = \arg \min_{\theta} \| \boldsymbol{W}(a_k)(\boldsymbol{y} - \boldsymbol{H}\theta)\|_2^2, \qquad (6.34)$$

with initial condition $\theta_0 = 0$.

6.3 State-Space System Realization

System realization is a technique to determine an internal state-space description for a system given with an external description, typically its TFM or impulse response. The name reflects the fact that if a state-space description is available, an electronic circuit can be built in a straightforward manner to realize the system response. There is a great amount of literature on this subject both from a system theoretical point of view (Antsaklis and Michel, 1997) and from a practical system identification point of view (Juang, 1994). In the following, a well-developed method in the second category, the eigensystem realization algorithm (ERA), is selected to construct a model in the state space form. First presented are the formulas to generate the Markov parameters from the TFM, which are the starting point for the ERA method.

6.3.1 Markov Parameters Generation

To calculate the **Markov parameters** $Y_0, Y_1, Y_2, \ldots$ from the system TFM, first note that:

$$G(z^{-1}) = \sum_{i=0}^{\infty} Y_i z^{-i}. \qquad (6.35)$$

For the case when $G(z^{-1})$ is parameterized in the MF form (i.e., $G(z^{-1}) = Q^{-1}(z^{-1})R(z^{-1})$), the system Markov parameters can be determined from:

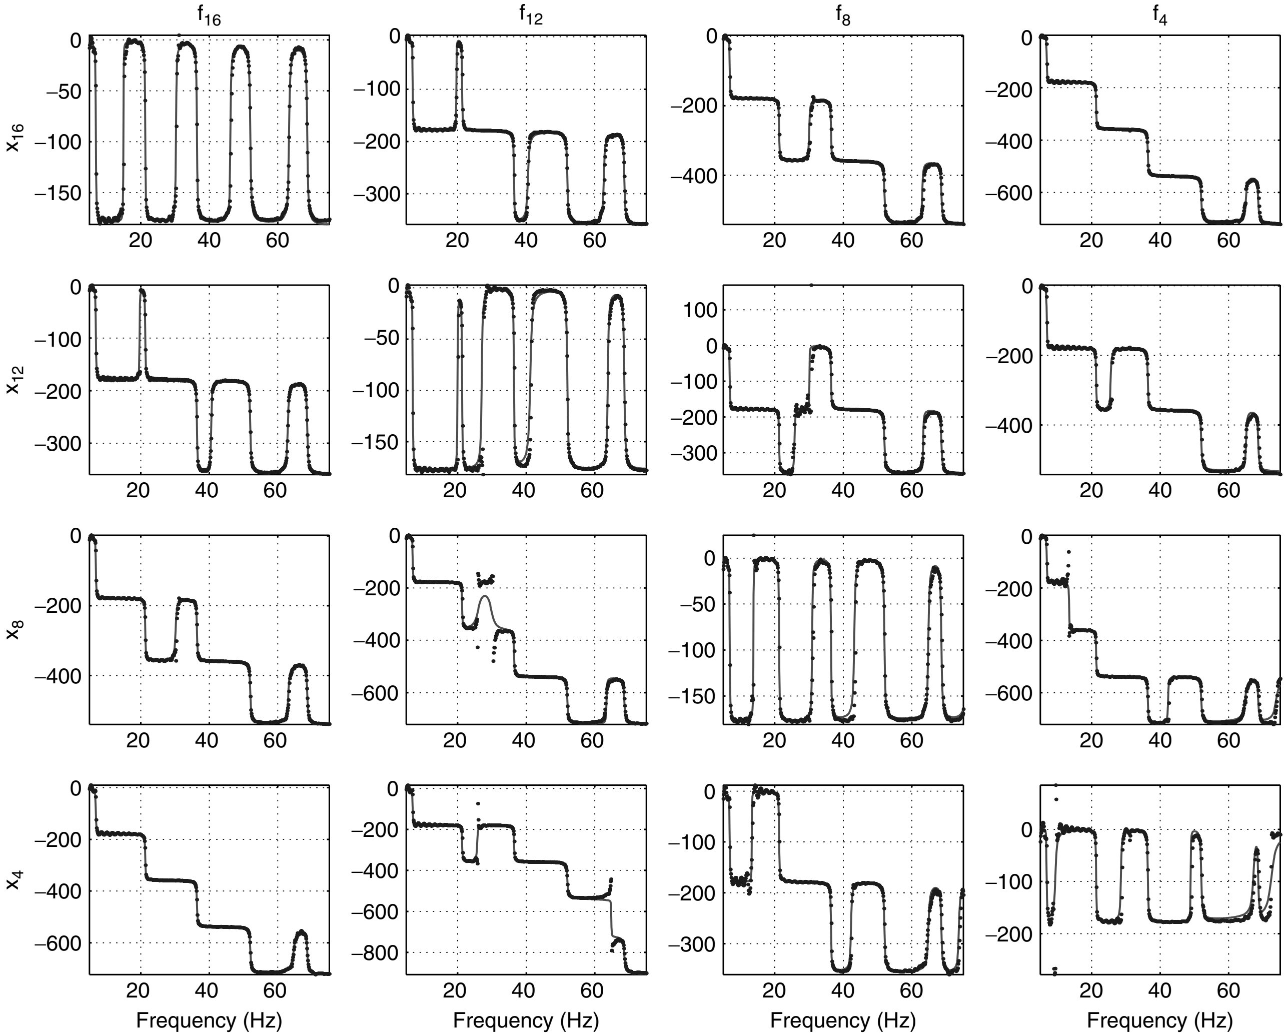

FIGURE 6.4 Comparison of Experimental and Model FRF for the 16-Story Structure: Phase Plot. Same notations are used as in Figure 6.3.

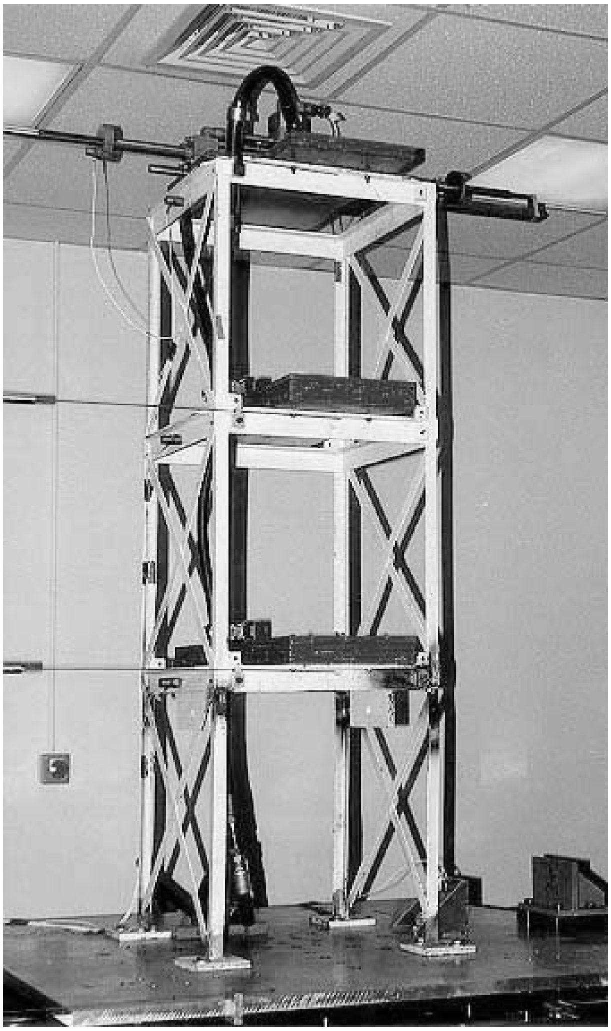

FIGURE 6.5 Picture of the Seismic-AMD Benchmark Structure

$$\left(\sum_{i=0}^{p} Q_i z^{-i}\right)\left(\sum_{i=0}^{\infty} Y_i z^{-i}\right) = \sum_{i=0}^{p} R_i z^{-i}, \tag{6.36}$$

by the following iterative calculations starting from $Y_0 = R_0$:

$$Y_k = \begin{cases} R_k - \sum_{i=1}^{k} Q_i Y_{k-i}, & \text{for } k = 1, \ldots, p. \\ -\sum_{i=1}^{p} Q_i Y_{k-i}, & \text{for } k = p+1, \ldots, \infty. \end{cases} \tag{6.37}$$

If the TFM is parameterized in the PM form, the derivation of the system Markov parameters is almost the same: one starts with $Y_0 = B_0$, and continues with the following iterative procedure:

$$Y_k = \begin{cases} B_k - \sum_{i=1}^{k} a_i Y_{k-i}, & \text{for } k = 1, \ldots, p. \\ -\sum_{i=1}^{p} a_i Y_{k-i}, & \text{for } k = p+1, \ldots, \infty. \end{cases} \tag{6.38}$$

TABLE 6.2 PM Iteration Record

Iteration type	Iteration index	FRF residue	α Step norm	β Step norm
	1	651.47	100%	100%
S	2	159.46	1.91%	14.8%
K	3	156.75	0.16%	1.36%
	4	156.74	0.24%	0.84%
	1	137.03	10.9%	21.8%
	2	133.47	4.23%	8.31%
G	3	128.03	0.56%	2.15%
N	4	123.81	0.21%	0.50%
	5	123.34	0.40%	1.07%
	6	123.48	0.15%	0.37%

6.3.2 The ERA Method

To solve for a state-space model (A, B, C, D) using the **ERA method**, first form the generalized Hankel matrices:

$$H(k-1) = \begin{bmatrix} Y_k & Y_{k+1} & \ldots & Y_{k+\beta-1} \\ Y_{k+1} & Y_{k+2} & \ldots & Y_{k+\beta} \\ \vdots & \vdots & \ddots & \vdots \\ Y_{k+\alpha-1} & Y_{k+\alpha} & \ldots & Y_{k+\alpha+\beta-2} \end{bmatrix}. \tag{6.39}$$

Note that in general, α and β are chosen to be the smallest numbers such that $H(k)$ has as large row and column ranks are possible. Additional suggestions to determine their optimal values are given in Juang (1994). Let the singular value decomposition of $H(0)$ be $H(0) = U\Sigma V^T$, and let n denote the index where the singular values have the largest drop in magnitude. Then, $H(0)$ can be approximated by:

$$H(0) \approx U_n \Sigma_n V_n^T, \tag{6.40}$$

where U_n and V_n are the first n columns of U and V, respectively, and Σ_n is the diagonal matrix containing the largest n singular values of $H(0)$. Finally, an nth order state-space realization (A, B, C, D) can be calculated by:

$$\begin{aligned} &A = \Sigma_n^{-1/2} U_n^T H(1) V_n \Sigma_n^{-1/2}, \quad B = \Sigma_n^{1/2} V_n^T E_r, \\ &C = E_m^T U_n \Sigma_n^{1/2}, \quad D = Y_0, \end{aligned} \tag{6.41}$$

where E_r and E_m^T are the elementary matrices that pick out the first r (the number of system inputs) columns and first m (the number of system outputs) rows of their multiplicands, respectively.

6.4 Application Studies

This section presents two experimental level application studies conducted in the Structural Dynamics and Control/

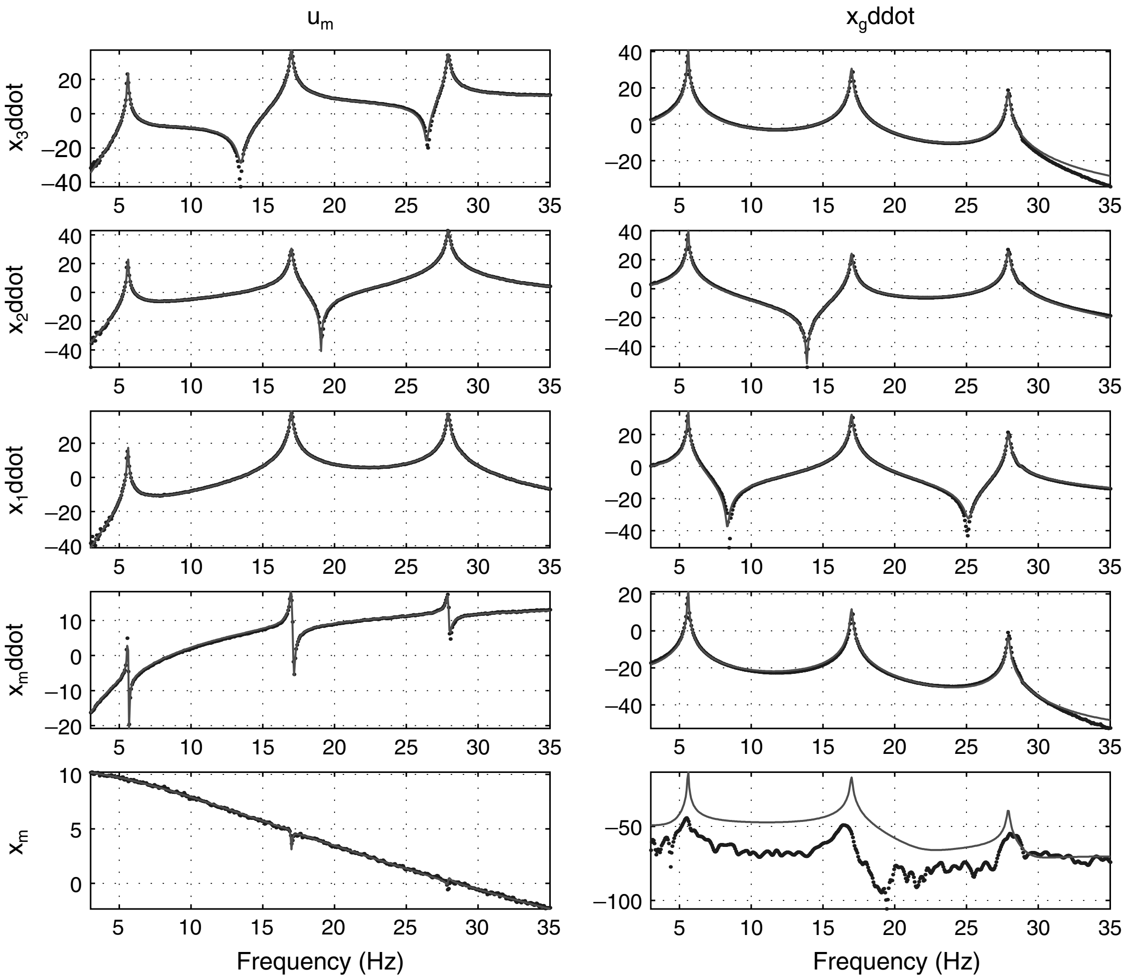

FIGURE 6.6 Comparison of Experimental and Model FRF for the Seismic-AMD Benchmark Structure: Magnitude Plot. u_m denotes the input command to the AMD; $x_g ddot$ denotes the input ground acceleration to the structure; $x_j ddot$ denotes the output acceleration of the *j*th floor; $x_m ddot$ denotes the output acceleration of the AMD; x_m denotes the output displacement of the AMD; dotted lines are for measurement data; solid lines are for model output.

Earthquake Engineering Laboratory (SDC/EEL) at University of Notre Dame. This section only presents the results pertinent to identification studies discussed so far in this chapter. For detailed information about these experiments, including experimental setups and/or control developments, the reader may refer to Jin *et al.* (2000), Jin (2002), and Dyke *et al.* (1994), respectively.

6.4.1 Identification of a 16-Story Structure

The first identification target is a 16-story steel structure model shown in Figure 6.2. The system is excited by impulse force produced by a PCB hammer and applied individually at the 16th, 12th, 8th, and 4th floors. The accelerations of these floors are selected as the system measurement outputs and are sensed by PCB accelerometers. The goal of the identification is to capture accurately the first five pairs of the complex poles of the structure. For this purpose, a DSPT Siglab spectrum analyzer is used to measure the FRF data. The sampling rate is set at 256 Hz, and the frequency resolution is set at 0.125 Hz. The experimental FRF is preconditioned to eliminate the second order direct current (dc) zeros from acceleration measurement. The MF parameterization is chosen for the curve-fitting, which is complemented by the ERA method for state-space realization. The key identification parameters are given in Table 6.1. The final discrete-time state-space realization has 10 states. The magnitude and phase plots of its transfer functions are compared to the experimental FRF data in Figures 6.3 and 6.4. Excellent agreements are found in all but the very high frequency range. The mismatch there is primarily due to the unmodeled high-frequency dynamics.

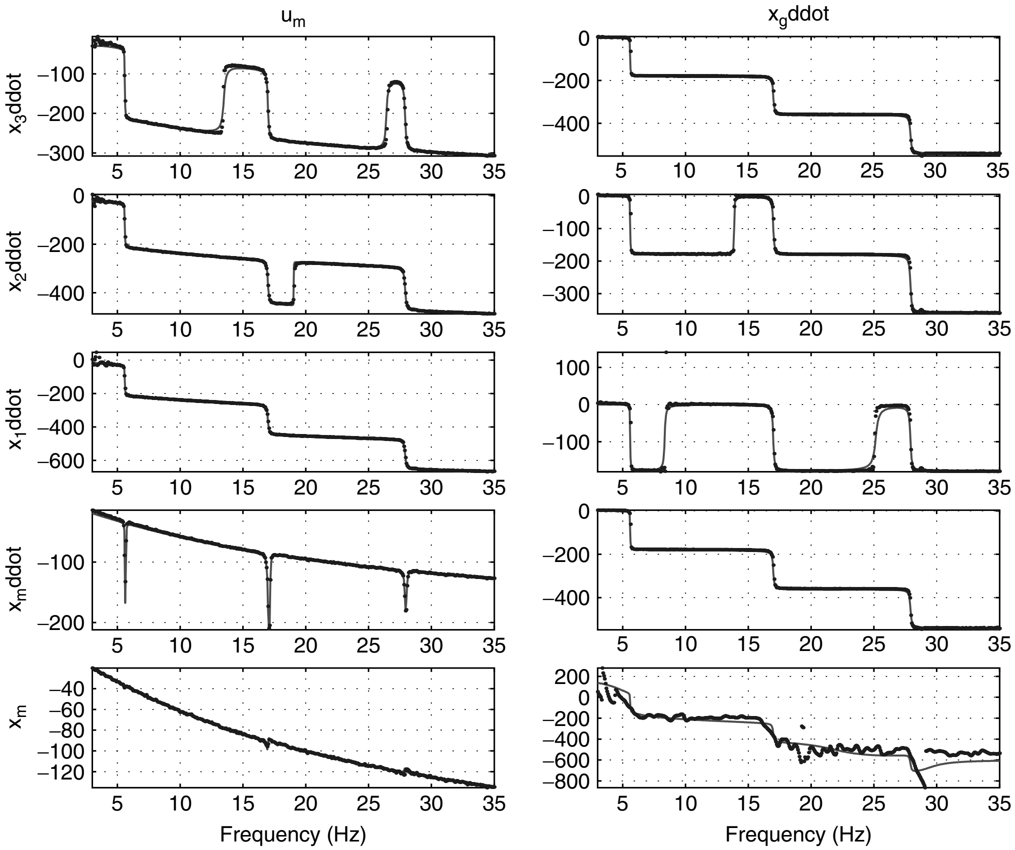

FIGURE 6.7 Comparison of Experimental and Model FRF for the Seismic-AMD Benchmark Structure: Phase Plot. Same notations are used as in Figure 6.6.

6.4.2 Identification of the Seismic-Active Mass Driver Benchmark Structure

The second identification target of this discussion is a three-story steel structure model, with an active mass driver (AMD) installed on the third floor to reduce the vibration of the structure due to simulated earthquakes. A picture of the system is given in Figure 6.5. This system has been used recently as the ASCE first-generation seismic-AMD benchmark study. The benchmark structure has two input excitations: the voltage command sent to the AMD by the control computer and the ground acceleration generated by a seismic shaker. The system responses are measured by four accelerometers for the three floors and the AMD and one linear variable differential transformer (LVDT) for the displacement of the AMD. The sampling rate is 256 Hz, and the frequency resolution is 0.0625 Hz. Due to noise and nonlinearity, only the frequency range of 3 to 35 Hz of the FRF data is considered to be accurate and, thus, this range is used for the identification.

A preliminary curve-fitting is carried out using the MF parameterization. The identified model matches the experimental data accurately in all but the low-frequency range of channels corresponding to the AMD command input and the acceleration outputs. A detailed analytical modeling of the system reveals that there are four (respectively two) fixed dc zeros from AMD command input to the structure (respectively AMD) acceleration outputs:

$$\lim_{s\to 0}\frac{G_{\ddot{x}_i u_m}(s)}{s^4} = k_i, \quad i = 1, 2, 3. \tag{6.42}$$

$$\lim_{s\to 0}\frac{G_{\ddot{x}_m u_m}(s)}{s^2} = k_m. \tag{6.43}$$

The $G_{\ddot{x}_i u_m}$ and $G_{\ddot{x}_m u_m}$ are the transfer functions from AMD command input u_m to structure and AMD acceleration outputs, respectively. The k_i and k_m are the static gains of these transfer functions with the fixed dc zeroes removed. These fixed zeros dictate the use of the PM curve-fitting technique to explicitly include such a priori information.

Again, key identification parameters are presented in Table 6.1. The outputs of the parameter optimization iterations are documented in Table 6.2. The final discrete-time state-space realization has eight states as predicted by the analytical modeling. The magnitude and phase plots of its transfer functions are compared to the experimental FRF data in Figures 6.6 and 6.7. All the input output channels are identified accurately except for the (5,2) element, which corresponds to the ground acceleration input and the displacement output of the AMD. The poor fitting there is caused by the extremely low signal-to-noise ratio.

6.5 Conclusion

This chapter discusses the identification of linear dynamic systems using frequency domain measurement data. After outlining a general modeling procedure, the two major computation steps, frequency domain curve-fitting and state-space system realization, are illustration with detailed numerical routines. The algorithms employ TFM models in the form of matrix fraction or polynomial matrix and require respectively linear or nonlinear parameter optimizations. Finally, the proposed identification schemes are validated through the modeling of two experimental test structures.

Modeling Interconnected Systems: A Functional Perspective

Stanley R. Liberty
Academic Affairs, Bradley University, Peoria, Illinois, USA

7.1 Introduction

This chapter, adapted from Liberty and Saeks (1973, 1974), contains a particular viewpoint on the mathematical modeling of systems that focuses on an explicit algebraic description of system connection information. The resulting system representation is called the **component connection model**. The component connection approach to system modeling provides useful ways to tackle a variety of system problems and has significant conceptual value. The general applicability of this viewpoint to some of these system problems is presented here at a conceptual level. Readers interested in specific examples illustrating the component connection model should first refer to Decarlo and Saeks (1981). Additional references are provided on specific applications of the component connection philosophy to system problems. Readers with a clear understanding of the general concept of function should have no difficulty comprehending the material in this section.

7.2 The Component Connection Model

A system, in simplistic mathematical terms, is a mapping from a set of inputs (signals) to a set of outputs (signals) (i.e., an input/output relation with a unique output corresponding to each input). (In using this external system description, the context of an internal system state has been deliberately suppressed for simplicity of presentation in this chapter.) This may be abstractly notated by:

$$y = Su, \tag{7.1}$$

where S is the symbol for the input/output relation (the system). On the other hand, one may think of the physical system symbolized by S as an interconnection of components. Engineering experience explains that a particular S is determined by two factors: the types of components in the system and the way in which the components are interconnected. This latter observation on the physical structure of a system gives rise to the **component connection viewpoint**.

Again, thinking of a physical system, the system's connection structure can be held fixed while the types of system components or their values change. Experience explains that for each distinct set of components or component values, a unique input/output relation is determined. From a mathematical perspective, a given connection description determines a mapping of the internal component parameters to the input/output relation.

Now, one can generalize this slightly by thinking of the physical system as an interconnection of subsystems, each with its own input/output relation. Note that a subsystem may be either a discrete component, an interconnection of components, or an interconnection of "smaller" subsystems. This hierarchical structure is germane to the component connection philosophy and is precisely the fundamental concept of large-scale system theory.

Thinking in this way, one notes that a given connection description determines a system-valued function of a system-valued variable. Because this function is entirely determined by the connections, it is called the connection function:

$$S = f(Z), \tag{7.2}$$

where Z symbolizes the internal subsystem descriptions or component parameters and where f symbolizes the connection function. In the special case where the subsystems represented by Z are linear and time-invariant, Z may be interpreted as a matrix of component transfer functions, gains, or immitances (the precise physical interpretation is unimportant), which is also the case for S. One should not, however, restrict the thinking process to linear time-invariant systems. In addition, it is important to point out that, even when all of the subsystems are linear, the connection function f is nonlinear.

What may be surprising is that for most commonly encountered systems, the nonlinear function f can be completely described by four matrices that permit the connection function to be manipulated quite readily. Indeed, feasible analytical and computational techniques based on this point of view have been developed and applied to problems in system analysis (Singh and Trauboth, 1973; Prasad and Reiss, 1970; Trauboth and Prasad, 1970), sensitivity studies (Ransom, 1973, 1972; Ransom and Saeks, 1975; DeCarlo, 1983), synthesis (Ransom, 1973), stability analysis (Lu and Liu, 1972), optimization (Richardson, 1969; Richardson *et al.*, 1969), well-posedness (Ransom, 1972; Singh, 1972), and fault analysis (Ransom, 1973, 1972; Saeks, 1970; Saeks *et al.*, 1972; Ransom and Saeks, 1973a, 1973b; DeCarlo and Rapisarda, 1988; Reisig and DeCarlo, 1987; Rapisarda and DeCarlo, 1983; Garzia, 1971). The reason for this core of linearity in the f description is that connection information is generally contained in "conservation" laws that, upon the proper choice of system variables, yield linear "connection" equations.

To obtain an intuitive feel for what types of manipulations one performs on f to solve the systems problems previously mentioned, consider, for example, a classical passive network synthesis problem. In this problem, one is given the input/output relation S, and one knows what type of network structure is desired. For example, a ladder synthesis problem statement consists of a transfer function specification and the "connection information" of ladder structure. The S and f are specified, and it is desired to determine Z (the components). Clearly, to find Z, one must invert f. In this case, one seeks a right inverse of f because the uniqueness of Z is not a concern and f is viewed as "onto" the class of transfer functions of interest.

If, on the other hand, one is attempting to identify the value of a component in an interconnected system of components given external measurements and knowledge of the connections, then one seeks a left inverse of f. Here, the concern may be with uniqueness, and f is viewed as one-to-one and into the set of input/output relations.

Another classical system problem encountered in design analysis is that of determining the sensitivity of the input/output relation S to variations in certain component values. In this case, differentiation of the connection function f with respect to the component parameters of interest is the major constituent of the sensitivity analysis. Specific applications of the component connection model to sensitivity analysis are contained in Ransom (1973, 1972), Ransom and Saeks (1975), and DeCarlo (1983).

The conceptual description just described should provide the reader with a "feel" for the component connection philosophy. This chapter now provides more detailed insight.

7.2.1 Detailed Insight to Component Connection Philosophy

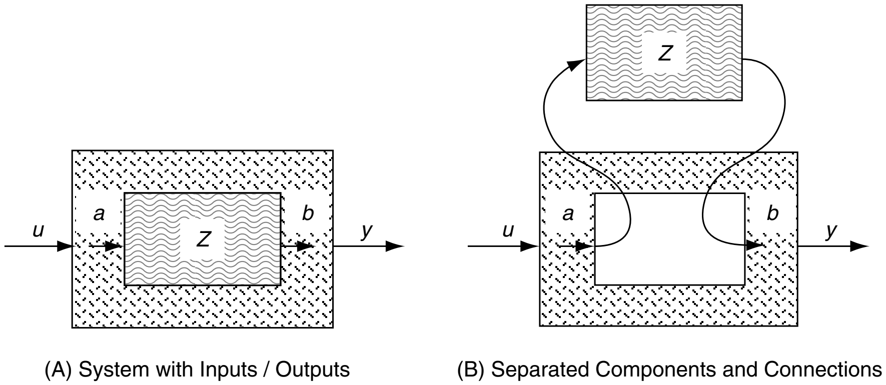
Although an abstract functional interpretation of the connections in a system is conceptually valid, it is of no practical value unless one has a specific and computationally viable representation of the function. Fortunately, there is such a representation, and the conceptual problem of inverting or differentiating the connection function may actually be carried out.

Classically, in circuit and system theory, connections are represented by some type of graph (e.g., linear graph, bond graph, signal flow graph) or block diagram. This graphical depiction of connection information can readily be converted into a set of linear algebraic constraints on the circuit or system variables for subsequent analysis. As such, it is natural to adopt an algebraic model of the connections from the start.

The precise form of the component connection model with its algebraic description of a system's connection information may be seen by examining Figure 7.1. Figure 7.1(A) shows a box depiction of a system with inputs u and outputs y. The inner box labeled Z represents the system components, and the outer donut shaped area represents the system connections (e.g., scalers, adders, Kirchhoff law constraints, etc.). Now, if Z represents a matrix of component input/output relations, the following may be abstractly written:

$$b = Za, \tag{7.3}$$

where b denotes the vector of component output variables and a the vector of component input variables. The component connection model can be obtained by redrawing the system of Figure 7.1(A) as in Figure 7.1(B), where the components and connections have been separated. Thus, the overall system is composed of two interconnected boxes. One box contains the components as described by equation 7.3, and the second donut-shaped box contains the connections. The donut-shaped box has inputs u and b and outputs a and y. Finally,



u
a
Z
b
y
(A) System with Inputs / Outputs
Z
u
a
b
y
(B) Separated Components and Connections

FIGURE 7.1 A System as an Interconnection of Components

since the connections are characterized entirely by linear algebraic constraints, the donut-shaped box may be mathematically modeled (i.e., the connections) by the matrix equation:

$$\begin{bmatrix} a \\ y \end{bmatrix} = \begin{bmatrix} L_{11} & L_{12} \\ L_{21} & L_{22} \end{bmatrix} \begin{bmatrix} b \\ u \end{bmatrix}. \tag{7.4}$$

The component connection model is thus a pair of equations, 7.3 and 7.4, with the matrix Z representing the components, and the set of four L matrices representing the connections.

An interesting observation can be made here. In the very special case where each component is an integrator, the following is true:

$$\dot{b} = a. \tag{7.5}$$

Substituting equation 7.5 into 7.4 yields:

$$\begin{aligned} \dot{b} &= L_{11}b + L_{12}u. \\ y &= L_{21}b + L_{22}u. \end{aligned} \tag{7.6}$$

The reader will recognize these equations as the familiar “state model” of linear dynamical system theory. Thus, intuitively, the component connection model may be viewed as a generalization of the linear state model. In fact, the L matrices describe how to interconnect subsystems to form a large-scale system S, just as integrators used to be patched together on an analog computer to simulate a system. If one views the L matrices as a generalization of the state model, where the integrators have been replaced by general components, a beneficial cross fertilization between component connection theory and classical system theory results. It is possible and indeed useful to talk about controllable or observable connections (Singh, 1972).

The component connection model was first used intuitively by Prasad and Trauboth (Singh and Trauboth, 1973; Prasad and Reiss, 1970; Trauboth and Prasad, 1970) and formalized by Saeks (Saeks, 1970; Saeks *et al*., 1972) for application in the fault isolation problem. Existence conditions for the L matrices were first studied by Prasad (Prasad and Reiss, 1970) and later by Singh (1972) who have shown that the existence of L matrices is a reasonable assumption. This is essentially the same type of assumption that one makes when assuming that the state equations of a system exist. As seen above, if the components in the system are integrators, then the L matrices are precisely the state matrices.

The advantage of the component connection model over the classical graphical and diagrammatic connection models is that, being inherently algebraic, the component connection model is readily manipulated and amenable to numerical techniques. Moreover, this model unifies the various graphical and diagrammatic models. In fact, electronic circuits, which are commonly described by hybrid block diagram-linear graph models, are handled as readily as passive circuits or analog computer diagrams [see DeCarlo and Saeks (1981) for some simple examples].

Using the component connection model, the desired representation for the connection function is obtained. This is illustrated by a linear example since the concept can be more intuitively understood in the linear case. It is important to point out again, however, that more generality is actually present. Viewing Z as a matrix of transfer functions, the overall system transfer function is desired. Simultaneous solution of equations 7.1, 7.3, and 7.4 yields:

$$S = L_{22} + L_{21}(1 - ZL_{11})^{-1}ZL_{12} = f(Z), \tag{7.7}$$

and we have a representation of the connection function in terms of the four L matrices even though the connection function is nonlinear in Z. This matrix representation facilitates manipulation of the connection function as shown later (Ransom, 1973, 1972; Saeks, 1970; Ransom and Saeks, 1973b, 1973a). The first observation that the connection function could be so represented was made by Saeks (1970), while the first exploitation of the concept is attributable to Ransom (1973, 1972) and Saeks (1973b, 1973a).

7.3 System Identification

In a **system identification problem**, one is normally asked to identify the mathematical input/output relation S from input/output data. In theory, this is straightforward if the system is truly linear (Chang, 1973), but in practice this may be difficult due to noisy data and finite precision arithmetic. The nonlinear case is difficult in general because series approximations must be made that may not converge rapidly enough for large signal modeling (Bello *et al.*, 1973). In both linear and nonlinear identification techniques, random inputs are commonly used as probes (Bello *et al.*, 1973; Cooper and McGillem, 1971; Lee and Schetzen, 1961). The identification of S is then carried out by mathematical operations on the system input and output autocorrelations and the cross-autocorrelations between input and output.

This section does not contain a discussion of such techniques, but some observations are presented. It should be noted that if only input/output information is assumed known (as is the case in standard identification techniques), then system identification does not supply any information on the system structure or the types or values of components. In such cases, the component connection model cannot be used. In many applications, however, connection information and component type information are available. In such cases, the component connection model may be applicable. Indeed, for identification schemes using random inputs, it is easily shown that the component correlation functions and the overall system correlation functions are related by:

$$R_{yy} = L_{21}R_{bb}L_{21}^T + R_{yu}L_{22}^T + L_{22}R_{uy} - L_{22}R_{uu}L_{22}^T. \tag{7.8}$$

$$R_{aa} = L_{11}R_{bb}L_{11}^T + L_{11}R_{bu}L_{12}^T + L_{12}R_{ub}L_{11}^T + L_{12}R_{uu}L_{12}^T. \tag{7.9}$$

$$L_{21}R_{bu} = [R_{yu} - L_{22}R_{uu}]. \tag{7.10}$$

$$R_{ab} = L_{11}R_{bb} + L_{12}R_{ub}. \tag{7.11}$$

The R_{jk} is the crosscorrelation of signal j and signal k. If the left inverse of L_{21} exists, then the subsystem correlation functions can be determined and used to identify the subsystems via standard identification techniques. However, in general, this left inverse does not exist and either the type information or the psuedo-inverse of L_{21} must be used to yield subsystem models.

7.4 Simulation

There are numerical challenges in computer simulation of large-scale systems. These difficulties are due to the simultaneous solution of large numbers of differential equations. The efficiency in solving a single differential equation is entirely determined by the numerical techniques employed. However, in analyzing a large-scale system from the component connection viewpoint, the starting point is a specified collection of decoupled component differential equations and a set of coupled algebraic connection equations. Thus, it is possible to take advantage of the special form of the equations characterizing a large-scale dynamical system and to formulate analysis procedures that are more efficient than those which might result from a purely numerical study of the coupled differential equation characterizing the entire system.

Such a procedure, namely a **relaxation scheme**, wherein one integrates each of the component differential equations by separately iterating through the connection equations to obtain the solution of the overall system, was implemented over 30 years ago at the Marshall Space Flight Center (Prasad and Reiss, 1970; Trauboth and Prasad, 1970; Saeks, 1969). The feasibility of the scheme was verified, and significant computer memory savings resulted. The key to this approach of the numerical analysis of a large-scale system is that numerical routines are applied to the decoupled composite component differential equations rather than an overall equation for the entire system. Thus, the complexity of the numerical computations is determined by the complexity of the largest component in the system. In contrast, if the numerical procedures are applied directly to a set of differential equations characterizing the entire system, the complexity of the numerical computations is determined by the complexity of the entire system (the sum of the complexities of all the components).

Since 1970, computer simulation software has evolved substantially, and packages that deal with large-scale systems either explicitly or implicitly exploit the component connection philosophy. One of the more recent software developments for modeling and simulation of large-scale heterogeneous systems is an object-oriented language called Modelica; see Mattson *et al.* (1998) for additional information.

7.5 Fault Analysis

Fault analysis is similar to system identification in that the system is reidentified to determine if the component input/output relations have changed. It should be clear that connection information is essential to detection of a faulty component. As before, note that fault analysis is not restricted to linear systems. To illustrate some of the technique, the discussion will focus on a linear time-invariant situation.

To attack the fault analysis problem, assume that there is a given set of external system parameters measured at a finite set of frequencies $S(\omega_i)$, $i = 1, 2, \ldots, n$ and that there are the connection matrices, L_{11}, L_{12}, L_{21}, and L_{22}. Compute or approximate $Z(\omega)$. For simplicity of presentation, assume that $L_{22} = 0$. There is no loss of generality with this assumption since one can always replace $S(\omega_i)$ by $\tilde{S}(\omega_i) = S(\omega_i) - L_{22}$ and then work with the system whose measured external parameters are given by $\tilde{S}$ and whose connection matrices are $\tilde{L}_{11} = L_{11}$, $\tilde{L}_{12} = L_{12}$, $\tilde{L}_{21} = L_{21}$, and $\tilde{L}_{22} = 0$.

In the most elementary form of the fault analysis problem, assume that $S(\omega)$ is given at only a single frequency and compute $Z(\omega)$ exactly. This form of the problem was first studied by Saeks (1970) and then extended by Saeks and colleagues (Ransom and Saeks, 1975; Saeks *et al.*, 1972). Its solution is based on the observation that the connection function f can be decomposed into two functions (under the assumption that $L_{22} = 0$) as:

$$f = hog. \tag{7.12}$$

Here, g is a nonlinear function that maps the component parameter matrix Z into an intermediary matrix R via:

$$R = g(Z) = (1 - ZL_{11})^{-1}Z, \tag{7.13}$$

and h is a linear function that maps R into the external parameter matrix S via:

$$S = h(R) = L_{21}RL_{12}. \tag{7.14}$$

The left inverse of f is given in terms of g and h via:

$$f^{-L} = g^{-L}oh^{-L}. \tag{7.15}$$

A little algebra will reveal that g^{-L} always exists and is given by the formula:

$$Z = g^{-L}(R) = (1 + RL_{11})^{-L}R. \tag{7.16}$$

Thus, the fault isolation problem is reduced to that of finding the left inverse of the linear function h. This is most easily done by working with the matrix representation of h as:

$$\underline{h} = [L_{12}^{T} \otimes L_{21}], \tag{7.17}$$

where $\otimes$ is the matrix tensor (Kronecker) product (Ransom, 1972; Saeks *et al.*, 1972; Rao and Mitra, 1971). Standard matrix algebraic techniques can be used to compute h^{-L}. Indeed, the rows of $\underline{h}$ can each be identified with external input/output "gains." Thus, the problem of choosing a minimal set of external parameters for fault analysis is reduced to the problem of choosing a minimal set of rows in $\underline{h}$ that render its columns linearly independent (Singh, 1972). There are difficulties with this technique in certain cases, but fortunately, a number of approaches have been developed for alleviating these (Ransom, 1973, 1972; Ransom and Saeks, 1973b).

7.6 Concluding Remarks

Although this chapter has not provided a complete or detailed explanation of component connection philosophy, the reader should now have a fundamental understanding of the power and utility of the philosophy. Even though the component connection approach to modeling large-scale systems originated over three decades ago, it is likely that its full potential has not been realized. There are several areas of research in which the component connection approach might lead to new results. One of these is the area of optimal decentralized control of large-scale systems.

Fault-Tolerant Control

Gary G. Yen
Intelligent Systems and Control Laboratory, School of Electrical and Computer Engineering, Oklahoma State University, Stillwater, Oklahoma, USA

8.1 Introduction

While most research attention has been focused on fault detection and diagnosis, much less research effort has been dedicated to "general" failure accommodation mainly because of the lack of well-developed control theory and techniques for general nonlinear systems. Because of the inherent complexity of nonlinear systems, most of model-based analytical redundancy fault diagnosis and accommodation studies deal with the linear system that is subject to simple additive or multiplicative faults. This assumption has limited the system's effectiveness and usefulness in practical applications. In this research work, the online fault accommodation control problems under catastrophic system failures are investigated. The main interest is dealing with the unanticipated system component failures in the most general formulation. Through discrete-time Lyapunov stability theory, the necessary and sufficient conditions to guarantee the system online stability and performance under failures are derived, and a systematic procedure and technique for proper fault accommodation under the unanticipated failures are developed. The approach is to combine the control technique derived from discrete-time Lyapunov theory with the modern intelligent technique that is capable of **self-optimization** and **online adaptation** for real-time failure estimation. A complete architecture of fault diagnosis and accommodation has also been presented by incorporating the developed intelligent fault-tolerant control (FTC) scheme with a cost-effective fault-detection scheme and a multiple model-based failure diagnosis process to efficiently handle the false alarms and the accommodation of both the anticipated and unanticipated failures in online situations.

8.2 Overview of Fault Diagnosis and Accommodation

Because of the increasing demands of system safety and reliability in modern engineering design, research issues dealing with failure diagnosis and accommodation have attracted significant attention in the control society, as the first page of references at the end of this chapter indicates. System failures caused by unexpected interference or aging of system components will possibly result in changes or changing of system dynamics. Thus, the original design under the fault-free condition is no longer reliable and possibly leads to instability. More serious problems, such as the survivability of the system, may arise when the instability of the system may cause the loss of human life. The research work dealing with the underlying problems is usually referred to as **fault diagnosis and accommodation** (FDA). The major objectives of FDA or FTC is to detect and isolate the encountered failures and to take the necessary actions to prevent the system from getting and unstable and maintain the successful control mission.

Traditional FDA approaches are based on so-called hardware redundancy where extra components are used as backup in case of failures. Because of the additional cost, space, weight, and complexity of incorporating redundant hardware, model-based methods (in the spirit of analytical redundancy) with inexpensive and high performance microprocessors have dominated the FDA research activities. The major reason for the prevalence of this approach is information processing techniques using powerful computing devices and memory systems can be used to establish the necessary redundancy without the need of hardware instrumentation in the system (Polycarpou and Helmicki, 1995). Under the model-based analytical redundancy, system behaviors are compared with the analytically obtained values through a mathematical model. The resulting differences are so-called residuals (Gertler, 1988). In the ideal situation, the residuals will be zeros in the fault-free system, and any deviation will be interpreted as an indication of faults. This is rarely true, however, in practice with the presence of measurement noise disturbances and modeling errors. The deviation can be the combinational results of noises, disturbances, modeling errors, and faults. Naturally, with the presence of significant noises, statistical analysis of the residuals becomes a reasonable procedure to generate a logical pattern called the **signature of the failure** for the proper fault detection and isolation. Many research activities have also been dedicated to investigate a proper residual generation to facilitate the fault isolation process (Garcia and Frank, 1999; Garcia *et al.*, 1998; Gertler and Hu, 1999; Gertler *et al.*, 1995; Gertler and Kunwer, 1995). Generally speaking, residual generation, statistical testing, and logical analysis are usually combined as the three stages of the fault detection and isolation (Gertler, 1988). Due to the inherent complexity of nonlinear systems, most model-based analytical redundancy fault diagnosis studies deal with the linear system that is subject to simple additive or multiplicative faults. This assumption has limited its effectiveness and usefulness in practical applications (Polycarpou and Helmicki, 1995; Polycarpou and Vemuri, 1995). A series of research works that is devoted to more general failure cases is reported in Polycarpou and Helmicki (1995), Polycarpou and Vemuri (1995), Zhang *et al.*, (1999, 2000), Vemuri and Polycarpou (1997) and Trunov and Polycarpou (1999). Although significant progress has been made in the theoretical analysis for fault detection and sensitivity conditions, more practical and complicated fault detection and diagnosis (FDD) problems, such as detection and diagnosis of possible multiple failures, still remain to be solved. The representative fault diagnosis methods are shown in Figure 8.1.

Similar to fault detection and diagnosis research work, most of the fault accommodation schemes are mainly designed based on the powerful and well-developed linear design methodology to obtain the desired objectives. Typical approaches for failure accommodation techniques include the pseudo-

inverse method or model-following method (Gao and Antsaklis, 1991, 1992), eigenstructure assignment (Jiang, 1994), LQC (Sauter *et al.*, 1998), additive compensation for sensor and actuator failures (Noura *et al.*, 2000; Theilliol *et al.*, 1998), reconfiguration control with parameter identification (Rauch, 1995; Bodson and Grosz-Kiewicz, 1997), state-space pole placement (Jiang and Zhao, 1998, 1999); and (interactive) multiple model method (IMM) (Maybeck and Stevens, 1991; Zhang and Li, 1998; Zhang and Jiang, 1999) as shown in Figure 8.2. However, this is rarely the case in practice since all the systems are inherently nonlinear, and the system dynamics under failure situations are more likely to be nonlinear and time varying. The failure situations can be further categorized into anticipated and unanticipated faults where the anticipated ones are referred to as the known faults based on the prior knowledge of the system or possibly the history of system behavior, and the unanticipated ones are the unexpected failure situations, which have to be identified online. In general, the recognition and accommodation of the anticipated failures are considered relatively easier to solve because of the availability of the prior information and sufficient time for the development of solutions (i.e., off-line). The details of the systematic procedure of the proper failure isolation and accommodation for anticipated faults, such as the generation of residuals, fault signature identification, and the selection logic of the proper control actions, however, are still left unanswered. For unanticipated failures under general format, the online identification and accommodation are even more difficult and rarely touched. When a dynamic system encounters failures possibly caused by unexpected interferences, it is not a reasonable approach to assume certain types of dynamic change caused by those unexpected failures. Of course, the faulty system is possibly uncontrollable if the failure is very serious and fatal. It is absolutely crucial to take early actions to properly control the system behavior in time to prevent the failure from causing more serious loss if the system under failures is controllable at that time.

Because the successful fault accommodation relies on precise failure diagnosis and both processes have to be successfully achieved in the *online and real-time* situation for the unanticipated failures, it has been almost impossible to accomplish and guarantee the system safety based solely on the contemporary control technique with insufficient and/or imprecise information of the failure. Nevertheless, it is believed that technology breakthrough will not happen overnight. Instead, it occurs with slow progress, one step at a time. An early work (Yen and Ho, 2000), where two online control laws were developed and reported for a special nonlinear system with unanticipated component failures, focuses on dealing with the **general unanticipated system component failures** for the **general nonlinear** system. Through discrete-time Lyapunov stability theory, the necessary and sufficient conditions to guarantee the system online stability and performance under failures were derived, and a systematic procedure and technique for proper fault accommodation under unanticipated failures were developed. The approach is to combine the control technique derived from discrete-time Lyapunov stability theory with the modern intelligent technique that is capable of **self-optimization** and **online adaptation** for real-time failure estimation. A more complete architecture of fault diagnosis and accommodation has also been presented by incorporating the developed intelligent fault-tolerant control technique with a cost-effective fault detection scheme and a multiple model-based failure diagnosis process to efficiently handle the false alarms, to accommodate the anticipated failures, and to reduce the unnecessary control effort and computational complexity in online situations.

This chapter is organized as follows. In Section 8.3, the online fault accommodation control problems of interest are defined. In Section 8.4, through theoretical analysis, the necessary and sufficient conditions to maintain the system's online stability are derived together with the proposed intelligent fault accommodation technique. The complete multiple model-based FDA architecture is presented in Section 8.5 with the suggested cost-effective fault detection and diagnosis scheme. An online simulation study is provided in Section 8.6 to demonstrate the effectiveness of the proposed online accommodation technique in various failure scenarios. The conclusion is included in Section 8.7 with the discussion of the current and future research directions.

8.3 Problem Statement

A general n-input and m-output dynamic system can be described by equation 8.1.

$$\begin{aligned} &y_l(k+d) = f_l(\bar{y}_1, \bar{y}_2, \ldots \bar{y}_m, \bar{u}_1, \bar{u}_2, \ldots \bar{u}_n). \\ &\bar{y}_i = \{y_i(k+d-1), y_i(k+d-2), \ldots, y_i(k+d-p_i)\}. \\ &\bar{u}_j = \{u_j(k), u_j(k-1), \ldots u_j(k-q_j)\}. \\ &p_i, q_j \in \Re^+, i = 1, 2, \ldots, m., j = 1, 2, \ldots, n., \text{ and } l = 1, 2, \ldots, m. \end{aligned} \tag{8.1}$$

In equation 8.1, $f_1: \Re^P \times \Re^Q \mapsto \Re$, with $P = \sum_{i=1}^{m} p_i$ and $Q = \sum_{j=1}^{n} q_j$ as the mathematical realization of the system dynamics for the lth output. The $y_l, y_i, u_j \in \Re$ are the lth and ith system outputs and jth input, respectively. The d is the relative degree of the system (the smallest delay from the input signal to the system output). In general, f_l may not be readily available in mathematical format all the time due to the difficulty of modeling a complex dynamic system. It is possible, however, to develop a realization to describe the system behavior off-line with a known bounded uncertainty in the desired working region of the system using all the existing modeling techniques; technique include the modern intelligent technology, such as artificial neural networks or fuzzy logics provided there is enough computing resource and there is sufficient time for the development of the realization (Narendra and Parthasathy, 1990; Narendra and Mukhopaelhyay, 1997; Nie and Linkens, 1993) as shown in equation 8.2:

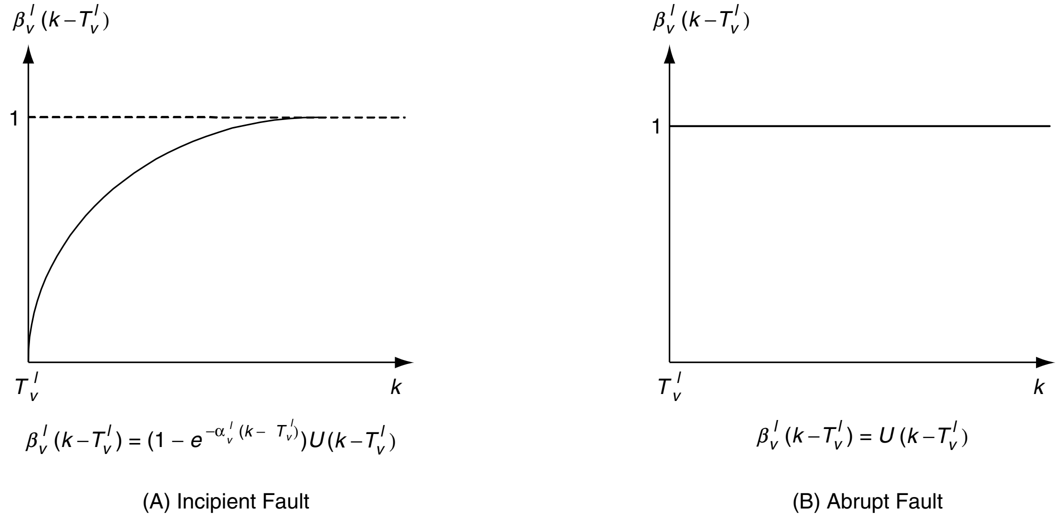
$$y_l(k+d) = \hat{f}_l(\bar{y}_1, \bar{y}_2, \ldots, \bar{y}_m, \bar{u}_1, \bar{u}_2, \ldots \bar{u}_n) + \eta_l(y, u), \tag{8.2}$$

where $\|\eta_1(y, u)\|_2 \le \delta_0, \forall (y, u) \subseteq (\mathbf{Y}, \mathbf{U})$, and $(\mathbf{Y}, \mathbf{U})$ represent the desired working region, and $\delta_0 \in \Re$ is a known constant. Thus, $\hat{f}_l$, the realization of the real system with a known bounded uncertainty in the desired working region of the system, will be either a mathematical, numerical or a combined realization; it is assumed that this realization is developed off-line and available. Equation 8.1 denotes a healthy system under the fault-free situation and equation 8.2 is the corresponding nominal model. Under different component failures, the system dynamics are represented by the following equation:

$$\begin{aligned} y_l(k+d) &= f_l(\bar{y}_1, \bar{y}_2, \ldots \bar{y}_m, \bar{u}_1, \bar{u}_2, \ldots \bar{u}_n) \\ &+ \sum_{\nu=1}^{r} \beta_\nu^l(k - T_\nu^l) F_\nu^l(\bar{y}_1, \bar{y}_2, \ldots \bar{y}_m, \bar{u}_1, \bar{u}_2, \ldots \bar{u}_n, k), \end{aligned} \tag{8.3}$$

where $F_\nu^l(\cdot): \Re^P \times \Re^Q \times \Re^+ \mapsto \Re$ with $P = \sum_{i=1}^{m} p_i$ and $Q = \sum_{j=1}^{n} q_j$ representing the dynamic change (a general **time-varying** function depends on past system outputs, past control inputs, and the current control input) caused by the unknown and possibly unanticipated failure mode $^{\nu}$ for the lth output. The $F_\nu^l(\cdot), \beta_\nu^l(\cdot)$, and T_ν^l are assumed unknown due to the possible occurrence of unanticipated failures. The r is the number of system failures. All the cases in which $r > 1$ are referred to as multiple-failure cases. Two typical faults, incipient faults and abrupt faults, are considered to be involved online. Their characteristics can be described by the time-varying constant gain, $\beta_\nu^l(\cdot)$, shown in Figure 8.3.

In Figure 8.3, $\alpha_\nu^l \in \Re^+$ is an unknown constant that defines the time profile of the incipient failure mode ν, and $U(k)$ denotes the unit step function. Abrupt failures are used to represent the sudden change of the system dynamics, and the incipient failures are used to describe the slow-varying aging effect of the system component. The control objective is to generate appropriate control signals to stabilize the system and, possibly, drive the system outputs back to the desired trajectories, $y_1(k+d) \in \Re, \forall l = 1, 2, \ldots, m,$ in online situations with the presence of the abrupt and/or incipient faults. Under the presence of component failures, the system dynamics may change dramatically or keep changing with time, and the change cannot be detected until it actually happens. Thus,



(A) Incipient Fault

(B) Abrupt Fault

FIGURE 8.3 Time-Varying Constant Gains

the fault accommodation problem has to be solved in the online real-time fashion, which significantly increases the complexity and technical difficulty. To avoid instability problems caused by failures, the online, real-time adjustment of the control law or the reconfiguration of the control actions becomes essential.

8.4 Online Fault Accommodation Control

In this section, the general online fault accommodation problems will be analyzed from both theoretical and realistic points of view. The major focus of interest is to develop an online failure accommodation technique for the general nonlinear dynamic system under general unanticipated catastrophic system failures.

Without loss of generality, let $d = 1$ and consider the SISO system to simplify the analysis. Define a sliding surface function representing the desired dynamics as shown in equation 8.4:

$$S(k) = \frac{y_d(k) - y_d(k-1)}{\Delta t} - \frac{y(k) - y(k-1)}{\Delta t} + a(y_d(k) - y(k)), \tag{8.4}$$

where $y_d(k)$ and $y(k)$ represent the desired system output and the actual system output at time step k, respectively. The Δt represents the sampling period, and $a \in \Re^+$ defines how fast the system output will converge to the desired output. If Lyapunov function is defined as $V(y(k)) = S^2(y(k))$, make $V(y(k+1)) \leq V(y(k))$ and $\forall k \geq 0$, and the sliding surface will be an equation of the tracking error. This implies that the desired dynamics represented by $S = 0$ are attractive, and the desired trajectory can be obtained.

Apparently, the controller's design objective becomes seeking the control input that will satisfy $S^2(k+1) < S^2(k)$, which is equivalent to $[S(k+1) + S(k)][S(k+1) - S(k)] < 0$. This is the same as satisfying the following inequalities:

$$\begin{aligned} -S(k) < S(k+1) < S(k) \quad & \text{when } S(k) > 0. \\ S(k) < S(k+1) < -S(k) \quad & \text{when } S(k) < 0. \end{aligned} \tag{8.5}$$

For $S(k) > 0$, plugging in equation (8.4) yields:

$$\begin{aligned} -S(k) < \frac{y_d(k+1) - y_d(k)}{\Delta t} - \frac{y(k+1) - y(k)}{\Delta t} \\ + a(y_d(k+1) - y(k+1)) < S(k). \end{aligned} \tag{8.6}$$

Reorganizing the inequality results in:

$$-S(k) - \bar{Y}(k) < (-a - \frac{1}{\Delta t})y(k+1) < S(k) - \bar{Y}(k), \tag{8.7}$$

where $\bar{Y}(k) = \dfrac{y_d(k+1) - y_d(k) + y(k)}{\Delta t} + ay_d(k+1)$. This can be further simplified as:

$$(\bar{Y}(k) + S(k))\left(a + \frac{1}{\Delta t}\right)^{-1} > y(k+1) > (\bar{Y}(k) - S(k))\left(a + \frac{1}{\Delta t}\right)^{-1}. \tag{8.8}$$

For $S(k) < 0$, the following equation applies:

$$(\bar{Y}(k) - S(k))\left(a + \frac{1}{\Delta t}\right)^{-1} > y(k+1) > (\bar{Y}(k) + S(k))\left(a + \frac{1}{\Delta t}\right)^{-1}. \tag{8.9}$$

Notice that the left-hand side and the right-hand side of the inequalities in equations 8.8 and 8.9 are known and can be computed at each time-step. Thus, the online fault-tolerant control problems become finding the effective control signal that satisfies the inequality of equation 8.8 when $S(k) > 0$ or equation 8.9 when $S(k) < 0$ at every time-step.

Let $y(k+1) = \bar{\Theta}[\bar{y},\ \bar{u}]$, which represents the system dynamics under failures, where $\bar{y}$ and $\bar{u}$ represent the regression vectors of system outputs and inputs, respectively. Based on the implicit function theorem (Apostol, 1974), the control law can be written as $u(k) = \bar{G}[\bar{y},\ \bar{Y}(a + 1/\Delta t)^{-1}, \bar{u}\backslash\{u(k)\}]$ provided $\bar{G}$ exists [i.e., $\bar{u}\backslash\{u(k)\}$ denotes the set containing the regression vector of input excluding the current item, $u(k)$. Because the nonexistence of $\bar{G}$ corresponds to the cases where the system becomes uncontrollable under failure situations, the existence problem becomes trivial. Unfortunately, the realization of $\bar{G}$ cannot be provided without knowing the true structures of the system dynamics and the failure dynamics. Thus, the control law cannot be implemented in reality. Through the modern computational intelligence approaches, the effective control input satisfying inequalities of equation 8.8 or 8.9 can be found using optimization algorithms without the complete realization of $\bar{G}$. The systematic procedure is described as follows.

The unknown failure dynamics can be realized through an online estimator. The true system output, $y(k+1)$, can be approximated by the sum of the outputs from the nominal model, $N\hat{y}(k+1)$, and the online estimator, $nf\hat{y}(k+1)$, as follows:

$$\begin{aligned} y(k+1) &= Ny(k+1) + fy(k+1) \\ &= N\hat{y}(k+1) + N\tilde{y}(k+1) + nfy(k+1) + nf\tilde{y}(k+1). \end{aligned} \tag{8.10}$$

In equation 8.10, the following is true:

- $Ny(k+1)$ is the output of the actual system.
- $fy(k+1)$ is the output of the failure dynamics.
- $N\hat{y}(k+1)$ is the output of the nominal model.
- $N\tilde{y}(k+1)$ is the remaining uncertainty between the nominal system and the nominal model.
- $nfy(k+1)$ is the output of the online estimator.
- $nf\tilde{y}(k+1)$ is the remaining uncertainty between the estimator and the failure dynamics.

In addition, the following applies:

$$\begin{aligned} Ny(k+1) &= N\hat{y}(k+1) + N\tilde{y}(k+1);\ fy(k+1) \\ &= nfy(k+1) + nf\tilde{y}(k+1). \end{aligned}$$

The using equation 8.10, the inequalities become for $s(k) > 0$:

$$\begin{aligned} (S(k)+\bar{Y}(k))\left(a+\frac{1}{\Delta t}\right)^{-1} &> N\hat{y}(k+1) + N\tilde{y}(k+1) + nfy(k+1) \\ &+ nf\tilde{y}(k+1) > (\bar{Y}(k) - S(k))\left(a+\frac{1}{\Delta t}\right)^{-1}. \end{aligned} \tag{8.11}$$

For $S(k) < 0$, the inequalities become the following:

$$\begin{aligned} (\bar{Y}(k) - S(k))\left(a+\frac{1}{\Delta t}\right)^{-1} &> N\hat{y}(k+1) + N\tilde{y}(k+1) + nfy(k+1) \\ &+ nf\tilde{y}(k+1) > (\bar{Y}(k) + S(k))\left(a+\frac{1}{\Delta t}\right)^{-1}. \end{aligned} \tag{8.12}$$

Modern intelligent optimization techniques, such as genetic algorithms, immune algorithms, simulated annealing, and reinforcement learning, have been exploited in a variety of areas and applications (Chun *et al.*, 1997; Chun *et al.*, 1998; Marchesi *et al.*, 1994; Tanaka and Yoshida, 1999; Marchesi, 1998; Juang *et al.*, 2000; Offner, 2000; Ho and Huang, 2000). Although the effectiveness in achieving successful optimization objectives has been demonstrated, most of them are still applied in off-line situations due to the time-consuming iterative process. From the computational complexity point of view, and the well-known and efficient gradient descent algorithm will be considered and used in the rest of this chapter because of its popularity and effectiveness in online applications. The optimization procedure is shown as follows.

The desired point at every time-step is written as:

$$\begin{aligned} \text{Desire}(k) &= \left[(\bar{Y}(k) + S(k))\left(a+\frac{1}{\Delta t}\right)^{-1}\right. \\ &\quad \left. +(\bar{Y}(k) - S(k))\left(a+\frac{1}{\Delta t}\right)^{-1}\right]/2 \\ &= \bar{Y}(k)\left(a+\frac{1}{\Delta t}\right)^{-1}. \end{aligned} \tag{8.13}$$

Define the error as:

$$\begin{aligned} \text{Error}(k) &= \text{Desire}(k) - N\hat{y}(k+1) - N\tilde{y}(k+1) \\ &\quad - nfy(k+1) - nf\tilde{y}(k+1). \end{aligned} \tag{8.14}$$

The effective control input can be searched based on the gradient descent algorithm for square error:

$$\begin{aligned} \frac{\partial \text{Error}(k)^2}{\partial u(k)} &= 2\ \text{Error}(k)\frac{\partial\ \text{Error}(k)}{\partial u(k)} \\ &= -2\ \text{Error}(k)\left[\frac{\partial N\hat{y}(k+1)}{\partial u(k)} + \frac{\partial N\tilde{y}(k+1)}{\partial u(k)}\right. \\ &\quad \left. + \frac{\partial nfy(k+1)}{\partial u(k)} + \frac{\partial nf\tilde{y}(k+1)}{\partial u(k)}\right]. \end{aligned} \tag{8.15}$$

The resulting control input will be updated by:

$$u(k)_{\text{new}} = u(k)_{\text{old}} - \alpha\frac{\partial\ \text{Error}(k)^2}{\partial u(k)}, \tag{8.16}$$

where α is the learning rate parameter. The searching procedure is repeated until inequalities of equations 8.11 and 8.12 hold, the control input converges, or the maximum number of iterations is reached. Of course, the term $nf\tilde{y}(k+1)$, the remaining uncertainty of the failure dynamics, and the remaining uncertainty of the nominal system $N\tilde{y}(k+1)$ are unknown; the terms $\partial nf\tilde{y}(k+1)/\partial u(k)$ and $\partial N\tilde{y}(k+1)/\partial u(k)$ cannot be computed either. So, the actual searching procedure is based on the approximated values:

$$\text{Er}\hat{\text{r}}\text{or}(k) = \text{Desire}(k) - N\hat{y}(k+1) - nfy(k+1). \tag{8.17}$$

$$\frac{\partial \text{Er}\hat{\text{r}}\text{or}(k)^2}{\partial u(k)} = -2\text{Er}\hat{\text{r}}\text{or}(k)\left[\frac{\partial N\hat{y}(k+1)}{\partial u(k)} + \frac{\partial nfy(k+1)}{\partial u(k)}\right]. \tag{8.18}$$

At every time step, the desired point of $\bar{Y}(k)(a+1/\Delta t)^{-1}$ is computed, and the effective control signal is searched to ensure the actual result is as close to the desired point as possible through the realizations of the nominal system dynamics and failure dynamics. Observing inequalities of equations 8.11 and 8.12 closely, if $nf\tilde{y}(k+1)$ and $N\tilde{y}(k+1)$, the remaining uncertainty of the failure dynamics and the nominal system are bounded, combining these results with equations 8.13 and 8.14 determines that the desired dynamics, represented by S function, are also bounded. This can be proven and summarized in theorem 8.1:

8.4.1 Theorem 1

If the nominal system model is accurate and precise enough such that $N\tilde{y}(k+1)$, the remaining uncertainty of the nominal system, is bounded by $\sup\limits_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}$ and the online estimator is accurate enough such that the remaining uncertainty of the failure dynamics, $nf\tilde{y}(k+1)$, is bounded by the least upper bound, $\sup\limits_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}$, and $\Delta Error(k)$, then the error after the searching effort of the optimization algorithm is finite (i.e., bounded by $\sup\limits_{\forall k>T_f}\{|\Delta Error(k)|\}$). In addition, the system stability after time-step T_f under arbitrary unanticipated system failures is guaranteed in an online situation, and the sliding surface function, S, defined by the system performance error is also bounded as follows:

$$\boldsymbol{\Sigma \le S(k+1) \le \Xi},$$

where the following two equations apply:

$$\Sigma = -\left[\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\} + \sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\} + \sup_{\forall k>T_f}\{|\Delta\text{Error}(k)|\}\right]\left(a+\frac{1}{\Delta t}\right).$$

$$\Xi = \left[\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\} + \sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\} + \sup_{\forall k>T_f}\{|\Delta\text{Error}(k)|\}\right]\left(\frac{a+1}{\Delta t}\right).$$

The sliding surface function, S, is defined as:

$$S(k) = \frac{y_d(k) - y_d(k-1)}{\Delta t} - \frac{y(k) - y(k-1)}{\Delta t} + a(y_d(k) - y(k));\ a > 0,$$

where $y_d(k)$ is the desired trajectory at time step k.

Proof

Let $\Delta\text{Error}(k)$ represent the error after the searching effort of the optimization algorithm. Then:

$$\Delta\text{Error}(k) = \text{Desire}(k) - N\hat{y}(k+1) - nfy(k+1).$$

By equation 8.13:

$$\bar{Y}(k)\left(a+\frac{1}{\Delta t}\right)^{-1} - \Delta\text{Error}(k) = N\hat{y}(k+1) + nfy(k+1). \tag{8.19}$$

For $S(k) > 0$ plugging in equation 8.19 into inequality 8.11, the result is as follows:

$$(\bar{Y}(k) + S(k))\left(a+\frac{1}{\Delta t}\right)^{-1} > \bar{Y}(k)\left(a+\frac{1}{\Delta t}\right)^{-1} - \Delta Error(k) + N\tilde{y}(k+1) + nf\tilde{y}(k+1) > (\bar{Y}(k) - S(k))\left(a+\frac{1}{\Delta t}\right)^{-1}.$$

Simplifing the inequality yields these two functions:

$$S(k) > [N\tilde{y}(k+1) + nf\tilde{y}(k+1) - \Delta\text{Error}(k)]\left(a+\frac{1}{\Delta t}\right).$$
$$-S(k) < -[N\tilde{y}(k+1) + nf\tilde{y}(k+1) - \Delta\text{Error}(k)]\left(a+\frac{1}{\Delta t}\right). \tag{8.20}$$

Since $S(k) > 0$, $-S(k) < [\sup\limits_{\forall k>T_f}\{|N\tilde{y}(k+1)|\} + \sup\limits_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\} + \sup\limits_{\forall k>T_f}\{|\Delta\text{Error}(k)|\}](a+1/\Delta t$ is always true. By assumptions 1, 2, and 3, the following inequalities will hold for the worst condition:

$$S(k) > [\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\} + \sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\} + \sup_{\forall k>T_f}\{|\Delta\text{Error}(k)|\}]\left(a+\frac{1}{\Delta t}\right). \tag{8.21}$$

Apparently, $[\sup\limits_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup\limits_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}+\sup\limits_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}](a+1/\Delta t)=\inf\limits_{\forall k>T_f}\{S(k)\}$, which is the greatest lower bound of $S(k)$. In addition, $-[\sup\limits_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup\limits_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}+\sup\limits_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}](a+1/\Delta t)=\sup\limits_{\forall k>T_f}\{-S(k)\}$, which is the least upper bound of $-S(k)$. Since $S(k)> S(k+1)$ and $-S(k)<-S(k+1)$, the following inequalities will always hold:

$$\begin{aligned}&[\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}\\&+\sup_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}]\left(a+\frac{1}{\Delta t}\right)\geq S(k+1).\\&-[\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}\\&+\sup_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}](a+\frac{1}{\Delta t})\leq -S(k+1).\end{aligned}\tag{8.22}$$

These hold true for both situations, $S(k+1)>0$ and $S(k+1)<0$, which implies:

$$\Sigma\leq S(k+1)\leq\Xi,\tag{8.23}$$

where:

$$\begin{aligned}\Sigma=-[&\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}\\&+\sup_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}]\left(a+\frac{1}{\Delta t}\right).\\\Xi=[&\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}\\&+\sup_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}]\left(a+\frac{1}{\Delta t}\right).\end{aligned}$$

For $S(k)<0$, plugging in equation 8.19 into inequality 8.12, the result is the following:

$$\begin{aligned}&(\bar{Y}(k)-S(k))\left(a+\frac{1}{\Delta t}\right)^{-1}>\bar{Y}(k)\left(a+\frac{1}{\Delta t}\right)^{-1}-\Delta\mathrm{Error}(k)\\&\quad+N\tilde{y}(k+1)+nf\tilde{y}(k+1)>(\bar{Y}(k)+S(k))\left(a+\frac{1}{\Delta t}\right)^{-1}.\end{aligned}$$

Simplifing the inequality gets:

$$\begin{aligned}&-S(k)>[N\tilde{y}(k+1)+nf\tilde{y}(k+1)-\Delta\mathrm{Error}(k)]\left(a+\frac{1}{\Delta t}\right).\\&S(k)<[N\tilde{y}(k+1)+nf\tilde{y}(k+1)-\Delta\mathrm{Error}(k)]\left(a+\frac{1}{\Delta t}\right).\end{aligned}\tag{8.24}$$

Because $S(k)<0$, $S(k)<[\sup\limits_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup\limits_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}+\sup\limits_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}](a+1/\Delta t)$ is always true. By assumptions 1, 2, and 3, the following inequalities will hold for the worst condition:

$$\begin{aligned}-S(k)>[&\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}\\&+\sup_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}]\left(a+\frac{1}{\Delta t}\right).\end{aligned}\tag{8.25}$$

Apparently, $[\sup\limits_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup\limits_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}+\sup\limits_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}]\ (a+1/\Delta t)=\inf\limits_{\forall k>T_f}\{-S(k)\}$, which is the greatest lower bound of -$S(k)$.

In addition $-[\sup\limits_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup\limits_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}+\sup\limits_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}](a+1/\Delta t)=\sup\limits_{\forall k>T_f}S(k)\}$, which is the least upper bound of $S(k)$. For both of these equations, since $-S(k)>S(k+1)$ and $S(k)<-S(k+1)$, the following inequalities will always hold:

$$\begin{aligned}&[\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}\\&+\sup_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}]\left(a+\frac{1}{\Delta t}\right)\geq S(k+1).\\&-[\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}\\&+\sup_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}]\left(a+\frac{1}{\Delta t}\right)\leq -S(k+1).\end{aligned}\tag{8.26}$$

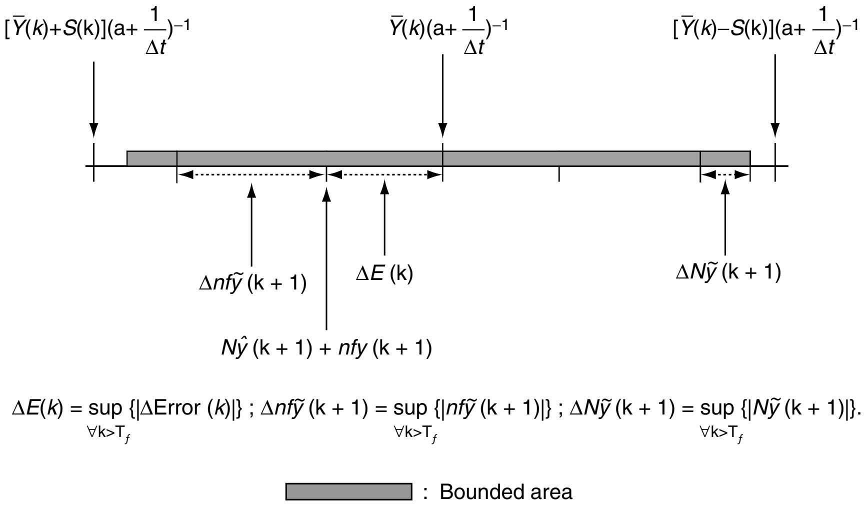
This is true for both situations, $S(k+1)>0$ and $S(k+1)<0$, which implies:

$$\Sigma\leq S(k+1)\leq\Xi,\tag{8.27}$$

where:

$$\begin{aligned}\Sigma=-[&\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}\\&+\sup_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}]\left(a+\frac{1}{\Delta t}\right).\\\Xi=[&\sup_{\forall k>T_f}\{|N\tilde{y}(k+1)|\}+\sup_{\forall k>T_f}\{|nf\tilde{y}(k+1)|\}\\&+\sup_{\forall k>T_f}\{|\Delta\mathrm{Error}(k)|\}]\left(a+\frac{1}{\Delta t}\right).\end{aligned}$$

The result is exactly the same result as for equation 8.23. Thus, the sliding surface function, S, is bounded by the value defined by the least upper bounds of the remaining



$[\bar{Y}(k)+S(k)](a+\frac{1}{\Delta t})^{-1}$
$\bar{Y}(k)(a+\frac{1}{\Delta t})^{-1}$
$[\bar{Y}(k)-S(k)](a+\frac{1}{\Delta t})^{-1}$
$\Delta nf\tilde{y}\,(k+1)$
$\Delta E\,(k)$
$\Delta N\tilde{y}\,(k+1)$
$N\hat{y}\,(k+1) + nfy\,(k+1)$
$\Delta E(k) = \sup\limits_{\forall k>T_f} \{|\Delta \text{Error}\ (k)|\}$; $\Delta nf\tilde{y}\,(k+1) = \sup\limits_{\forall k>T_f} \{|nf\tilde{y}\,(k+1)|\}$; $\Delta N\tilde{y}\,(k+1) = \sup\limits_{\forall k>T_f} \{|N\tilde{y}\,(k+1)|\}$.

FIGURE 8.4 The Bound of the Sliding Surface Function

uncertainties of the nominal system, the failure dynamics, and the error by the optimization algorithm.

The discrete-time Lyapunov stability theory indicates that the control problem can be solved as long as **the numerical value of the failure dynamics** is realized at each **time-step**, which is a measure of how far the failure drives the system dynamics away from the desired dynamics. Based on the above theoretical analysis, the system under unexpected catastrophic failures can be stabilized online, and the performance can be recovered provided an effective online estimator for the unknown failure dynamics such that the necessary and sufficient condition in theorem 1 is satisfied. Moreover, since the online estimator is used to provide the approximated numerical value of the failure dynamics at each time-step based on the most recent measurements (i.e., the failure may be time varying), no specific structure or dynamics is required for the estimator. In other words, only a static function approximator that approximates the most recent behavior of the failure is needed for the control purpose. Figure 8.4 indicates how the S function is bounded by the upper bounds of the nominal model uncertainty, $\Delta N\tilde{y}(k+1)$, optimization error, $\Delta E(k)$, and the prediction error of the failure dynamics, $\Delta nf\tilde{y}(k+1)$.

8.4.2 Online Learning of the Failure Dynamics

With the universal approximation capability for any piecewise continuous function to any degree of accuracy (Hordik *et al.*, 1989), **artificial neural networks** become one of the most promising candidates for the online control problems of our interest. In this research work, neural network is exploited and used as the online estimator for the unknown failure dynamics. Some important features of the online learning using neural networks should first be addressed here. The structure of the online estimator needs to be decided (i.e., in neural networks, the number of layers, number of neurons in each layer, and neuron transfer functions have to be specified). It is known that neural networks are sensitive to the number of neurons in the hidden layers. Too few neurons can result in underfitting problems (poor approximation), and too many neurons may contribute to an overfitting problem, where all the training patterns are well fit, but the fitting curve may take wild oscillations between the training data points (Demuth and Beale, 1998). The criterion for stopping of the training process is another important issue in the real applications. If the mean square error of the estimator is forced to reach a very small value, the estimator may perform poorly for the new input data slightly away from the training patterns. This is the well-known generalization problem. Besides, in the real applications, the training patterns may contain some noise since they are the measurements from real sensors. The estimator may adjust itself to fit the noise instead of the real failure dynamics. Some methods proposed to improve these problems, such as early stopping criterion and generalization network training algorithms, may be useful to remedy these situations (Demoth and Beale, 1998; Mackey, 1992)

In the online situation, the number of input output data for the training process becomes a very important design parameter. The system dynamics may keep changing because of different fault situations (i.e., the incipient fault, abrupt fault, and multiple faults). Apparently, using all input/output measurements to train the online estimator does not make too much sense since it is possible to use invalid training patterns to mislead the estimator, and it is also unrealistic for online applications. In other words, only finite and limited number of data sets should be used as training patterns to adjust the parameters of the estimator. A reasonable way is to use the most recent input/output measurements. A set, B, that contains the most recent measurements in a fixed length of a time-shifting data window is used to collect the training patterns:

$$B = \{(p(m), t(m) | p \in \Re^S;\ t \in \Re^T;\ k - j + 1 \leq m \leq k\}, \quad (8.28)$$

where $p(m)$ and $t(m)$ are the network input vector and desired output vector at time-step m, respectively. The k is the current time-step, and j represents the length of the time-shifting data window, which is a design parameter. This parameter has to be decided based on the system computational capability, sampling rate, and the performance requirement. In addition, the maximum number of the effective control signal searching iterations is another important design parameter in real-time applications. The number has to be within an allowable range according to the system computational capacity in the online situation. For gradient descent-type of optimization algorithms, a time-varying learning rate can be used to possibly reduce the searching time.

8.5 Architecture of Multiple Model-Based Fault Diagnosis and Accommodation

Although the online control law in closed form is not available for general online failure accommodation due to the unknown dynamic changes caused by the failures, based on the above analysis and theorem, the successful control mission can still be achieved provided sufficient online computational power and the satisfaction of the necessary and sufficient conditions. In other words, a substantial amount of computational cost may be paid for maintaining the control mission. In many real systems, the failures could be well-known or anticipated according to the history of system behavior and/or the aging degree of the system components. For those known and/or expected faults, it is apparently not necessary to waste the computational source for failure accommodation. Those fault patterns or signatures and the corresponding control actions can be developed off-line and prestored in a database for an online control purpose. The appropriate online failure accommodation actions are then suggested by a fault detection and diagnosis scheme that detects and identifies the failure patterns online. This idea has been adopted in many (interactive) multiple model-based FTC research works (Maybeck and Stevens, 1991; Zhang and Li, 1998; Zhang and Jiang, 1999; Laparo *et al.*, 1991).

Although there is no solid theoretical result to guarantee the stability of multiple model switching, this idea has attracted substantial attention and been widely used in many areas (Murray-Smith and Johansen, 1997). Inspired by the same spirit, a basic architecture of an intelligent fault diagnosis and accommodation framework is suggested as shown in Figure 8.5. The developed intelligent online fault-tolerant

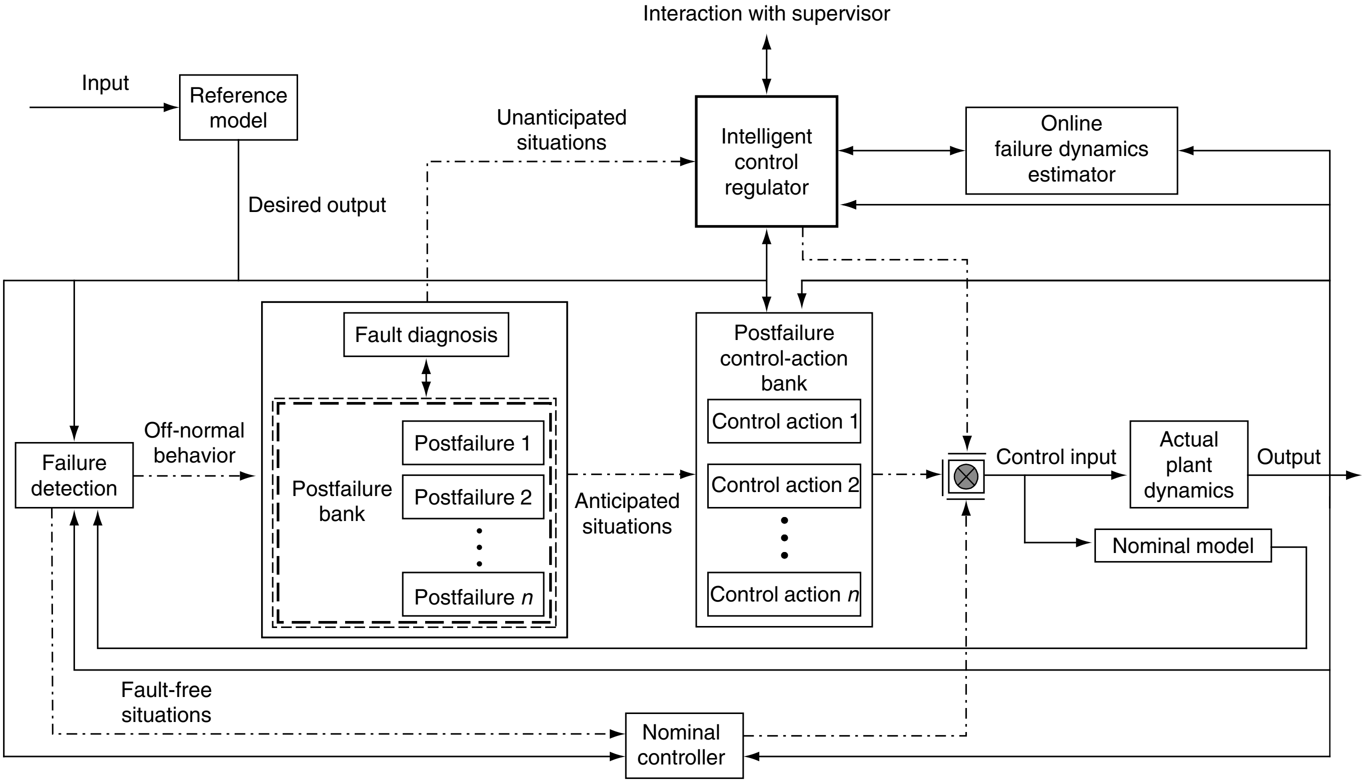

FIGURE 8.5 A Multiple Model-Based Fault Diagnosis and Accommodation Architecture

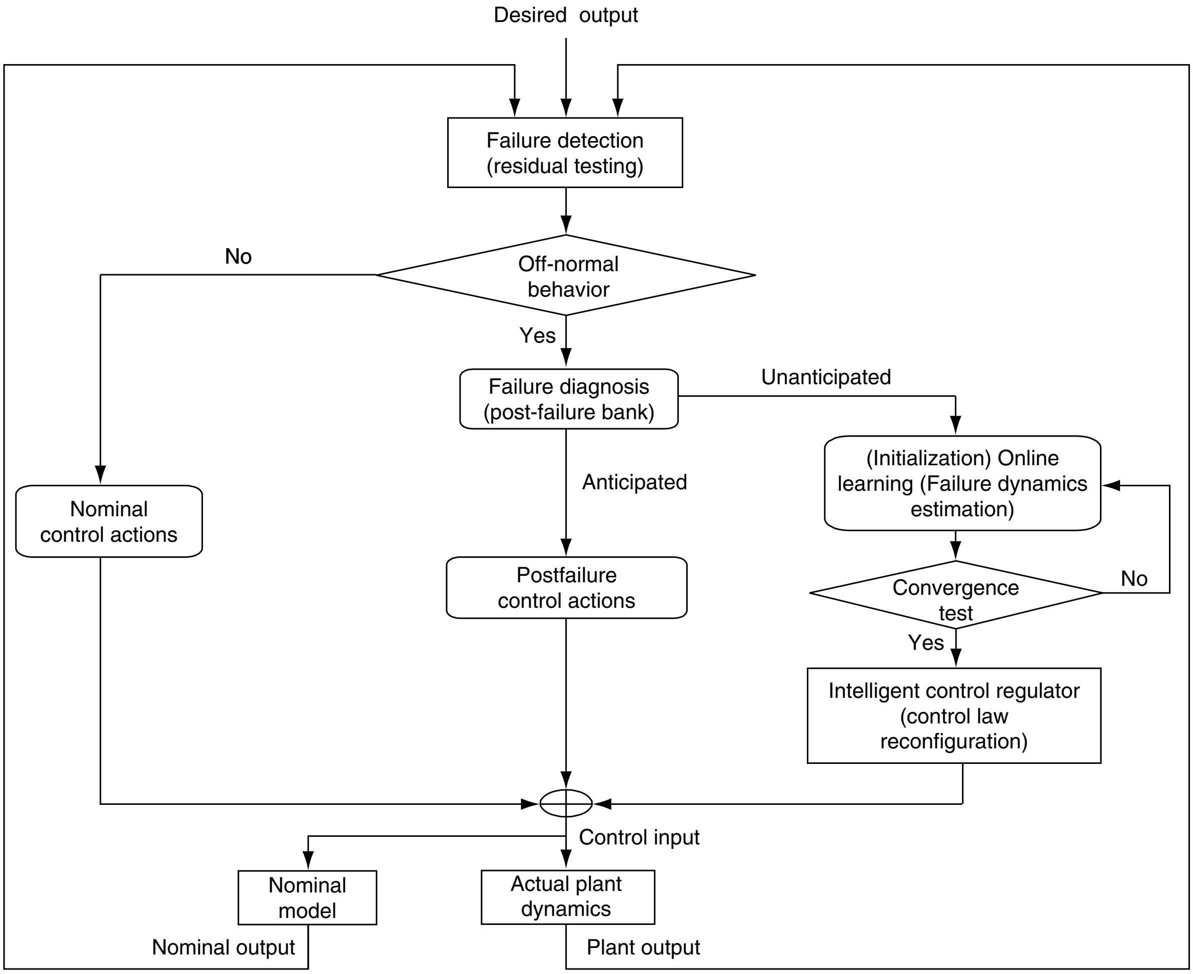
control technique incorporates a separate fault detection scheme, a failure diagnosis mechanism, and postfailure control actions to form a more sophisticated and complete FDA methodology. An intelligent control regulator is parallel with the postfailure control actions and the nominal controller to emphasize that, in online situations, the effective control actions that may come from one of the three sources [the **nominal controller** (corresponding to fault-free situations), the **post-failure control actions** (corresponding to expected failure modes), and the **intelligent control regulator** (corresponding to the unanticipated failure scenarios)] are decided based on system behavior or health. The intelligent fault accommodation technique will be applied only when it is necessary for control purposes. Under this framework, the unnecessary computational waste for anticipated failures and false alarms could be avoided. A clearer picture of how this idea works is depicted in a flow chart shown in Figure 8.6. The system "health" is continuously monitored by the fault-detection scheme with the knowledge of the nominal system behavior every certain period of time. Any abnormal behavior will trigger the failure diagnosis mechanism to analyze the situation and further decide which control actions should be taken. If the failure is recognized as an expected fault by comparing the failure signatures with those of the existing post failures, the corresponding postfailure control actions will be selected as the current effective control commands. Otherwise, the developed intelligent FTC technique is initialized. Notice that the dashed line shown in Figure 8.5 indicates that only one action will be taken at every time instant.

8.5.1 The Dilemma of Online Fault Detection and Diagnosis

With the presence of measurement noises, disturbances, and modeling errors, the problems of fault detection and diagnosis, such as sensitivity, robustness, false alarm, missed detection, and failure isolability, are substantially difficult issues to solve. In spite of many research efforts dedicated to addressing the FDD problems (Zhang *et al*., 1999, 2000; Vemuri and Polycarpou, 1997; Trunov and Polycarpou, 1999; Zhang and Li,



Desired output

FIGURE 8.6 The Flow Chart of the Multiple Model-Based FDA Framework

1998; Zhang and Jiang, 1999; Laparo *et al.*, 1991), complete online fault detection and diagnosis are still impossible at present due to the inherent complexity of the problems and the time constraint in online operations. Until the invention of breakthrough technology for FDD, from the realistic point of view, finding a better trade-off solution for real implementation based on contemporary technology is the best an engineer can do. Moreover, from the system online safety point of view, false alarms are always preferable over missed detection. Thus, a conservative fault-detection scheme with least computational cost is a good choice to guarantee avoidance of missed detection in online situations. The problem of failure isolation is even more difficult to solve when there is more than one fault involved. Similarly, the conservative diagnostic attitude should be preferable since the price of the misdiagnosis and mistreatment could be instability and unaffordable loss. A possible cost-effective and conservative fault-detection and diagnosis schemes used in the later online simulation section is shown in equations 8.29 and 8.30, respectively:

$$\psi_f = \frac{1}{\omega_f} \sum_{k=k_0-\omega_f+1}^{k_0} (ny(k) - y(k))^2. \tag{8.29}$$

$$\psi_{f\,\mathrm{diag}_i} = \sum_{k=k_0-\omega_{f\,\mathrm{diag}+1}}^{k_0} ([y(k) - ny(k)] - pf_i(k))^2. \tag{8.30}$$

In equations 8.29 and 8.30, k_0 is the current time-step, pf_i, and ny represent the time domain signatures of the postfailure model i and the nominal model, respectively. Equation 8.29 will examine the system's state every ω_f time-steps. In cases of failure alarms caused by unexpected disturbances or measurement noises, the detection scheme will eventually recognize the false alarm situations by comparing the signatures of the actual system behavior with the nominal system using a prespecified threshold value and recommend nominal control actions to avoid the unnecessary control effort after the effect resulting from unexpected disturbances or noises decay. Sharing the spirit of the multiple model approach, the effective control actions to achieve successful failure accommodations for anticipated faults are selected based on the matching conditions of the signatures between the actual failures and the multiple model-based failures. The fault isolation process is to compare the most recent time domain signatures between the actual failure and the postfailures. The differences between the actual measurements and the outputs of the nominal model are considered as the outputs from the failure dynamics, and they are compared with the "signatures," outputs, from the postfailure models within a certain length of time-shifting window, $\omega_{f\,\mathrm{diag}}$. A prespecified threshold value is used to compare with $\psi_{f\,\mathrm{diag}_i}$ for the proper selection of the anticipated failure condition. If none of the "signatures" of the anticipated failures meets the criterion, the system status will be switched to the unanticipated failure situation, and the intelligent online FTC approach will be initialized. The ω_f, $\omega_{f\ diag}$, and the threshold values of fault detection and diagnosis are the design parameters that should be selected under considerations of computational capacity, modeling uncertainty, expected noises, and the accuracies of the postfailure model.

8.6 Simulation Study and Discussions

8.6.1 Online Fault Accommodation Technique for Unanticipated System Failures

Consider a multiple inputs and/or outputs (MIMO) system under different failures as shown in equation 8.31:

$$\begin{aligned}
y_1(k+1) &= \frac{y_1(k)}{1+y_2(k)^2} + u_1(k)^2 + u_2(k)^2 - 16u_1(k) - 20u_2(k) + \Delta f_1(k).\\
y_2(k+1) &= \frac{y_1(k)y_2(k)}{1+y_2(k)^2} + u_1(k)u_2(k) + 20u_1(k) - 5u_2(k) + \Delta f_2(k).\\
\Delta f_1(k) &= \beta_{10}(k-T_{10}) \times 0.1 \times \frac{k-25}{20} y_1(k)\cos(u_1(k)) + \beta_{11}(k-T_{11})\\
&\quad \times 0.6 y_1(k)y_2(k).\\
\Delta f_2(k) &= \beta_{20}(k-T_{20}) \times 0.1 \times y_1(k)y_2(k).
\end{aligned} \tag{8.31}$$

In equation 8.31, $\beta_{10}(k-T_{10}) = U(k-T_{10})$, $\beta_{11}(k-T_{11}) = U(k-T_{11})$, $\beta_{20}(k-T_{20}) = U(k-T_{20})$, $T_{10} = 25$, $T_{20} = 15$, and $T_{11} = 123$. No information about the failures is assumed known. The nominal system is first realized through a multilayer perceptron (MLP) network with 4 input neurons, 75 hidden neurons, and 2 output neurons (4–75–2). The 2000 input/output training patterns are collected by supplying uniformly distributed random inputs varying from -1.5 to 1.5 to the nominal system in equation (8.31). A 4–40–2 MLP network is used as a nominal controller trained off-line using the similar idea discussed in Section 8.4 [i.e., use equations 8.13 through 8.18 with the pretrained nominal model (4–75–2 MLP network) to collect training patterns]. A 3–4–2 MLP network is chosen as the online estimator to approximate the most recent behavior of the unanticipated multiple failure dynamics online (i.e., Δf_1, Δf_2), and the Levenberg-Marquardt with Bayesian regularization algorithm (Demouth and Beale, 1998; Mackey, 1992) is used in all the training processes (i.e., off-line training for the nominal model and nominal controller; online training for the failure estimator). Figures 8.7 and 8.8 show the system responses for the first output and the second output together with the desired outputs, respectively. The failures have been properly accommodated by online adjustment of the control signals, while the nominal controller alone fails to maintain the system stability under multiple failures. Figures 8.9 and 8.10 show the online estimations together with the numerical values of the actual failures at each time-step.

The actual control inputs are shown in Figures 8.11 and 8.12. In this example, the length of the time-shifting data

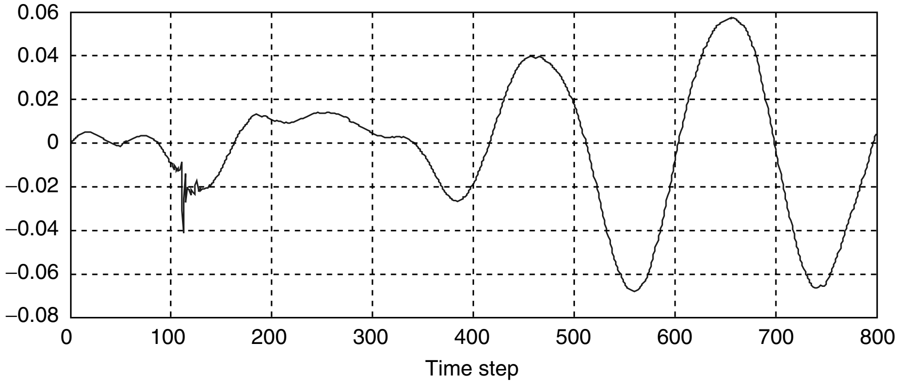

FIGURE 8.11 Control Input *u*1 (MIMO System; 25-Data Window)

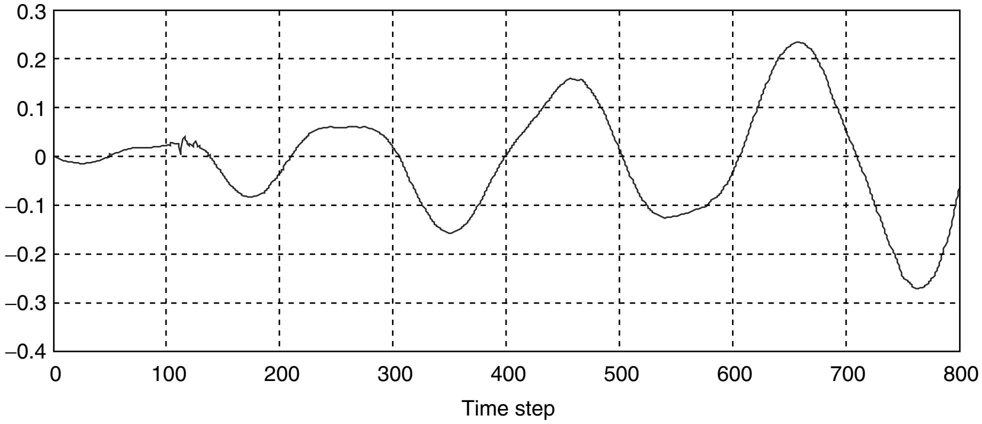

FIGURE 8.12 Control Input *u*2 (MIMO System; 25-Data Window)

window is selected as 25. Simulation tests show that this is a good trade-off number under the constraints of the system performance and the computational complexity. Two *S* functions are defined separately for system output 1 and 2 in the form of equation (8.4) with $a = 10$. A simple mean value of the two estimated gradient directions realized through the *NN* online estimator is used for searching the effective control inputs. This approach is based on the assumption that the searching directions of the effective control signals to accommodate failure dynamics do not conflict, which may not always be true under unanticipated catastrophic system failures. In general, this becomes a multiobjective optimization problem that remains to be an open issue (Zitzler and Thiele, 1999).

8.6.2 Intelligent FDA framework

To obtain a deeper insight into the online FDA problems in the real applications, a separate simulation study has been performed to test the proposed FDA framework. The design parameters, including the threshold value of failure alarms, threshold value in the failure diagnosis process, lengths of the evaluating windows for fault detection and for failure diagnosis, are preselected as $7.0 \times e^{-5}$, $5.0 \times e^{-6}$, 5, and 10, respectively. Consider a nominal system described in equation 8.32 where the system dynamics is not in linear-in-control format, and the nominal model is first realized by a 3–30–1 MLP network. The nominal controller is designed using the same technique described in Subsection 8.6.1:

$$y(k+1) = 0.3y(k) + 0.6y(k-1) + u(k)^2 - 5u(k). \quad (8.32)$$

Three postfailure modes are shown in equation 8.33:

- **Postfailure 1:** $pf_1(k+1) = -(0.3y(k) + 0.6y(k-1) + u(k)^2 - 5u(k)) + 0.06y(k)^2 + 4u(k). \quad (8.33a)$
- **Postfailure 2:** $pf_2(k+1) = 0.05 \times y(k) \times \cos(u(k)). \quad (8.33b)$
- **Postfailure 3:** $pf_3(k+1) = -0.8 \times u(k)^2 + 3.5u(k). \quad (8.33c)$

To simulate the failures in a real dynamic system, the specific mathematical formats of these failure dynamics are assumed unknown and have to be realized by separate network models. The idea is described in the following steps:

1. Place the system under failure situations (i.e., using the nominal mathematical model with the failure dynamics in simulation stage).
2. Feed in 3000 uniformly distributed random input signals varying from −1.5 to 1.5 with selected initial conditions.
3. Collect the training patterns. The desired outputs are computed by using the differences between the system outputs and the outputs from the nominal model.
4. Train the model for the failure dynamics.

Three separate MLP networks with different structures, 3–30–1, 2–20–1, 1–20–1, are used to realize the three post failures offline, respectively, by following the above steps. The postfailure control actions are also realized by using *NN* controllers (i.e., 3–20–1, 3–20–1, and 3–10–1 MLP networks), and they are obtained using the same technique as described in Section 5.1. The preselected value for the diagnosis process is $1.0 \times e^{-4}$ and the rest of the design parameters are the same as those in Subsection 8.6.1.

Scenario 1

Consider the failure situation containing an **abrupt anticipated failure mode 3** starting at time step 70 and an **incipient unanticipated time-varying failure** with the corresponding time profile shown in equation 8.34:

$$\begin{aligned} f_2(\cdot) &= \frac{ky(k)}{320 \times (1 + y(k-1)^2)}; \\ \beta_2(k - T_2) &= \left(1 - e^{-0.2\times(k-T_2)}\right) U(k - T_2);\ T_2 = 314. \end{aligned} \quad (8.34)$$

Figures 8.13 through 8.15 show the online simulation results under the intelligent FDA framework. The abrupt anticipated failure mode 3 that occurred at time-step 70 is quickly recognized by the diagnosis process, and the effective control commands are then switched to the corresponding postfailure control actions. This is clearly seen in the online system status plot shown in Figure 8.14 and the system online response shown in Figure 8.13. Observing Figure 8.15 closely, one can also find that the time domain signatures of actual failure dynamics and the postfailure mode 3 are almost undistinguishable from time-step 80 to 320. After the second change of the system dynamics caused by another time-varying incipient failure, the discrepancy between the signatures are getting large, which indicates that an unanticipated situation has occurred.

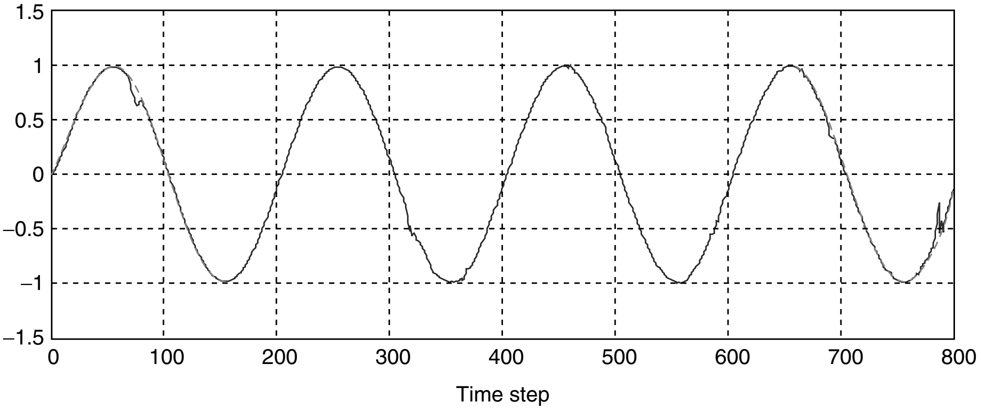

FIGURE 8.13 System Response Versus Desired Output (Scenario 1; General Case; FDA Simulation). Solid line: Acutal output/Dashed line: Desired output.

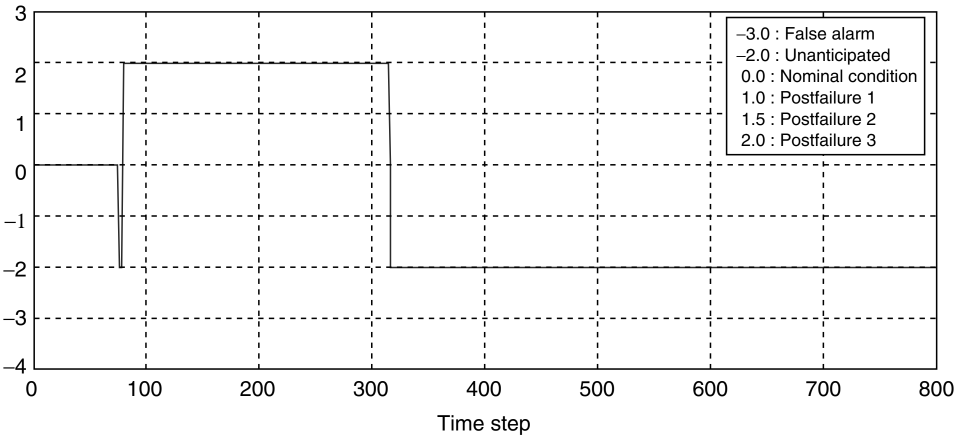

FIGURE 8.14 System Status (Scenario 1; General Case; FDA Simulation)

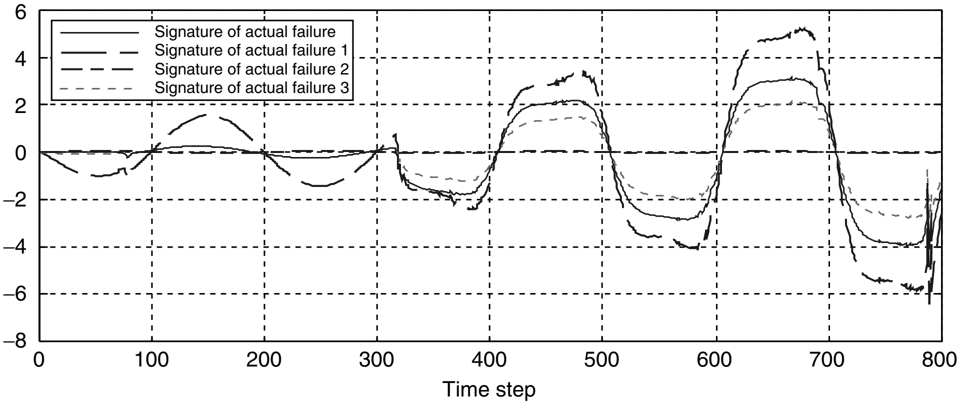

FIGURE 8.15 Signatures of Postfailures Versus Actual Failure Dynamics (Scenario 1; General Case; FDA Simulation)

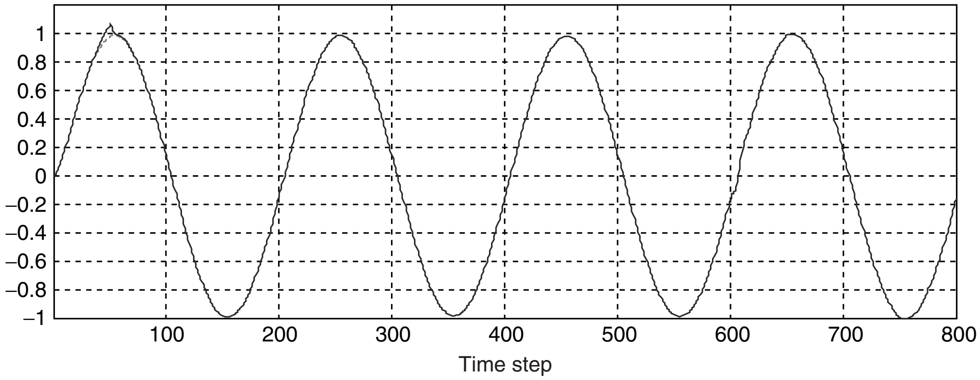

FIGURE 8.16 System Response Versus desired Output (Scenario 2; General Case; FDA Simulation). Solid line: Acutal output/Dashed line: Desired output.

Scenario 2

Consider the failure situation containing an **incipient anticipated failure mode 2** with the time profile shown in equation (8.35) and an **abrupt anticipated failure mode 3** starting at time-step 601:

$$\beta_1(k - T_1) = (1 - e^{-0.009\times(k-T_1)})U(k - T_1);\ T_1 = 25. \quad (8.35)$$

Figures 8.16 through 8.18 are the plots of the test results. Due to the slow variation of the failure dynamics (with $\alpha_1 = 0.009$), the incipient fault is not identified as quickly as an abrupt

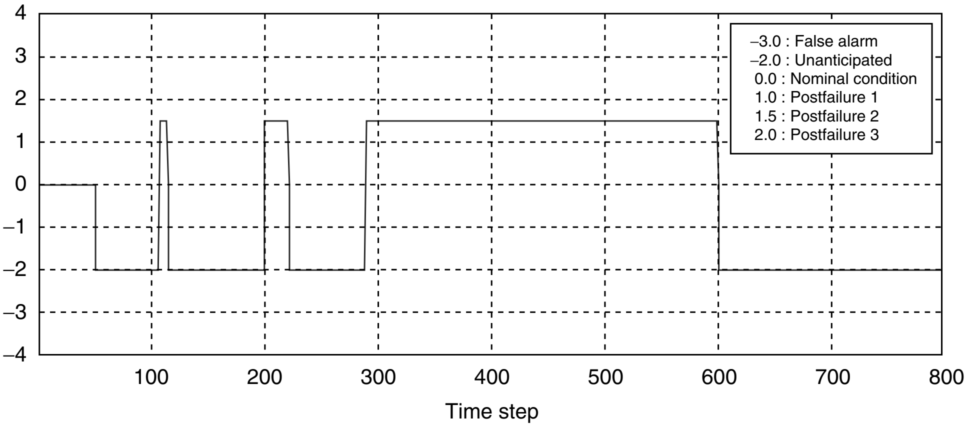

FIGURE 8.17 System Status (Scenario 2; General Case; FDA Simulation)

failure since this incipient time profile will take almost 300 time-steps to converge (i.e., 300 time-steps are required for the time profile to reach 0.9328). Figure 8.17 shows this expected result. The failure diagnosis scheme cannot be sure of the actual failure situation until the time-step almost reaches 300. This is also a correct decision since both the failure dynamics and the corresponding control actions are realized by *NN* under the abrupt failure situation. However, diagnostic oscillation is not observed before time-step 290. It appears that the diagnostic threshold value, $1.0 \times e^{-4}$, may be too big for the accuracy of the *NN* postfailure 2. Observing Figure 8.18 closely, it is easy to tell there are signature differences between the actual failure and the postfailure 2 from time-step 100 to 220. In other words, the *NN* postfailure model 2 in this case may be accurate enough to use a smaller threshold value to have a better diagnostic report. This result suggests that, for better failure diagnosis, the selection of the diagnostic threshold value should be failure-dependent and also should be chosen based on the accuracy of the *NN* postfailure model.

8.6.3 False Alarm Situations

The nominal system and the nominal controller in the general case are selected to test the false alarm situation under the intelligent FDA architecture. To simulate the false failure alarm possibly caused by *unexpected* measurement noises, uniformly distributed random white noises are generated and added to the measurements, which are used for fault detection defined in equation. The unknown and unexpected white noises are generated during three time periods: time-steps 78 to 81, 212 to 215, and 465 to 466. The added noises are varying from −0.3 to 0.3, -0.23 to 0.23, and -0.85 to 0.85, respectively. The simulation results are plotted and shown in Figures 8.19 through 8.21.

Figure 8.20 indicates how the proposed FDA framework reacts to the false alarm situation caused by unknown noises. Once the contaminated measurements trigger the alarm, the system behavior is immediately examined by failure diagnosis, and, since the measurements are contaminated by noises, it will not be recognized as any one of the anticipated failures.

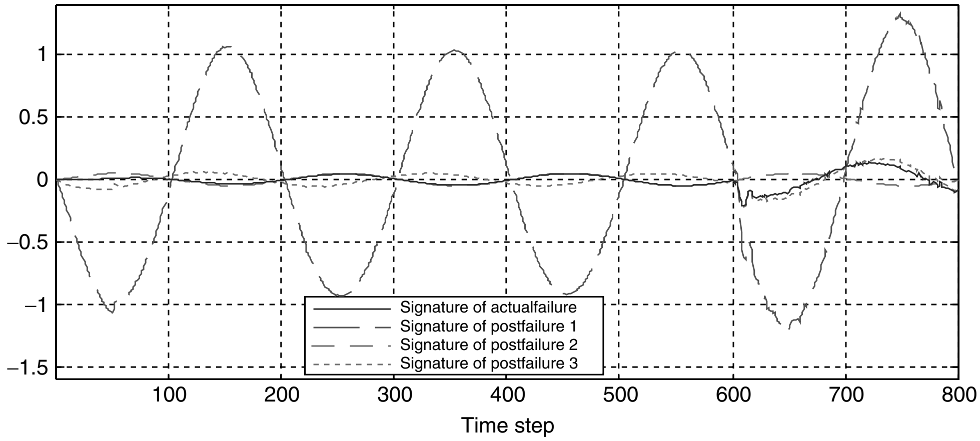

FIGURE 8.18 Signatures of Postfailures Versus Actual Failure Dynamics (Scenario 2; General Case; FDA Simulation)

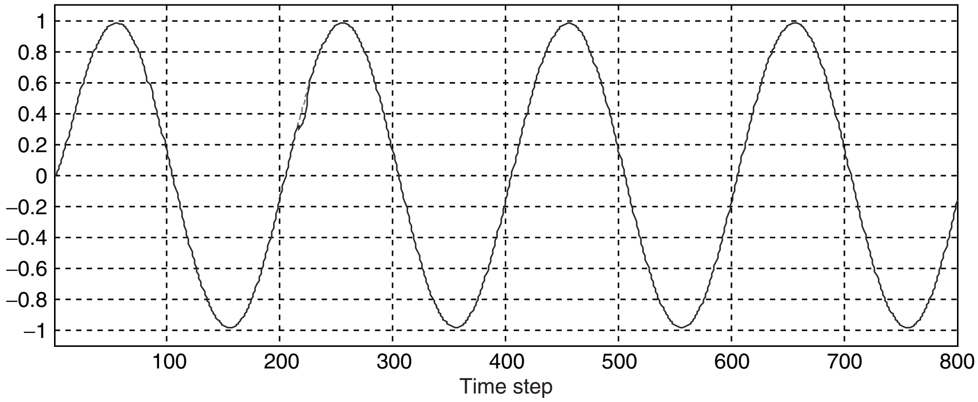

FIGURE 8.19 System Response Versus Desired Output (False Alarm Situations; FDA Simulation). Solid line: Acutal output/Dashed line: Desired output.

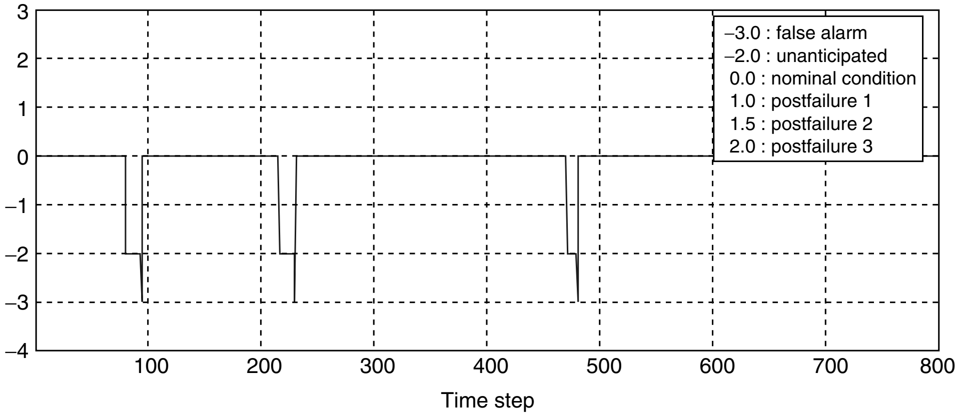

FIGURE 8.20 System Status (False Alarm Situations; FDA Simulation)

Thus, the diagnostic result will suggest an unanticipated situation. However, after the effect resulting from unexpected noises decays, the fault-detection scheme discovers that the system behavior is as normal as it is under the nominal situation. After double checking that this situation, the fault-detection scheme flags a false alarm signal, and the system status is switched back to the nominal condition. Figure 8.19 shows some slight deviations of the system output away from the desired trajectory during the periods of noisy data, which is apparently caused by the fact that the contaminated measurements are used directly in the fault-detection scheme and in the unanticipated failure conditions as the learning targets for failure accommodation.

8.6.4 Comments and Discussions

Many simulation tests have been omitted in this chapter due to space limitation. The following summaries, however, can be drawn:

1. The design parameters of the fault-detection scheme, such as the length of the time-shifting evaluating window and threshold values, have direct effects on the system performance. Short-evaluating window in the fault-detection scheme may result in a sensitive failure detector, while a long one may appear to be too slow to take proper accommodation.
2. Similar conditions also exist for failure diagnosis. The smaller threshold value gives more restriction in failure recognition and thus provides a more conservative diagnostic result. It also implies that more computational cost may possibly be spent due to the conservative attitude. On the other hand, if the value appears to be too big, large uncertainty may exist in the diagnostic result. Thus, the control actions may switch among nominal controller, postfailure control actions, and intelligent control regulator. The best design of these parameters should be on system-dependent bases.

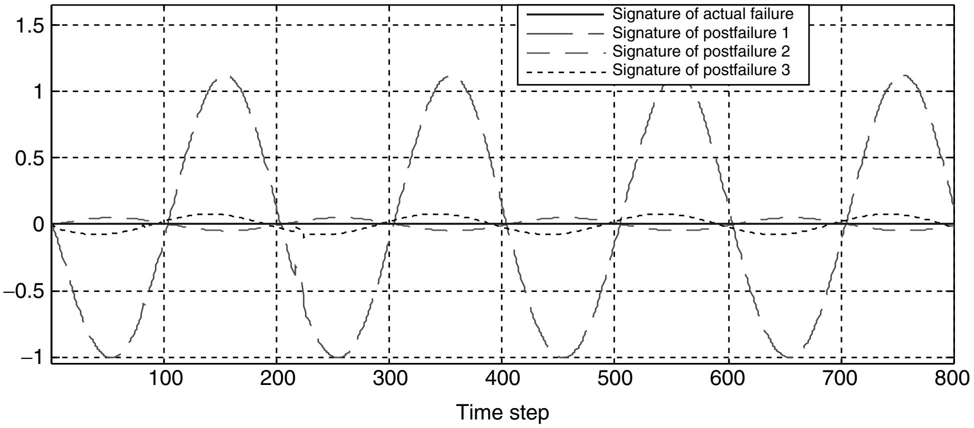

FIGURE 8.21 Signatures of Postfailures Versus Actual Failure Dynamics (False Alarm Situations; FDA Simulation)

8.7 Conclusion

In research work presented in this chapter, the online fault accommodation control problems under various system failures were investigated. The major interest was focused on dealing with the *unanticipated* system failures in the general formulation. Through discrete-time Lyapunov stability theory, the necessary and sufficient conditions to guarantee the system online stability and performance under failures were derived together with an online fault accommodation control technique. In general, the effectiveness of the developed online fault accommodation technique for unanticipated system failures was demonstrated through the simulation study. Based on modern intelligent techniques, the unexpected failures could be identified and properly accommodated online without the complete realization of the failure dynamics. The price paid for this achievement of the successful control mission relies on a certain degree of computational complexity. Simulation results indicate that, under the Levenberg-Marquardt training algorithm with Bayesian regularization (Demuth and Beale, 1998; Mackey, 1992), the online learning of the unanticipated failure dynamics usually converges within 10 iterations, and the online simulation speed can reach two to three time-steps per second under the Intel Pentium II 450 dual processors. Although this may not be fast enough in many real-time control systems that require a higher sampling rate, it is believed that with the continuous performance improvement of microprocessors and semiconductor technology, the proposed online fault accommodation technique will be implemented online in most of the real-time control systems in near future.

A complete architecture for intelligent fault diagnosis and accommodation has also been presented by incorporating the proposed intelligent fault-tolerant control technique with a cost-effective fault-detection scheme and a multiple model-based failure diagnosis process to efficiently handle the false alarms and the accommodation of the anticipated failure modes. Simulation results indicate that unnecessary control effort and computational complexity have been significantly reduced in online situations when the failures are anticipated. Under the multiple model-based failure diagnosis process together with the postfailure control actions, a successful fault isolation mission is quickly reached through the multiple model failure recognition. System performance recovery can be obtained through the multiple model switching in the postfailure control actions.

To obtain a sophisticated understanding for the speed limit of the developed online fault accommodation technique under the realtime control system with currently available microprocessors, an experimental online real-time fault-tolerant control test bed is currently under construction for examining the proposed control framework in real hardware. The major attention of the future research work is also focused on testing the online fault accommodation control framework in general MIMO cases where the control problems are both theoretically and technically complicated since the searching of effective control signals to accommodate the multiple failures becomes a multiobjective optimization problem, which is still one of the remaining open research issues. Thus, how to systematically reorganize the priorities of the control missions related to both system stability and performance for the general MIMO system under multiple failures in the online situation becomes challenging work.

Gain-Scheduled Controllers

Christopher J. Bett
Raytheon Integrated Defense Systems,
Tewksbury, Massachusetts, USA

9.1 Introduction

Gain scheduling is a practical and powerful method for the control of nonlinear systems. A gain-scheduled controller is formed by interpolating between a set of linear controllers derived for a corresponding set of plant linearizations associated with several operating points. The interpolation is based on exogenous scheduling parameters that vary slowly and capture the plant nonlinearities. The resulting controller is a linear system whose parameters (gains) are adjusted (scheduled) as a function of the exogenous scheduling variables.

Gain scheduling is attractive because it exploits linear control design methods that are theoretically mature, are well-understood, and involve computationally efficient synthesis procedures. Because the control design is based on linear approximations to the plant, the designer can guarantee that at each operating point, the feedback system has the desired stability and performance properties. In addition, because the controller gains are adjusted to reflect the plant operating conditions, the gain-scheduled control system has the potential of responding rapidly to changing operating conditions. The gain-scheduling method has been proven sound by successful application throughout industry.

Although the gain-scheduling approach is a simple extension of linear design methods, the technique can guarantee closed-loop stability and performance only in a local sense. Stability and performance properties of the gain-scheduled designs must be inferred from extensive simulation studies. The operating region where stability and performance is ensured is difficult to quantify. Furthermore, the designer must typically resort to heuristic methods to derive the scheduling law.

This chapter describes the historical approach to gain scheduling, discussing options for developing the scheduling law and noting some of the gain-scheduling lessons that have received theoretical justification in recent years. More recent gain scheduling results are presented for the class of systems modeled as linear parameter varying (LPV) systems. For LPV systems, some of the difficulties associated with gain scheduling designs are alleviated. Specifically, recent theoretical developments have made it possible to simultaneously synthesize the controller and scheduling law to guarantee stability and performance over a known set of parameter variations.

9.2 Gain-Scheduling Design Through Linearization

In the classical approach to gain scheduling, the nonlinear plant is linearized about a set of operating conditions or equilibrium points. For each linearized plant, a linear controller is derived to satisfy applicable performance requirements, such as disturbance rejection or transient response specifications. The gain-scheduled controller is formed by interpolating, or **scheduling**, among the set of linear control laws.

Gain scheduling is typically performed on an exogenous scheduling parameter that characterizes the operating environment. In a missile guidance application, for example, autopilot gains might be scheduled on temperature, air pressure, Mach number, or a combination of these. The scheduling parameter will be denoted by an s-dimensional vector, θ, that takes values in a compact subset, $\Theta \subset \Re^s$, called the **parameter set**. Associated with Θ is a signal space known as the **parameter variation set**, $\mathcal{F}_\Theta$, that is the set of all continuous functions mapping $\Re^+$ into Θ.

The notation $\theta \in \mathcal{F}_\Theta$ denotes a function in the parameter variation set; $\theta \in \Theta$ denotes a vector in a compact subset of $\Re^s$. Note that both $\mathcal{F}_\Theta$ and, for instance, $\mathcal{L}_\infty^n$ represent signal spaces. Technically, $\mathcal{F}_\Theta \subset \mathcal{L}_\infty^s$ since $\mathcal{F}_\Theta$ consists of supremum bounded s-dimensional vectors that vary continuously in time. In this discussion, $\mathcal{F}_\Theta$ will always refer to parameter signals or parameter variations; $\mathcal{L}_\infty^n$ will refer to signals in the plant input, output, or state-space.

9.2.1 Linearization

Consider a nonlinear plant with dynamics represented by:

$$\begin{aligned} \dot{\bar{x}} &= f(\bar{x}, w, \bar{u}, \theta). \\ \bar{z} &= g(\bar{x}, w, \bar{u}, \theta). \\ \bar{y} &= h(\bar{x}, w, \bar{u}, \theta). \end{aligned} \tag{9.1}$$

The $\bar{x}$ is the $n \times 1$ state vector, w is the $n_w \times 1$ vector of exogenous disturbances, u is the $n_u \times 1$ control input vector, z is the $n_z \times 1$ error vector, and y is the $n_y \times 1$ measurement vector. Time dependency has been suppressed for notational convenience. For fixed θ, the nonlinear plant can be linearized in the usual fashion to yield:

$$\begin{bmatrix} \dot{x} \\ \hline z \\ y \end{bmatrix} = \left[\begin{array}{c|cc} A(\theta) & B_w(\theta) & B_u(\theta) \\ \hline C_z(\theta) & D_{zw}(\theta) & D_{zu}(\theta) \\ C_y(\theta) & D_{yw}(\theta) & D_{yu}(\theta) \end{array}\right] \begin{bmatrix} x \\ \hline w \\ u \end{bmatrix} =: P(\theta) \begin{bmatrix} x \\ \hline w \\ u \end{bmatrix}, \tag{9.2}$$

where

$$P(\theta) = \left.\left[\begin{array}{c|cc} \frac{\partial}{\partial x} f(x, w, u, \theta) & \frac{\partial}{\partial w} f(x, w, u, \theta) & \frac{\partial}{\partial u} f(x, w, u, \theta) \\ \hline \frac{\partial}{\partial x} g(x, w, u, \theta) & \frac{\partial}{\partial w} g(x, w, u, \theta) & \frac{\partial}{\partial u} g(x, w, u, \theta) \\ \frac{\partial}{\partial x} h(x, w, u, \theta) & \frac{\partial}{\partial w} h(x, w, u, \theta) & \frac{\partial}{\partial u} h(x, w, u, \theta) \end{array}\right]\right|_{(x,\, w,\, u) = (x_{eq}(\theta),\, 0,\, u_{eq}(\theta))},$$

and the pair $(x_{eq}(\theta), u_{eq}(\theta))$ represents the equilibrium point of the nonlinear system for a fixed value of θ; that is, the pair satisfies:

$$\begin{aligned} 0 &= f(x_{eq}(\theta), 0, u_{eq}(\theta), \theta). \\ z_{eq} &= g(x_{eq}(\theta), 0, u_{eq}(\theta), \theta). \\ y_{eq} &= h(x_{eq}(\theta), 0, u_{eq}(\theta), \theta). \end{aligned} \tag{9.3}$$

The input, output, and state vectors for the linearized system in equation 9.2 are the deviations from the operating point for a fixed value of θ:

$$\begin{aligned} x &:= \bar{x} - x_{eq}(\theta). \\ u &:= \bar{u} - u_{eq}(\theta). \\ z &:= \bar{z} - z_{eq}(\theta). \\ y &:= \bar{y} - y_{eq}(\theta). \end{aligned}$$

9.2.2 Scheduling Law

For linearizations associated with a fixed set of scheduling parameters, $\Theta_0 := \{\theta_i | i = 1, \ldots, N\} \subset \Theta$, there are the linear controllers:

$$\begin{bmatrix} \dot{v} \\ \hline u \end{bmatrix} = \left[\begin{array}{c|c} F_i & G_i \\ \hline H_i & J_i \end{array}\right] \begin{bmatrix} v \\ \hline y \end{bmatrix} =: K_i \begin{bmatrix} v \\ \hline y \end{bmatrix}, \tag{9.4}$$

which are designed for each $\theta_i \in \Theta_0$. The linear controllers can be designed by any applicable design technique. Here, v is the $m \times 1$ controller state vector, and the controller matrices are of the proper dimension.

The scheduling law is chosen, typically, in ad hoc fashion as either a continuous or discrete scheduling law. In continuous scheduling, parameters of the gain scheduled controller vary continuously with the scheduling parameter and are commonly formed through interpolation of the fixed-point controller parameters. The interpolated controller parameters may be feedback gains, elements of the controller matrices, or controller poles/zeros. While the fixed-point controllers are linear, the parameter interpolation method need obey no such restriction.

As an example, suppose that θ is a scalar and that the fixed operating points are ordered so that $\theta_1 < \theta_2 < \cdots < \theta_N$. A simple, continuous scheduling law is then given by:

$$K = \begin{cases} K_1 & \theta < \theta_1 \\ \left(\dfrac{\theta - \theta_i}{\theta_{i+1} - \theta_i}\right) K_i + \left(\dfrac{\theta_{i+1} - \theta}{\theta_{i+1} - \theta_i}\right) K_{i+1} & \theta_i \leq \theta \leq \theta_{i+1},\ i = 1, \ldots, N-1 \\ K_N & \theta \geq \theta_N \end{cases} \tag{9.5}$$

Note that no extrapolation is performed for $\theta < \theta_1$ or $\theta \geq \theta_N$. If the parameter is known to vary significantly beyond (θ_1, θ_N), then additional design points should be chosen.

In discrete scheduling, parameters of the gain-scheduled controller are switched when the parameter trajectory evolves out of a predefined subset of the parameter set, $\Theta_i \subset \Theta$. This is true, for instance, when the distance between the current operating condition and the design point associated with the current controller parameters exceeds a design threshold. Expanding on the preceding example, a simple discrete scheduling law is given by:

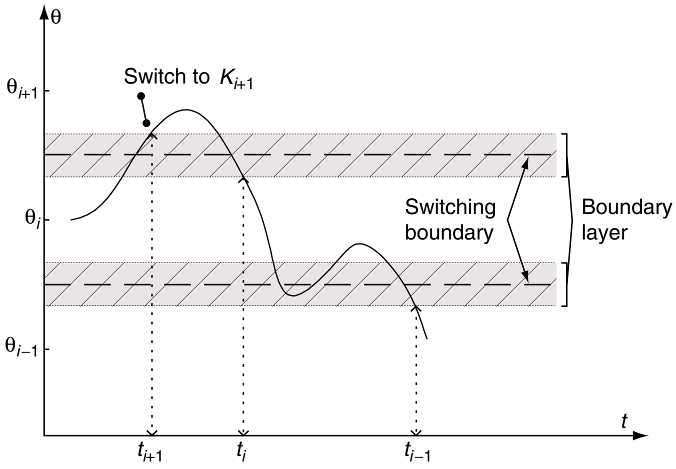

FIGURE 9.1 Hysteresis in Discrete Scheduling

$$K = \begin{cases} K_1 & \theta \leq \frac{1}{2}(\theta_1 + \theta_2). \\ K_i & \frac{1}{2}(\theta_{i-1} + \theta_i) < \theta \leq \frac{1}{2}(\theta_i + \theta_{i+1}), i = 2, \ldots, N-1. \\ K_N & \theta > \frac{1}{2}(\theta_{N-1} + \theta_N). \end{cases} \tag{9.6}$$

Often, the switching law will employ a hysteresis to prevent chattering (fast switching) if the scheduling parameter evolves near a switching boundary. The hysteresis simply delays the switch to new controller parameters until the parameter has moved beyond a boundary layer encompassing the switching boundary, as illustrated in Figure 9.1.

9.2.3 Discussion

It is important to remember that the gain scheduling methods just described are, in general, justified through repeated use and do not have rigorous theoretical justification. The methods are generally implemented in an ad hoc manner appropriate to the problem at hand; achievable performance may be sensitive to the form of scheduling law and the form of the controller matrices.

In some cases, scheduling parameters are chosen to be functions of the plant variables to make the problem more tractable from a design standpoint. Because the scheduling parameter is no longer independent of the plant variables (e.g., $\partial\theta/\partial x \neq 0$), the closed-loop system formed by the linearized plant and linear controllers does not match the linearized closed-loop plant. The differences in the closed-loop realizations are due to hidden coupling modes whose presence may degrade or limit achievable performance. Although there is no comprehensive theory for removing these modes from the gain-scheduled design, examples are present in the literature (Nichols *et al.*, 1993). As a rule, the designer must exhibit additional caution in ensuring that the scheduling parameter does not vary too rapidly.

For discrete scheduling designs, abrupt changes in the controller output can occur at switching instants. These changes may cause excitation of unmodeled plant dynamics, degrading performance and possibly leading to catastrophic failure. To mitigate these risks, one must resort to techniques such as bumpless transfer (Hanus *et al.*, 1987) or ensure that the design can tolerate the switching through other methods (Bett and Lemon, 1999).

In both the continuous, and discrete gain-scheduling designs, stability and performance of the gain-scheduled system can, in general, only be guaranteed in a neighborhood of the current operating condition. Specifically, the gain-scheduled design is not guaranteed stable or guaranteed to exhibit desired performance properties for all $\theta \in \Theta$, or for all $\theta \in \mathcal{F}_\Theta$. It is the latter of these two conditions that is the most difficult to guarantee. Further assurances of stability and performance must be derived from extensive simulation and testing. Successful designs typically involve scheduling on a slowly changing variable that captures the nonlinear behavior of the plant.

The difficulties associated with applying the gain-scheduling techniques just described stem from the local nature of the results and the lack of formal methods for deriving the scheduling law. These difficulties manifest themselves in increased simulation, test, and redesign. For the so-called linear parameter varying plants, these difficulties can be alleviated. For linear parameter varying plants, modern linear robust control techniques can be applied to the design of a gain-scheduled controller without the need for *ad hoc* interpolation methods.

9.3 Gain Scheduling for Linear Parameter Varying Systems

9.3.1 LPV Systems

A linear parameter varying system may be viewed as a linear system whose parameters depend on an exogenous variable, as stated in the following definition.

Definition 1 (LPV System)
Given a compact set $\Theta \subset \Re^s$ and continuous functions A: $\Re^s \to \Re^{n\times n}$, B: $\Re^s \to \Re^{n\times n_w}$, C: $\Re^s \to \Re^{n_z\times n}$, and D: $\Re^s \to \Re^{n_z\times n_w}$, an nth order linear parameter varying (LPV) system is a dynamical system whose dynamics evolve as:

$$\begin{bmatrix} \dot{x}(t) \\ z(t) \end{bmatrix} = \begin{bmatrix} A(\theta(t)) & B(\theta(t)) \\ C(\theta(t)) & D(\theta(t)) \end{bmatrix} \begin{bmatrix} x(t) \\ w(t) \end{bmatrix}, \tag{9.7}$$

where $\theta \in \mathcal{F}_\Theta$.

Although the trajectory of $\theta(t)$ is not known a priori, it is assumed to be measurable in real-time, thus providing real-time information on the behavior of the system. LPV systems can occur naturally (an LTI plant subject to a time-varying parameter uncertainty) or can be formed through linearization of a nonlinear plant. Given the latter interpretation, a gain-scheduled controller can be designed for the LPV system using the approach described in Section 9.2. The inherent structure of the LPV system, however, lends itself to the application of linear robust control design methods, and recent theoretical results have led to gain-scheduled controller synthesis approaches for LPV systems that form the controller and scheduling law directly.

The remainder of this section is concerned with determining an LPV controller, $K(\theta)$, with state-space realization:

$$\begin{aligned} \dot{v} &= A_k(\theta)v + B_k(\theta)y. \\ u &= C_k(\theta)v + D_k(\theta)y. \end{aligned} \tag{9.8}$$

Equation 9.8 applies to the LPV plant, $P(\theta)$, with LPV state-space realization:

$$\begin{aligned} \dot{x} &= A(\theta)x + B_w(\theta)w + B_u(\theta)u. \\ z &= C_z(\theta)x + D_{zu}(\theta)u. \\ y &= C_y(\theta)x + D_{yw}(\theta)w. \end{aligned} \tag{9.9}$$

The closed-loop LPV system shown in Figure 9.2, denoted $\mathcal{F}_\ell(P(\theta), K(\theta))$, is asymptotically stable and posesses the appropriate performance attributes. Synthesis conditions for induced-$\mathcal{L}_2$ and induced-$\mathcal{L}_\infty$ are presented. In both cases, gain-scheduled controller synthesis is achieved by solving a set of linear matrix inequalities.

9.3.2 Controller Synthesis for Induced-$\mathcal{L}_2$ Performance

The induced-$\mathcal{L}_2$ norm is commonly interpreted as the gain applied to the energy of an input signal; designing a controller to limit the induced-$\mathcal{L}_2$ norm of various system loops ensures that internal or output signal energy does not exceed prescribed thresholds. This has obvious implications for overall system performance. The design objective is commonly applied in loop shaping and disturbance rejection problems when the energy spectral density of the input disturbance is known (or bounded). Induced-$\mathcal{L}_2$ controller synthesis is also known as $\mathcal{H}_\infty$ synthesis.

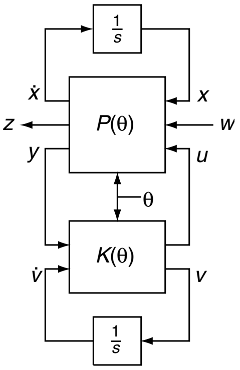

FIGURE 9.2 LPV Control System

The induced-$\mathcal{L}_2$ gain is defined in the usual manner from the associated signal norm.

Definition 2 (Induced-$\mathcal{L}_2$ Gain)
The two-norm of a signal $f: \Re^+ \to \Re^n$ is defined as:

$$\|f\|_2 := \left(\int_0^\infty f'(t)f(t)dt \right)^{1/2}.$$

The $\mathcal{L}_2^n$ denotes the normed n-dimensional signal space in the usual fashion under the above signal norm definition. Consider the LPV system of definition 9.1. For any $\theta \in \mathcal{F}_\Theta$ with $x(t_0) = 0$, the causal linear input/output mapping, $G_\theta: \mathcal{L}_2^{n_w} \to \mathcal{L}_2^{n_z}$, of the linear time-varying system described in equation 9.7 is defined as:

$$G_\theta w(t) = \int_{t_0}^{t} C(\theta(\tau))\Phi_\theta(t, \tau)B(\theta(\tau))w(\tau)d\tau + D(\theta(t))w(t),$$

where $\Phi_\theta(t, t_0)$ is the associated state transition matrix. The induced-$\mathcal{L}_2$ norm of G_θ is given by:

$$\|G_\theta\|_{i2} := \sup_{w \in \mathcal{L}_2^{n_w}, \|w\|_2 < 1} \|G_\theta w\|_2. \tag{9.10}$$

The induced-$\mathcal{L}_2$ synthesis conditions presented here are valid under the assumptions that, for all $\theta \in \Theta$:

- $(A(\theta), B_u(\theta), C_y(\theta))$ are controllable and detectable;
- $D_{zu}(\theta)$ has full column rank; and
- $D_{yw}(\theta)$ has full row rank.

Fix a performance level $\gamma > 0$ and consider the LPV plant in equation 9.9 under the preceding assumptions. A sufficient condition for the existence of a finite-dimensional LPV controller $K(\theta)$ that internally stabilizes the system and renders:

$$\|\mathcal{F}_\ell(P(\theta), K(\theta))\|_{i,2} < \gamma,$$

for all $\theta \in \mathcal{F}_\Theta$ is the existence of matrices $\hat{A} \in \Re^{n \times n}$, $\hat{B} \in \Re^{n \times n_y}$, $\hat{C} \in \Re^{n_u \times n}$, and $\hat{D} \in \Re^{n_u \times n_y}$, along with $n \times n$ positive definite symmetric matrices X and Y, so that for all $\theta \in \Theta$:

$$R(\theta) < 0 \quad \text{and} \quad \begin{bmatrix} X & I \\ I & Y \end{bmatrix} > 0, \tag{9.11}$$

where the (i, j)th blocks of the symmetric matrix $R(\theta)$ are given by:

$$
\begin{aligned}
[R(\theta)]_{1,1} &= XA(\theta) + A(\theta)'X + \hat{B}C_y(\theta) + C_y(\theta)'\hat{B}'.\\
[R(\theta)]_{1,3} &= XB_w(\theta) + \hat{B}D_{yw}(\theta).\\
[R(\theta)]_{2,1} &= \hat{A}' + A(\theta) + B_u(\theta)D_kC_y(\theta).\\
[R(\theta)]_{2,2} &= A(\theta)Y + YA(\theta)' + B_u(\theta)\hat{C} + \hat{C}'B_u(\theta)'.\\
[R(\theta)]_{2,3} &= B_w(\theta) + B_u(\theta)D_kD_{yw}(\theta).\\
[R(\theta)]_{3,3} &= \text{-}\gamma I_{n_w}.\\
[R(\theta)]_{4,1} &= C_z(\theta) + D_{zu}(\theta)D_kC_y(\theta).\\
[R(\theta)]_{4,2} &= C_z(\theta)Y + D_{zu}(\theta)\hat{C}.\\
[R(\theta)]_{4,3} &= D_{zu}(\theta)D_kD_{yw}(\theta).\\
[R(\theta)]_{4,4} &= \text{-}\gamma I_{n_z}.
\end{aligned}
\tag{9.12}
$$

If the matrix inequalities admit a solution, then a parameter-dependent controller is found by solving the factorization problem for matrices M and N such that:

$$I - XY = NM'. \tag{9.13}$$

The controller is also found by forming the parameter-dependent controller matrices from:

$$
\begin{aligned}
A_k(\theta) = N^{-1}(\hat{A} - X(A(\theta) - B_u(\theta)D_kC_y(\theta))Y\\
- \hat{B}C_y(\theta)Y - XB_u(\theta)\hat{C})(M^{-1})'.
\end{aligned}
\tag{9.14}
$$

$$B_k(\theta) = N^{-1}(\hat{B} - xB_u(\theta)D_k). \tag{9.15}$$

$$C_k(\theta) = (\hat{C} - D_kC_yY)(M^{-1})'. \tag{9.16}$$

The matrix inequality conditions of equation 9.11 represent a set of constraints that must be satisfied for each $\theta \in \Theta$; hence, they represent an infinite number of constraints. There are a variety of methods to make the problem tractable. The most attractive require a simple parameter-set geometry and linear fractional parameter dependence. When Θ is a polytope and the parameter dependence is multiaffine, then it is sufficient to evaluate the matrix inequalities simultaneously at the vertices of the polytope. If the dimension of Θ is small enough, the resulting set of linear matrix inequalities (LMIs) can typically be solved quickly using commercially available software on desktop computers. If the parameter dependence in the system matrix coefficients is linear fractional, then a technique known as the *S*-procedure (Boyd *et al.*, 1994) may be applied, though this technique can yield conservative results (Apkarian and Adams, 1998).

When the parameter set is not polytopic, one must typically resort to gridding the parameter set and simultaneously solving a set of LMIs defined at each grid point. The grid is refined until it is apparent (through solution convergence) that the solution will be valid for points not on the grid. Figure 9.3 illustrates the gridding approach for a parameter set defined by $\Theta := \{(\theta_1, \theta_2) : \theta_2 = \theta_1^2, \theta_1 \in [-1, 1]\}$. Note that as the grid is refined, the number of LMI constraints multiplies; LPV controller synthesis may become impractical from a computational standpoint.

Another approach is to attempt to satisfy the conditions for a polytopic set that contains Θ. In the preceding example, the synthesis problem could be approached by solving a set of LMIs defined at the vertices of the polytope $\{(\theta_1, \theta_2) : \theta_1 \in [-1, 1], \theta_2 \in [0, 1]\}$, as illustrated in Figure 9.3. The results of this alternative are potentially conservative since they must account for parameter variations that will not occur; worse, controllability or observability may be lost at some points in the larger parameter set so that the conditions of equation 9.11 do not admit a solution for any $\gamma > 0$.

9.3.3 Controller Synthesis for Induced-$\mathcal{L}_\infty$ Performance

A measure of system performance that frequently arises in control problems is the **peak value** of an appropriately selected

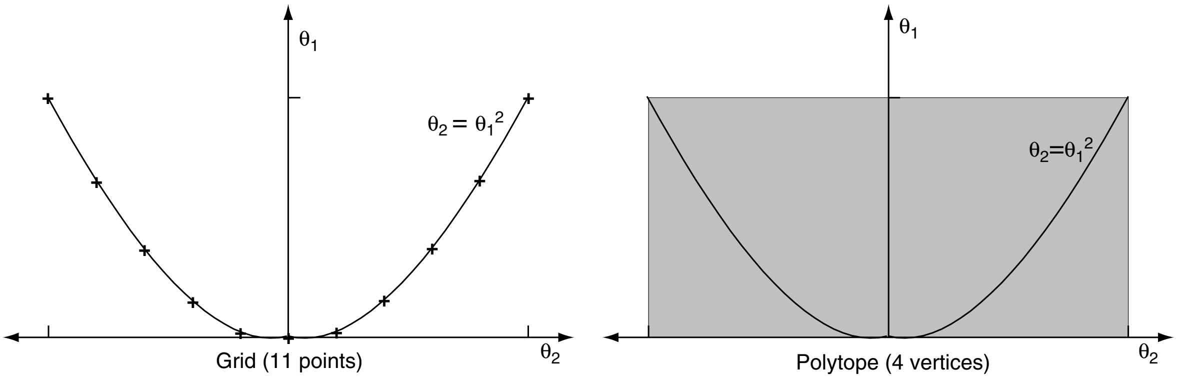

FIGURE 9.3 Alternatives for Nonpolytopic Parameter Sets

plant signal. Control problems in which this performance measure arise are prevalent in the literature: motor control problems with electrical (voltage or current) or mechanical (motion) restrictions and process control problems with chemical concentration restrictions are two examples. In each of these examples, violation of the amplitude restrictions can lead to performance degradation and possibly catastrophic system failure. In these types of performance problems, energy-based design techniques, such as the technique described in Subsection 9.3.1 are often inadequate. The problem considered in this section is that of synthesizing LPV controllers so that the controlled system satisfies bounded amplitude performance constraints; the approach presented here is based on results reported in Bett and Lemmon (1997).

The induced system gains are defined in the usual manner from the associated signal norms.

Definition 3 (Induced-$\mathcal{L}_\infty$ Gain)
The infinity norm of a signal $f: \Re^+ \rightarrow \Re^n$ is defined as:

$$\|f\|_\infty := \operatorname*{ess\,sup}_{t \geq 0} \|f(t)\|,$$

where $\|\cdot\|$ denotes the Euclidean vector norm and where $\mathcal{L}_\infty^n$ denotes the normed n-dimensional signal space in the usual fashion under the above signal norm definition. Consider the LPV system of definition 1. For any $\theta \in \mathcal{F}_\Theta$ with $x(t_0) = 0$, the causal linear input/output mapping, $H_\theta: \mathcal{L}_\infty^{n_w} \rightarrow \mathcal{L}_\infty^{n_z}$, of the linear time-varying system described in equation 9.7 is defined as:

$$H_\theta w(t) = \int_{t_0}^{t} C(\theta(\tau))\Phi_\theta(t, \tau)B(\theta(\tau))w(\tau)d\tau + D(\theta(t))w(t),$$

where $\Phi_\theta(t, t_0)$ is the associated state transition matrix. The induced-$\mathcal{L}_\infty$ norm of H_θ is given by:

$$\|H_\theta\|_{i\infty} := \sup_{w \in \mathcal{L}_\infty^{n_w},\ \|w\|_\infty < 1} \|H_\theta w\|_\infty. \tag{9.17}$$

The induced-$\mathcal{L}_\infty$ synthesis conditions presented here are valid under the assumptions that, for all $\theta \in \Theta$:

- $(A(\theta), B_u(\theta), C_y(\theta))$ are controllable and detectable;
- $D_{yw}(\theta)$ has full row rank; and
- $B_w(\theta)D_{yw}^{'}(\theta) = 0$.

Fix any number $\alpha > 0$ and performance level γ, and consider the LPV plant in equation 9.9 under the preceding assumptions. A sufficient condition for the existence of a strictly proper and finite-dimensional LPV controller $K(\theta)$ that internally stabilizes the system and renders:

$$\|\mathcal{F}_\ell(P(\theta), K(\theta))\|_{i,\infty} < \gamma,$$

for all $\theta \in \mathcal{F}_\Theta$, is the existence of matrices $Z = Z' > 0$ and V such that:

$$\begin{bmatrix} A(\theta)(Z - Y_\alpha) + (Z - Y_\alpha)A'(\theta) + B_u(\theta)V & Y_\alpha C_y^{'}(\theta) \\ +V'B_u^{'}(\theta) + \alpha(Z - Y_\alpha) & \\ C_y(\theta)Y_\alpha & -\frac{1}{\alpha}D_{yw}(\theta)D_{yw}^{'}(\theta) \end{bmatrix} \leq 0 \tag{9.18}$$

$$\begin{bmatrix} (Z - Y_\alpha) & (Z - Y_\alpha)C_z^{'}(\theta) + V'D_{zu}^{'}(\theta) \\ C_z(\theta)(Z - Y_\alpha) + D_{zu}(\theta)V & \gamma^2 I - C_z(\theta)Y_\alpha C_z^{'}(\theta) \end{bmatrix} > 0 \tag{9.19}$$

These equations apply for all $\theta \in \Theta$, where Y_α is the minimal stabilizing solution of the Riccati inequality:

$$\begin{aligned} &\left(A(\theta) + \frac{1}{2}\alpha I\right)Y_\alpha + Y_\alpha\left(A(\theta) + \frac{1}{2}\alpha I\right)' \\ &-\alpha Y_\alpha C_2^{'}(\theta)D_{21}(\theta)(D_{21}^{'}(\theta))^{-1}C_2(\theta)Y_\alpha + \frac{1}{\alpha}B_1(\theta)B_1^{'}(\theta) \leq 0 \end{aligned} \tag{9.20}$$

(Y_α is the minimal stabilizing solution of equation 9.20 if for any other positive definite solution, Y, to equation 9.20 $Y_\alpha - Y$ is negative definite.) In addition, if the above matrix inequalities admit a solution, then one controller that renders

$$\|\mathcal{F}_\ell(P(\theta), K(\theta))\|_{i,\infty} < \gamma$$

for all $\theta \in \mathcal{F}_\Theta$ is given by:

$$K = \left[\begin{array}{c|c} A(\theta) + B_u(\theta)\bar{J} - \alpha Y_\alpha C_y^{'}(\theta) & \alpha Y_\alpha C_y{}'(\theta)(D_{yw}(\theta)D_{yw}(\theta)')^{-1} \\ (D_{yw}(\theta)D_{yw}(\theta)')^{-1}C_y(\theta) & \\ \hline \bar{J} & 0 \end{array}\right], \tag{9.21}$$

where $\bar{J} := V(Z - Y_\alpha)^{-1}$.

If Θ is a singleton, then the above conditions are strengthened to necessary and sufficient. It should also be noted that the restriction that Y_α in equation 9.20 be a minimal stabilizing solution is overly restrictive for the existence of a self-scheduled controller. If this restriction, however, is removed, the results do not reduce to necessary and sufficient conditions in the LTI case.

The preceding result represents the key analytical device for the synthesis of LPV controllers satisfying prespecified amplitude performance constraints. Gain-scheduled controller synthesis is accomplished in an iterative fashion: perform a line search for values of $\alpha > 0$, solving (at each α) the synthesis conditions of equations 9.18 through 9.20 for the required matrices and/or the required performance level, γ. When the required performance has been achieved, the LPV controller is formed from the realization in equation 9.21.

The bounded amplitude performance results are intuitively satisfying because they are similar in flavor to the $\mathcal{H}_\infty$ results of Becker and Packard (1994); parameter-dependent controller synthesis requires the feasibility of a "controller" Riccati inequality (equation 9.18), an "observer" Riccati inequality (equation 9.20), and a "spectral radius" coupling inequality (equation 9.19). Thus, the approach to bounded amplitude control described here requires the same type of numerical solutions as, for example, induced-$\mathcal{L}_2$ control, though the bounded amplitude problem may be more computationally intensive due to the line search over α.

As in the induced-$\mathcal{L}_2$ problem, the synthesis conditions are represented by a set of constraints that must be satisfied for each $\theta \in \Theta$ and therefore represent an infinite number of constraints. The techniques discussed for the induced-$\mathcal{L}_2$ problem are applicable here as well.

9.4 Conclusions

Historically, gain scheduled controllers have been comprised of a set of linear controllers whose gains are adjusted according to a scheduling law derived via heuristic methods, such as interpolating on gains, poles and zeros. Gain scheduling via the linearization techniques described in Section 9.2 has traditionally been justified through successful application. For additional theoretical justification, see Rugh (1991) and Shamma and Athans (1990, 1991). Related theoretical work can be found in the area of extended linearization Baumann and Rugh (1986), which can be viewed as gain scheduling on input, output, or state variables rather than exogenous scheduling variables. This approach involves nonlinear control design in the spirit of the gain-scheduling approach described in Section 9.2.

Gain-scheduling methods for LPV systems have emerged only recently. The relationship between gain scheduling via linearization and parameter-dependent systems is explained in Shamma and Athans (1990, 1991). Early work on parameter-dependent controllers is covered in Kamen and Khargonekar (1984); more recently, parameter-dependent synthesis approaches based on Lyapunov and small-gain techniques have appeared (Becker and Packard, 1994; Packard, 1994; Apkarian and Gahinet, 1995) and frame the synthesis problem as a convex optimization problem. These approaches generalize $\mathcal{H}_\infty$ techniques for LTI systems to LPV systems. Other methods are described in Apkarian and Adams (1998) and Apkarian *et al.* (1995).

The primary advantage of dealing with LPV systems is that difficulties associated with the derivation of the scheduling law and verifying performance of the controlled system are alleviated. The methods applied to LPV systems inherently account for the time-varying nature of the plant and handle the entire parameter set with a single design. The need for extensive simulations can be significantly reduced.

The LPV synthesis conditions described here make use of a fixed Lyapunov function (as opposed to one that depends on the scheduling variables) to characterize stability and performance. Such approaches are potentially conservative because they allow for arbitrary rates of variation in the scheduling variables, a generalization that may render the synthesis conditions infeasible. A significant improvement over such techniques can be obtained by exploiting the concept of parameter-dependent Lyapunov functions. Parameter-dependent Lyapunov functions allow incorporation of knowledge on the parameter variation rate into the analysis or synthesis technique and can lead to less conservative answers. Implementation of solutions based on parameter-dependent Lyapunov functions require not only the real-time measurement of the parameter but also its time derivative. This is generally prohibitive because such values are either unavailable or difficult to estimate in real-time. Generally speaking, there is no systematic rule for selecting the functional dependence of the Laypunov function on the parameter. The key idea is to mimic the parameter dependence of the plant in the Lyapunov function variables.

Sliding-Mode Control Methodologies for Regulating Idle Speed in Internal Combustion Engines

10.1 Introduction

Generally speaking, sliding-mode control (SMC) is a robust nonlinear control algorithm that employs discontinuous control to force system state trajectories to lie on some prescribed sliding surface (Utkin, 1992; DeCarlo *et al.*, 2000, 1996, 1988). Used widely for its robustness to model parameter uncertainties and external disturbances, SMC methodology has had great success in a wide variety of practical applications due to its ease of implementation and its favorable robustness properties. It can be argued, in fact, that this tendency toward successful application (a tendency enjoyed by only a few nonlinear design methodologies) has given rise to several new areas of active research in the general field of SMC. For example, until recent years, the bulk of research in SMC has been on systems without time delay and on continuous-time systems; thus, two other areas of research are addressed in this chapter, namely **SMC for systems with inherent delay** in the state and input and SMC for **discrete-time, sampled-data systems**.

An important issue in practical applications is how to address transport delay inherent in many physical systems. Although relatively little attention has been given to SMC for this class of systems in the open literature, several good works have recently appeared that address some of the associated difficulties. For example, necessary and sufficient conditions for the existence of sliding modes for a multidimensional system are given in Jafarov (1990), where the asymptotic stability of the system on the sliding surface using a Lyapunov-Krasovsky functional is proved. Drakunov and Utkin (1992) give the two-stage design procedure for dynamic systems that can be written in differential-difference equations in the block form. A linear transformation for distributed time-delay systems is proposed in Zheng *et al.* (1995), and the developed SMC algorithm is applied to liquid propellent rocket motors. In Hu *et al.* (1998), a transformation for systems with delay only in the control is used to design a sliding-mode controller for the transformed systems; the advantages over state feedback control are given. Sufficient conditions for sliding-mode control of systems with uncertain, continuously differentiable, and bounded time delay in the states are given in Sinha *et al.* (1997), using an invariant cone of positive initial functions. Finally, we note that El-Khazali (1998) proposes an output feedback sliding-mode control design method for similar uncertain time-delay systems.

With respect to the second area, discrete-time systems, it is well-known that "chattering" or oscillation problems occur at the boundary layer when the controls are implemented by digital computers at a given sampling frequency (Furuta, 1990). For this reason, researchers have been investigating the development of discrete sliding-mode control (DSMC) for more than 10 years; see, for example, the works of Furuta (1990), Sira-Ramirez (1991), Spurgeon (1991), and Kaynak and Denker (1993). One particular direction of research along these lines has been toward the coupling of adaptation with DSMC, primarily because the discrete sliding-mode control might not exist in the presence of system parameter uncertainties or external disturbances; this, in fact, is one of the main differences between DSMC and continuous sliding-mode control. There have appeared several good works on adaptive DSMC for linear time-invariant systems. For example, Chan (1997) proposes a nonswitching type of adaptive DSMC design method for a minimum-phase plant in the input/output form with bounded disturbances, whereas Furuta suggests using a switching type control law (Furuta, 1993). Both of these works prove that the state trajectories will converge to a small neighborhood of the defined sliding surface in finite time. Bartolini *et al.* (1995) combined adaptive control with sliding-mode control for discrete linear systems in state-space forms.

This chapter describes two recently developed theoretical results, extensions to the existing theory highlighted in the previous paragraphs for SMC based on Li and Yurkovich (2000, 2001). In the first technique (Li and Yurkovich, 2001), where SMC is extended for a class of point-delayed systems, a linear transformation is applied to convert the delayed system to a delay-free system whose spectra embed all the unstable poles of the original system with a given stability margin. It can be proven that the delayed system is asymptotically stable with SMC, based on the delay-free system. In the second approach, an adaptive SMC design method for discrete nonlinear systems, where explicit knowledge of the system dynamics is not available, is developed. A three layer feed-forward neural network is used as a function approximator for the unknown dynamics. The control law is designed based on the outputs of the approximators, and the sliding surface is defined in terms of a stable polynomial of the system outputs.

The focus for applications of these new techniques is on a representative problem from automotive engineering, that of idle speed control for the typical spark-ignited, internal combustion (IC) engine. Idle is one of the most frequently encountered operating conditions in city driving. Thus, there is motivation for adjustment to the lowest possible idle speed (i.e., while keeping smooth engine performance) as a way of reducing fuel consumption. Factors that most affect the idle speed are the intake-airflow and the ignition timing. The idle speed can therefore be controlled by changing the air quantity (charge adjustment) and/or the ignition timing. In this chapter, we will be concerned with disturbance torques acting on the plant model and being able to maintain nearly constant idle speed. These disturbance torques may arise from several sources, such as the engagement of the automatic transmission, the turning-on (cycling) of the air conditioner unit, or the effects of loading with the power steering system.

Characteristics inherent to the IC engine idle speed control problem—an induction-to-power delay and finite sensor/actuator response time—can lead to design challenges with respect to disturbance rejection and/or lead to problems of chattering with traditional SMC designs. For this reason, the idle speed control problem is chosen as a focus for application here, and both techniques for SMC described in this chapter (for point-delay systems and adaptive DSMC) are applied to the problem, where simulation and experimental results are provided.

10.2 SMC for Systems with Delay

In this section, we describe an extension of an idea that first appeared in Fiagbedzi and Pearson (1986, 1987) for transforming delayed systems. Dividing the unstable poles of the delayed system with a given stability margin into N sets, where each set contains n unstable poles, N characteristic matrices can be found that inherit the nN unstable poles. A linear transformation can then be applied to convert the original delayed system to a delay-free system with the state matrix being the direct sum of the N characteristic matrices. The novelty of the approach described here is in showing that SMC can then be designed based on the delay-free system, and **asymptotic stability** can be shown for *both* **delay-free** and **delayed systems** on certain sliding surfaces. The reaching condition is proved in the case of bounded and matched external disturbance, and the sliding surface is chosen by the means of a Lyapunov function. It should be noted that the sliding surface is a function of previous system states and controls and has intuitive appeal for time-delay systems.

10.2.1 Problem Formulation

We consider a system with point delay in both states and control described by:

$$\Sigma\colon \dot{x}(t) = A_0 x(t) + A_1 x(t-r) + B_0 u(t) + B_1 u(t-h) + Df(t), \tag{10.1}$$

where r and h are the delays with the system states and control respectively, $x \in \mathcal{R}^n$ represents the system states, $u \in \mathcal{R}^m$ represents the control, $f \in \mathcal{R}^k$ is the (bounded) disturbance, A_0 and A_1 are $n \times n$ matrices, B_0 and B_1 are $n \times m$ matrices, and D is an $n \times k$ matrix.

Denote $x_t(\theta) = x(t+\theta)$ for $\theta \in [-r, 0]$, and $u_t(\tau) = u(t+\tau)$ for $\tau \in [-h, 0]$. The initial conditions are given as $x(\theta) = x_0(\theta)$, $\theta \in [-r, 0]$ and $u(\tau) = u_0(\tau)$, $\tau \in [-h, 0]$, where $x_0 \in \mathcal{C}([-r, 0]; \mathcal{R}^n)$ and $u_0 \in \mathcal{C}([-h, 0]; \mathcal{R}^m)$; that is, x_0 is a real continuous function of $\theta \in [-r, 0]$, and u_0 is a real continuous function of $\tau \in [-h, 0]$.

10.2.2 Controller Design

Denote a non-negative real number ν_0 as the required "stability margin," and define the set of "unstable" poles (Fiagbedzi and Pearson, 1986) of Σ (given by equation 10.1) as:

$$\sigma_u(\Sigma) = \{s \in \mathcal{C} : \det(sI - A_0 - A_1 e^{-rs}) = 0,\ Re(s) \geq -\nu_0\}. \tag{10.2}$$

Because the number of the "unstable" poles is finite, one can generally find ways to divide $\sigma_u(\Sigma)$ as:

$$\sigma_u(\Sigma) = \Lambda_c = \Lambda_1 \cup \Lambda_2 \cup \ldots \cup \Lambda_N, \tag{10.3}$$

where Λ_i, $i = 1, 2 \ldots N$ includes n "unstable" poles. Assuming, for each Λ_i, there exists $A^{(i)}$ satisfying the characteristic matrix equation, then:

$$A^{(i)} = A_0 + e^{-rA^{(i)}} A_1, \tag{10.4}$$

and $\sigma(A^{(i)}) = \Lambda_i$; hence, one can obtain:

$$A_c = \bigoplus_{i=1}^{N} A^{(i)} \text{ and } \sigma(A_c) = \Lambda_c, \tag{10.5}$$

where $\oplus$ denotes the direct sum.

Defining a linear transformation as:

$$\begin{aligned} z_c(t) =& (\mathcal{T}_{AC}(x, u))(t) = \sum_{i=1}^{N} (e_i \otimes I_n) x(t) \\ &+ \int_{-r}^{0} e^{A_c \theta} \sum_{i=1}^{N} (e_i \otimes I_n) A_1 x(t-r-\theta) d\theta \\ &+ \int_{-h}^{0} e^{A_c \tau} \sum_{i=1}^{N} (e_i \otimes I_n) B_1 u(t-h-\tau) d\tau, \end{aligned} \tag{10.6}$$

where e_i is an N-dimensional unit column vector whose entries are 0 except for the ith entry, which is 1, $e_i \otimes I_n = [0_{n\times n}, \ldots, 0_{n\times n}, I_{n\times n}, 0_{n\times n}, \ldots, 0_{n\times n}]^T$. This is true with $I_{n\times n}$ as the ith entry, and one can obtain a delay-free system:

$$\Sigma'\colon \dot{z}(t) = A_c z(t) + B_c u(t) + D_c f(t), \tag{10.7}$$

where $B_c = \Sigma_{i=1}^{N} e_i \otimes (B_0 + e^{-hA^{(i)}} B_1)$, A_c is defined in equation 10.5, and $D_c = \Sigma_{i=1}^{N} e_i \otimes D$.

- **Assumption 1**: The characteristic matrices $A^{(i)}$, $i = 1, 2, \ldots, N$, exist [i.e., the n left eigenvectors of Σ corresponding to Λ_i are linearly independent (Fiagbedzi and Pearson, 1986)].
- **Assumption 2**: Σ is spectrally controllable (Olbrot, 1978):
$$\begin{aligned} &\operatorname{rank}\left[sI - A_0 - e^{-rs} A_1 | B_0 + e^{-hs} B_1\right] = n, \\ &\forall s \in \{s \in \mathcal{C},\ Re(s) \geq -\nu_0\}. \end{aligned} \tag{10.8}$$
- **Assumption 3**: The disturbance $D_c f(t)$ satisfies the matching conditions (i.e., D_c can be written in the form $D_c = B_c E$, where E is an $m \times k$ matrix). That is, $D = (B_o + \exp^{-hA^{(i)}} B_1)E$ for $i = 1, 2, \ldots, N$.

With this problem definition and these assumptions, we will need the following lemma. **Lemma 1**, (A_c, B_c) is controllable if **assumption 2** holds and the spectra of $A^{(i)}$, $i = 1, 2, \ldots N$ do not overlap (Fiagbedzi and Pearson, 1986).
We are now in a position to describe the controller design for systems of equations 10.1 and 10.7. Generally speaking, sliding-mode controller design consists of two steps, described next.

Sliding Surface Construction

An appropriate **sliding surface** on which the system has desired behavior must be constructed. Because (A_c, B_c) is controllable, one can find a feedback gain matrix $K \in \mathcal{R}^{m\times nN}$ such that $A_c + B_c K$ is asymptotically stable. Denote $A_s = A_c + B_c K$. Then there exists a positive definite matrix P satisfying the Ricatti inequality:

$$PA_s + A_s^T P < 0. \tag{10.9}$$

This leads to the following important lemma needed for a subsequent stability proof.

Lemma 2 The system equation 10.7 is asymptotically stable on the sliding surface:

$$S(t) = B_c^T P z(t) = 0. \tag{10.10}$$

Because the disturbance is matched, it will not affect the system behavior on the sliding surface. Write the sliding surface as:

$$S = B_c^T P z = Cz, \tag{10.11}$$

where $C = B_c^T P \in \mathcal{R}^{m \times nN}$. Substituting equation 10.6 into equation 10.11, we obtain the switching functional:

$$S(t) = C\left[\sum_{i=1}^{N}(e_i \otimes I_n)x(t) + \int_{-r}^{0} e^{A_c\theta}\sum_{i=1}^{N}(e_i \otimes I_n)A_1 x(t-r-\theta)d\theta \right.$$
$$\left. + \int_{-h}^{0} e^{A_c\tau}\sum_{i=1}^{N}(e_i \otimes I_n)B_1 u(t-h-\tau)d\tau\right]. \qquad (10.12)$$

Partitioning C as $C = [C^1, C^2, \ldots, C^N]$, where $C^i \in \mathcal{R}^{m \times n}$ and $i = 1, 2, \ldots, N$, rewrite S as:

$$S(t) = \left(\sum_{i=1}^{N} C^i\right)x(t) + \int_{-r}^{0}\left(\sum_{i=1}^{N} C^i e^{A^{(i)}\theta}\right)A_1 x(t-r-\theta)d\theta$$
$$+ \int_{-h}^{0}\left(\sum_{i=1}^{N} C^i e^{A^{(i)}\tau}\right)B_1 u(t-h-\tau)d\tau. \qquad (10.13)$$

The system is initially on the switching surface at t_r, $S(t) = 0$ and $\dot{S}(t) = 0$ for $t \geq t_r$. Furthermore:

$$\dot{S}(t) = C\dot{z}(t) = CA_c z(t) + CB_c u(t) + CD_c f(t)$$
$$= CA_c\left\{\sum_{i=1}^{N}(e_i \otimes I_n)x(t) + \int_{-r}^{0} e^{A_c\theta}\sum_{i=1}^{N}(e_i \otimes I_n)A_1 x(t-r-\theta)d\theta\right.$$
$$\left. + \int_{-h}^{0} e^{A_c\tau}\sum_{i=1}^{N}(e_i \otimes I_n)B_1 u(t-h-\tau)d\tau\right\} + CB_c u(t) + CD_c f(t). \qquad (10.14)$$

Assuming $(CB_c)^{-1}$ exists, one can usually obtain the equivalent control by letting $\dot{S}(t) = 0$. However, the disturbance term $CD_c f(t)$ is unknown. Hence, we will instead calculate an **equivalent control for the nominal system** given by:

$$u_{eq,\,nom}(t) = -(CB_c)^{-1}CA_c\left\{\sum_{i=1}^{N}(e_i \otimes I_n)x(t)\right.$$
$$+ \int_{-r}^{0} e^{A_c\theta}\sum_{i=1}^{N}(e_i \otimes I_n)A_1 x(t-r-\theta)d\theta$$
$$\left. + \int_{-h}^{0} e^{A_c\tau}\sum_{i=1}^{N}(e_i \otimes I_n)B_1 u(t-h-\tau)d\tau\right\}. \qquad (10.15)$$

Again, partitioning $CA_c \in \mathcal{R}^{m \times nN}$ as $CA_c = [\bar{C}^1, \bar{C}^2, \ldots, \bar{C}^N]$, where $\bar{C}^i \in \mathcal{R}^{m \times n}$, we have:

$$u_{eq,\,nom}(t) = -(CB_c)^{-1}\left\{\left(\sum_{i=1}^{N}\bar{C}^i\right)x(t)\right.$$
$$+ \int_{-r}^{0}\left(\sum_{i=1}^{N}\bar{C}^i e^{A^{(i)}\theta}\right)A_1 x(t-r-\theta)d\theta$$
$$\left. + \int_{-h}^{0}\left(\sum_{i=1}^{N}\bar{C}^i e^{A^{(i)}\tau}\right)B_1 u(t-h-\tau)d\tau\right\}. \qquad (10.16)$$

Note that $u_{eq,\,nom}$ is not the equivalent control for the system of equation 10.7. Rather, it is calculated solely for the purpose of control design.

Control Law Design

A **suitable control law** should be chosen to satisfy the reaching condition (i.e., global stability of the switching surface, $S = 0$). Specifically, for a Lyapunov function, $V = S^T S/2$, satisfaction of the inequality $\dot{V} = S^T\dot{S} < 0$ should be guaranteed.

With the choice of:

$$\dot{S} = -(CB_c)^{-1}D_1 sgn(S), \qquad (10.17)$$

where D_1 is a diagonal matrix with elements $d_i > 0$, $i = 1, 2, \ldots, m$ and $\text{sgn}(S) = [\text{sgn}(S_1), \ldots, \text{sgn}(S_m)]^T$; one can obtain the control with:

$$u(t) = -(CB_c)^{-1}\left\{\left(\sum_{i=1}^{N}\bar{C}^i\right)x(t)\right.$$
$$+ \int_{-r}^{0}\left(\sum_{i=1}^{N}\bar{C}^i e^{A^{(i)}\theta}\right)A_1 x(t-r-\theta)d\theta$$
$$\left. + \int_{-h}^{0}\left(\sum_{i=1}^{N}\bar{C}^i e^{A^{(i)}\tau}\right)B_1 u(t-h-\tau)d\tau\right\} - (CB_c)^{-1}D_1\text{sgn}(S). \qquad (10.18)$$

Stability Analysis

We now state, without proof [see Li and Yurkovich (2001)] the following **stability results**:

- **Theorem 1**: Suppose the disturbance is bounded and $\|f(x, t)\|_2 \leq \beta$. The system given by equation 10.7 with control given in equation 10.18 is asymptotically stable if $d_0 > \|CD\|_2\beta$, where $d_0 = \min(d_1, d_2, \ldots, d_m)$.
- **Theorem 2**: The system given by equation 10.1 with control given in equation 10.18 is asymptotically stable with a stability margin of ν_0 if $\sigma_u(\Sigma) \subseteq \bigcup_{i=1}^{N}\sigma(A^{(i)})$ and $\sigma(A^{(i)})\bigcap\sigma(A^j) = \varnothing$ for $i \neq j$, where $\varnothing$ denotes the void set.

10.3 Discrete Adaptive Sliding-Mode Control

Let us now move to the second method described in this chapter and give the theoretical development prior to presenting application results for both methods. As an extension to the works described in the previous sections, in this section we describe an **adaptive DSMC design method** for **nonlinear systems** having an **input/output form**. Explicit knowledge of the system dynamics is not required; instead, feed-forward neural networks are applied to approximate the unknown part of the system dynamics based on past system outputs and control inputs. The sliding surface, defined in terms of a stable polynomial of the system tracking error, is used to tune the neural network structure online using gradient methods. The **sliding-mode control law** is given based on the approximated system dynamics. It can be proved that the state trajectories will converge to a small sliding sector whose size could be as small as desired provided that the structure of the neural networks is large enough.

10.3.1 Problem Formulation

Consider a discrete nonlinear single-input, single-output feedback linearizing system defined by:

$$y(k+d) = \Phi[\lambda(k)] + \Gamma[\lambda(k)]u(k), \tag{10.19}$$

where $\Phi[\bullet]$ and $\Gamma[\bullet]$ are smooth nonlinear functions that might be unknown and where $\lambda(k)$ is a vector consisting of previous control inputs and system outputs given by:

$$\begin{aligned}\lambda(k) = [&y(k),\, y(k-1), \ldots,\, y(k-n),\, u(k-1),\\ &u(k-2), \ldots,\, u(k-m)]^T \in S_\lambda \subset \mathcal{R}^{n+m+1}.\end{aligned} \tag{10.20}$$

In addition, the $y(k)$ is the system output, the $u(k)$ is the control input satisfying $u(k) \in S_u \subset \mathcal{R}$, the S_λ and S_u denote complex sets, the n and m are constants that are not necessarily known, and the d is the (known) relative degree of the system.

The control objective is to have the system output $y(k)$ track a known reference input $r(k)$. Specifically, the objective of sliding-mode control is to steer the system state trajectories in a sliding surface that is defined in terms of a stable polynomial of the tracking error and to maintain the subsequent motion of the state trajectories on this surface.

10.3.2 Controller Design

Discrete Sliding-Mode Control

As an initial step in designing the control law, let us assume $\Phi[\bullet]$ and $\Gamma[\bullet]$ are known functions. Define the discrete sliding surface as:

$$s(k+d) = C(q^{-1})e(k+d), \tag{10.21}$$

where $C(q^{-1}) = 1 + c_O q^{-1} + \ldots + c_l q^{-1}$ is a Hurwitz polynomial, q^{-1} is a unit-delay operator, and $e(k+d) = y(k+d) - r(k+d)$ is the tracking error.

The equivalent control method (Drakunov and Utkin, 1992) can be applied to ensure $s(k+d) = 0$. Obviously if $s(k) = 0$ for all k, the error dynamics will be determined by $C(q^{-1})$ only. For a stable polynomial $C(q^{-1})$, $\lim_{k\to\infty} e(k) = 0$ if $\lim_{k\to\infty} s(k) = 0$. Hence, instead of trying to make the tracking error, $e(k)$, equal to zero directly, the control goal is changed to enforce the state trajectories on the manifold $s(k) = 0$ at each sampling instant. Note that the state trajectories can deviate from the sliding surface between the sampling points, which is different from continuous time sliding-mode control in which the state trajectories are kept on the sliding manifold at all times.

Upon substitution for the error in equation 10.21, we have the following:

$$\begin{aligned} s(k+d) &= C(q^{-1})y(k+d) - C(q^{-1})r(k+d)\\ &= C(q^{-1})\Phi[\lambda(k)] + C(q^{-1})\Gamma[\lambda(k)]u(k)\\ &\quad - C(q^{-1})r(k+d)\\ &= F[\lambda'(k)] + G[\lambda'(k)]u(k) - C(q^{-1})r(k+d). \end{aligned} \tag{10.22}$$

In equation 10.22, $F[\lambda'(k)] = C(q^{-1})\Phi[\lambda(k)]$ and $G[\lambda'(k)] = C(q^{-1})\Gamma[\lambda(k)]$, assumed to be bounded away from zero. Moreover, $\lambda'(k) = [y(k),\, y(k-1), \ldots,\, y(k-n-l),\, u(k-1),\, u(k-2), \ldots,\, u(k-m-l)]$.

Using the equivalent control method, we obtain the control $u_{eq}(k)$ by letting $s(k+d) = 0$, resulting in:

$$u_{eq}(k) = -G[\lambda'(k)]^{-1}\{F[\lambda'(k)] - C(q^{-1})r(k+d)\}. \tag{10.23}$$

After reaching the sliding surface, the system dynamics are described by these two equations:

$$s(k+d) = F[\lambda'(k)] + G[\lambda'(k)]u(k) - C(q^{-1})r(k+d) = 0. \tag{10.24}$$

$$\begin{aligned} y(k+d) =& \Phi[\lambda(k)] - \Gamma[\lambda(k)]G[\lambda'(k)]^{-1}\{F[\lambda'(k)]\\ &- C(q^{-1})r(k+d)\}. \end{aligned} \tag{10.25}$$

Adaptive Sliding-Mode Control

In most applications, exact knowledge of $F[\bullet]$ and $G[\bullet]$ is not possible. As a solution, some methodology should be used to approximate these nonlinear functions. Three-layer feed-forward neural networks are applied in this work, with output in the form:

$$y = \sum_{i=1}^{p} \omega_i \mathcal{H}\left(\sum_{j=1}^{r} \omega_{ij} x(j) + \hat{\omega}_j\right) + \hat{\omega}, \tag{10.26}$$

where p is the number of the neural nodes in the hidden layer; r is the number of the inputs; ω_i, ω_{ij}, and $(i = 1,\, 2, \ldots,\, p,$

$j = 1, 2, \ldots, r$) are the weights; $\hat{\omega}_j$ and $\hat{\omega}$ are the bias terms; and $\mathcal{H}$ is the squashing function that should be continuous, nonconstant, bounded, monotonically increasing (Funahashi, 1989), and differentiable (Chin and Coats, 1986). A hyperbolic tangent function is used for $\mathcal{H}$ in this work.

Denote the network output by $y = \mathcal{F}(x, A)$, where A represents the network structure and contains all the network weights and bias terms (i.e., $A = [\hat{\omega}, \omega_1, \ldots, \omega_p, \hat{\omega}_1, \ldots, \hat{\omega}_r, \omega_{11}, \ldots, \omega_{1r}, \omega_{21}, \ldots, \omega_{2r}, \ldots, \omega_{p1}, \ldots, \omega_{pr}]^T$). Define the change of the network output with respect to A as:

$$\zeta(x, A) = \frac{\partial \mathcal{F}(x, A)}{\partial A}. \tag{10.27}$$

It has been shown (Hornik *et al.*, 1989) that for any nonlinear function $f(x)$, there exists a neural network with the structure A^* that satisfies $|\mathcal{F}(x, A^*) - f(x)| \le \varepsilon$ given any small positive number ε (characteristics of universal approximators). Note that ε could be as small as desired, but decreasing ε generally increases the size of the neural networks. Denoting $\mathcal{F}(x, A)$ as the actual output of the neural networks, the representation error could be written in the form:

$$\begin{aligned} f(x) - \mathcal{F}(x, A) &= f(x) - \mathcal{F}(x, A^*) + \mathcal{F}(x, A^*) - \mathcal{F}(x, A) \\ &= \mathcal{O}(\varepsilon) + \mathcal{F}(x, A^*) - \mathcal{F}(x, A) \\ &= -\phi^T \zeta + \mathcal{O}(|\phi|^2) + \mathcal{O}(\varepsilon) \\ &= -\phi^T \zeta + \alpha. \end{aligned} \tag{10.28}$$

In equation 10.28, $\phi = A - A^*$, $\mathcal{O}(\varepsilon)$ is the ideal approximation error, $\mathcal{O}(|\phi|^2)$ represents residual terms after linearization, and $\alpha = \mathcal{O}(|\phi|^2) + \mathcal{O}(\varepsilon) \le \bar{\alpha}$.

Rewrite the control law of equation 10.23 as:

$$u(k) = -\hat{G}[\lambda'(k)]^{-1}\{\hat{F}[\lambda'(k)] - C(q^{-1})r(k+d)\}, \tag{10.29}$$

where $\hat{F}[\bullet]$ and $\hat{G}[\bullet]$ represent the approximation of the nonlinear functions F and G, respectively.

The sliding dynamics become the following:

$$\begin{aligned} s(k+d) &= F[\lambda'(k)] + G[\lambda'(k)]u(k) - C(q^{-1})r(k+d) \\ &= F[\lambda'(k)] - \hat{F}[\lambda'(k)] + (G[\lambda'(k)] - \hat{G}[\lambda'(k)])u(k) \\ &= F[\lambda'(k)] - \mathcal{F}[\lambda'(k), A_f(k+d-1)] \\ &\quad + (G[\lambda'(k)] - \mathcal{F}[\lambda'(k), A_g(k+d-1)])u(k) \\ &= -\phi_f^T(k+d-1)\zeta_f(k) + \alpha_f(k) - \phi_g^T(k+d-1)\zeta_g(k)u(k) \\ &\quad + \alpha_g(k)u(k) \\ &= -\phi^T(k+d-1)\zeta(k) + \alpha(k), \end{aligned} \tag{10.30}$$

where the following equations hold true:

$$\zeta_f(k) = \frac{\partial \mathcal{F}[\lambda'(k), A_f(k+d-1)]}{\partial A_f(k+d-1)}. \tag{10.31}$$

$$\zeta_g(k) = \frac{\partial \mathcal{F}[\lambda'(k), A_g(k+d-1)]}{\partial A_g(k+d-1)}. \tag{10.32}$$

$$\phi(k+d-1) = [\phi_f^T(k+d-1), \phi_g^T(k+d-1)]^T. \tag{10.33}$$

$$\zeta(k) = [\zeta_f^T(k), \zeta_g^T(k)u(k)]^T. \tag{10.34}$$

$$\alpha(k) = \alpha_f(k) + \alpha_g(k)u(k) \le \bar{\alpha}. \tag{10.35}$$

Defining a sliding sector $S = \{s(k) | |s(k)| \le \gamma\bar{\alpha}\}$, where $1 < \gamma < \infty$, we have the following theorem; for proof, see Hornik (1989).

- **Theorem 3:** With the adaptation law:

$$\phi(k) = \phi(k-1) + \frac{\kappa(k)\eta\zeta(k-d)}{1 + |\zeta(k-d)|^2} s(k), \tag{10.36}$$

where $\kappa(k) = \begin{cases} 0 & s(k) \in S \\ 1 & \text{otherwise,} \end{cases}$ and $0 < \eta < 2(1 - \frac{1}{\gamma})$.

1) $|\phi(k+1) - \phi(k)|$ will converge to zero;
2) $\lim_{k \to \infty} s(k) = 0$.

Calculation of $\zeta(k-d)$ in the statement of the theorem 3 is carried out using equation 10.27, with equation 10.31 and equation 10.32 as appropriate. We also note that a projection algorithm could be used to ensure $\hat{G}[\bullet]$ is bounded away from zero. Finally, in the case that we do not know the number of past outputs and control inputs that characterize the system (i.e., precise values of n and m), trial and error procedures can be used.

10.4 Application: IC Engine Idle Speed Control

The importance of idle speed control is due in part to vehicles (in a typical drive cycle) spending a large percentage of fuel in the idle condition. A satisfactory idle speed control algorithm should regulate the engine operating at a low speed while effectively rejecting typical torque disturbances due to accessory loads, such as the power steering pump, the air conditioning compressor, the various electrical loads, the engagement of the automatic transmission, and so on. A production idle speed controller generally consists of an anticipatory term using the information from the accessories, a proportional-integral feedback control term operating on the air mass signal, and a proportional feedback term for the spark timing. A survey of idle speed models and control methodologies is given by Hrovat *et al.* (1996).

To minimize fuel consumption, the engine should operate at a low speed; however, low idle speed could induce large engine speed variations or even cause the engine to stall in the presence of torque disturbances. Hence, a suitable control law should keep the idle speed as low as possible while minimizing speed variations and maintaining the capability of torque disturbance rejection. One of the main difficulties of idle speed control lies with the induction-to-torque delay; as an additional challenge in this application, the desired idle speed is set to 611 RPM instead of the normal (production) idle speed of 740 RPM.

10.4.1 Engine Model for Idle Speed Control

A highly simplified two-input (idle bypass valve opening and spark advance), two-output (engine speed and intake manifold pressure) **idle speed control model** for IC engines was developed by Yurkovich and Simpson (1997) and used in this work. The model includes intake manifold dynamics, induction-to-power delay, and engine rotational dynamics encompassed in the equations:

$$\frac{dp_m(\theta)}{d\theta} + \frac{\eta_\upsilon V_d}{4\pi V_m} p_m(\theta) = K_1 \frac{\alpha(\theta)}{\omega(\theta)}. \qquad (10.37)$$

$$\frac{d\omega(\theta)}{d\theta} = -\frac{B}{J} + \frac{\tau_e(\theta)}{J\omega(\theta)}. \qquad (10.38)$$

$$\tau_e(\theta) = K_\tau p_m(\theta - \theta_d) + K_\delta \Delta\delta(\theta) + \tau_f(\theta). \qquad (10.39)$$

The parameters for a Ford V-8 engine are shown in Table 10.1, and all of the variables used in these dynamical equations are defined in the Appendix.

Although simple in nature, we emphasize that this model encompasses the essential dynamics needed for control design. Note that the model is constructed in the crank angle domain instead of the time domain. Because the engine inherently divides its continuous physical processes into four distinct events (intake, compression, power, and exhaust), representation of the engine dynamics in the crank angle domain (as opposed to the time domain) is intuitively appealing and has certain advantages for control purposes, particularly for the idle speed control problem (Yurkovich and Simpson, 1997; Chin and Coats, 1986).

Letting $K_2 = \eta_\upsilon V_d / 4\pi V_m$ and linearizing equations 10.37, 10.38, and 10.39 about the nominal operating point (ω_0, p_{m0}) (using the notation Δ to denote increments), the state variable form of this model, with $x(\theta) = [\Delta\omega(\theta), \Delta p_m(\theta)]^T$ and control input $u(\theta) = [\Delta\alpha(\theta), \Delta\delta(\theta)]^T$ as well as $f(\theta) = \tau_f(\theta)$, is as follows:

$$\dot{x}(\theta) = A_0 x(\theta) + A_1 x(\theta - \theta_d) + B_0 u(\theta) + Df, \qquad (10.40)$$

where:

$$A_0 = \begin{pmatrix} \dfrac{-\tau_{e_o}}{J\omega_o^2} & 0 \\ \dfrac{-K_1\alpha_o}{\omega_o^2} & -K_2 \end{pmatrix}, \; A_1 = \begin{pmatrix} 0 & \dfrac{K_\tau}{J\omega_o} \\ 0 & 0 \end{pmatrix},$$

$$B_0 = \begin{pmatrix} 0 & \dfrac{K_\delta}{J\omega_o} \\ \dfrac{K_1}{\omega_o} & 0 \end{pmatrix}, \text{ and } D = \begin{pmatrix} \dfrac{1}{J\omega_o} \\ 0 \end{pmatrix}.$$

TABLE 10.1 The V-8 Engine Parameters

Parameter	Value	Units
η_υ	0.55	Dimensionless
V_d	0.0046	m^3
V_m	0.0029	m^3
J	0.0843	Nm − sec^2/rad
K_τ	5.7143	Nm/kPa
K_1	110	(kPa/sec)/deg
B	0.592	Nm − sec
θ_d	315	deg
ω_0	740	RPM

10.4.2 Engine Test Cell

A 4.6 L Ford V-8 fuel injected engine is used in this work. The engine has been removed from the vehicle and mounted on an engine test stand. The data is processed using a TMS320C30 digital signal processing (DSP) system, and two sensors are available for engine speed measurements. An optical encoder provides an analog pulse every two crankshaft degrees, while a flywheel sensor outputs a sinusoidal signal with a peak every crankshaft degree. The output of the optical encoder is used as a "clock" for the data sampling, and the output of the flywheel sensor provides the value of the engine speed.

For repeatability in the experiments, an electric load is added to the engine crankshaft through the alternator for the torque disturbances. This is accomplished via 12 vehicle headlights, which is equivalent to the disturbance encountered when the power steering pump or the air conditioning compressor is activated. When the nominal idle speed is 611 RPM, the load is about 12 Nm.

The mass airflow entering the engine is controlled by a pulse width-modulated signal to the idle bypass (actuator) solenoid, and the spark advance control is accomplished via a special circuit designed for these applications.

10.5 Application of SMC for Point-Delayed Systems

We now discuss results of the application of the **continuous SMC design for point-delayed systems** on the idle speed control problem described in the preceding section.

An overview of the control scheme and plant dynamics is shown in Figure 10.1. The characteristic polynomial of the system given by equation 10.40 is $(s + \tau_{e_o}/J\omega_o^2)(s + K_2) + K_1\alpha_o K_\tau e^{-\theta_d s}/J\omega_o^3$. Choosing the stability margin $\nu_0 = 1$, one can find four "unstable" poles, $\{-0.8656 \pm j0.8684,$

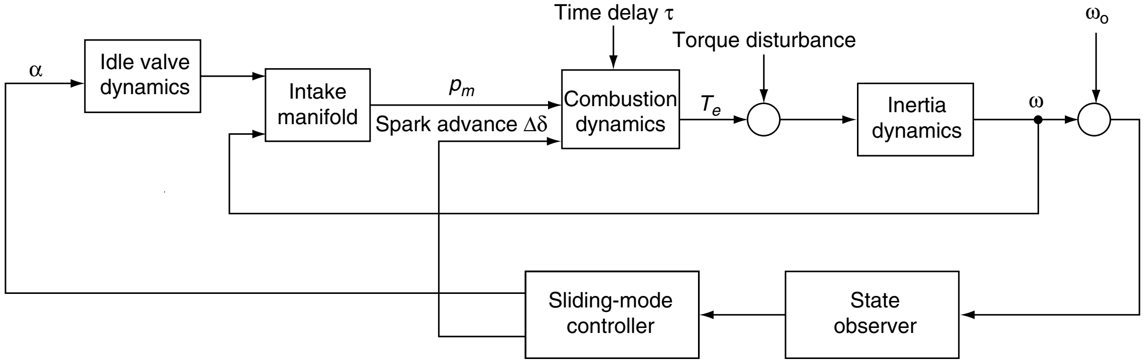

FIGURE 10.1 Point-Delayed SMC Structure

$- 0.0680 \pm j0.1123\} = \Lambda_1 \cup \Lambda_2\}$. Hence, $N = 2$. Furthermore, ranks $[sI - A_0 - A_1 e^{-\theta_d s} | B_0] = 2$ for all $s \in \{s \in C,\ Re(s) \geq -\nu_0\}$, and the system is spectrally controllable.

- For $s = -0.8656 + j0.8684 \in \Lambda_1$:

$$Q = \begin{pmatrix} -0.8656 & 1 \\ 0.8684 & 0 \end{pmatrix},\ J = \begin{pmatrix} -0.8656 & -0.8684 \\ 0.8684 & -0.8656 \end{pmatrix}, \text{and}$$

$$A^{(1)} = Q^{-1}JQ = \begin{pmatrix} -1.7312 & 1 \\ -1.5034 & 0 \end{pmatrix}.$$

- For $s = -0.0680 + j0.1123 \in \Lambda_2$:

$$Q = \begin{pmatrix} -0.0680 & 1 \\ 0.1123 & 0 \end{pmatrix},\ J = \begin{pmatrix} -0.0680 & -0.1123 \\ 0.1123 & -0.0680 \end{pmatrix}, \text{and}$$

$$A^{(2)} = Q^{-1}JQ = \begin{pmatrix} -0.0604 & 1.0046 \\ -0.0126 & -0.0756 \end{pmatrix}.$$

- The control matrix is the direct sum of $A^{(1)}$ and $A^{(2)}$; that is:

$$A_c = \bigoplus_{i=1}^{2} A^{(i)} = \begin{pmatrix} -1.7312 & 1 & 0 & 0 \\ -1.5034 & 0 & 0 & 0 \\ 0 & 0 & -0.0604 & 1.0046 \\ 0 & 0 & -0.0126 & -0.0756 \end{pmatrix}, \tag{10.41}$$

where $B_c = \sum_{i=1}^{2} e_i \otimes B_0$, and $D_c = \sum_{i=1}^{2} e_i \otimes D$.

Using a linear transformation:

$$z(\theta) = \sum_{i=1}^{2} (e_i \otimes I_n)x(\theta) + \int_{-\theta_d}^{0} e^{A_c\tau} \sum_{i=1}^{2} (e_i \otimes I_n)A_1 x(\theta - \theta_d - \tau)d\tau, \tag{10.42}$$

we obtain the delay-free system:

$$\dot{z}(\theta) = A_c z(\theta) + B_c u(\theta) + D_c f(\theta). \tag{10.43}$$

To reduce the steady-state error, choose the sliding surface as:

$$\begin{aligned} S &= C_1 z(\theta) + C_2 \int_0^{\theta} z(\theta')d\theta' \\ &= C_1 \left[\sum_{i=1}^{2} (e_i \otimes I_n)x(\theta) + \int_{-\theta_d}^{0} e^{A_c\tau} \sum_{i=1}^{2} (e_i \otimes I_n)A_1 x(\theta - \theta_d - \tau)d\tau \right] \\ &\quad + C_2 \int_0^{\theta} \left[\sum_{i=1}^{2} (e_i \otimes I_n)x(\theta') \right. \\ &\quad \left. + \int_{-\theta_d}^{0} e^{A_c\tau} \sum_{i=1}^{2} (e_i \otimes I_n)A_1 x(\theta' - \theta_d - \tau)d\tau \right] d\theta', \end{aligned} \tag{10.44}$$

where, for simplicity, $C_1 = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$, and $C_2 = \begin{pmatrix} 0 & 0 & c_1 & 0 \\ 0 & 0 & 0 & c_2 \end{pmatrix}$, $c_1,\ c_2 > 0$. $C_1 B_c = B_0$.

To increase the reaching speed, we choose:

$$\dot{S}(\theta) = -D_1 sgn(S(\theta)) - D_2 S(\theta), \tag{10.45}$$

where D_1 and D_2 are diagonal matrices with positive diagonal elements. Hence, the control law is as written here:

$$\begin{aligned} u(\theta) = &-B_0^{-1}(C_1 A_c + C_2) \left[\sum_{i=1}^{2} (e_i \otimes I_n)x(\theta) \right. \\ &\left. + \int_{-\theta_d}^{0} e^{A_c\tau} \sum_{i=1}^{2} (e_i \otimes I_n)A_1 x(\theta - \theta_d - \tau)d\tau \right] \\ &- B_0^{-1} D_1 sgn(S(\theta)) - B_0^{-1} D_2 S(\theta). \end{aligned} \tag{10.46}$$

Because the manifold pressure sensor is located upstream from the idle valve actuator (after the throttle plate), it cannot measure the pressure changes caused by the idle valve actuator. Thus, a state observer is necessary. Moreover, since the torque disturbance appears in the system state equations, it must also be estimated to estimate the intake manifold pressure accurately. Standard observer design methods are employed in the following simulation results (Li and Yurkovich, 2000).

10.5.1 Simulation Results

Figure 10.2 gives the engine speed variations and control inputs. A step disturbance of 15 Nm is loaded to the system after 20 engine cycles and unloaded after 150 engine cycles. The integral term in the control law is discretized using the trapezoidal rule with step size $\Delta\tau = 4$ crankshaft degrees. The plant is integrated using Euler's rule with sampling time $T = 32$ crankshaft degrees. It is evident that the controller maintains the idle speed at 611 RPM, and there is no steady-state error. After the torque disturbance is added to the system, the engine speed drops to 582 RPM, with a deviation of 29 RPM from the desired idle speed of 611 RPM. After the disturbance is removed, the engine speed increases to 642 RPM, with a deviation of 41 RPM. The disturbance is completely rejected in a few engine cycles for both loading and unloading cases (with residual oscillations due to the chattering in the spark advance). The controller thus has the capability of disturbance rejection for a typical "bad" disturbance. Note that the engine speed does not oscillate significantly although both of the control inputs have chattering characteristics (physical actuators would, of course, not be able to respond in this manner).

Figures 10.3 and 10.4 show the robustness of the controller to system parameter uncertainties. Variations in K_δ and K_1 are considered because they are crucial to controller design. Figure 10.3 gives the engine speed variations to a 15 Nm disturbance after 20 engine cycles for K_δ varying from 0.25 to 8. One can see that the controller can stabilize the system and reject the disturbance for all the cases. As K_δ decreases, however, the engine speed deviation from the nominal idle speed increases, whereas the chattering becomes significant when K_δ increases. Further increasing K_δ would lead to instability. Figure 10.4 gives the engine speed for $K_1 = 11$ and 220. Increasing K_1 would give higher chattering and even instability.

10.5.2 Experimental Results

The experimental results (engine speed variations and control inputs) are plotted in Figure 10.5 The integral term in the control law is discretized using the trapezoidal rule with $\Delta\tau = 32$ crankshaft degrees, while the control law is calculated every 120 crankshaft degrees. The electrical load is applied manually after about 64 engine cycles and removed after about 183 engine cycles.

From these results, one can see that the controller has the capability to reject the disturbance after about 10 engine cycles. After the torque disturbance is loaded, the engine speed drops to 545 RPM, which has a difference of 66 RPM from the nominal

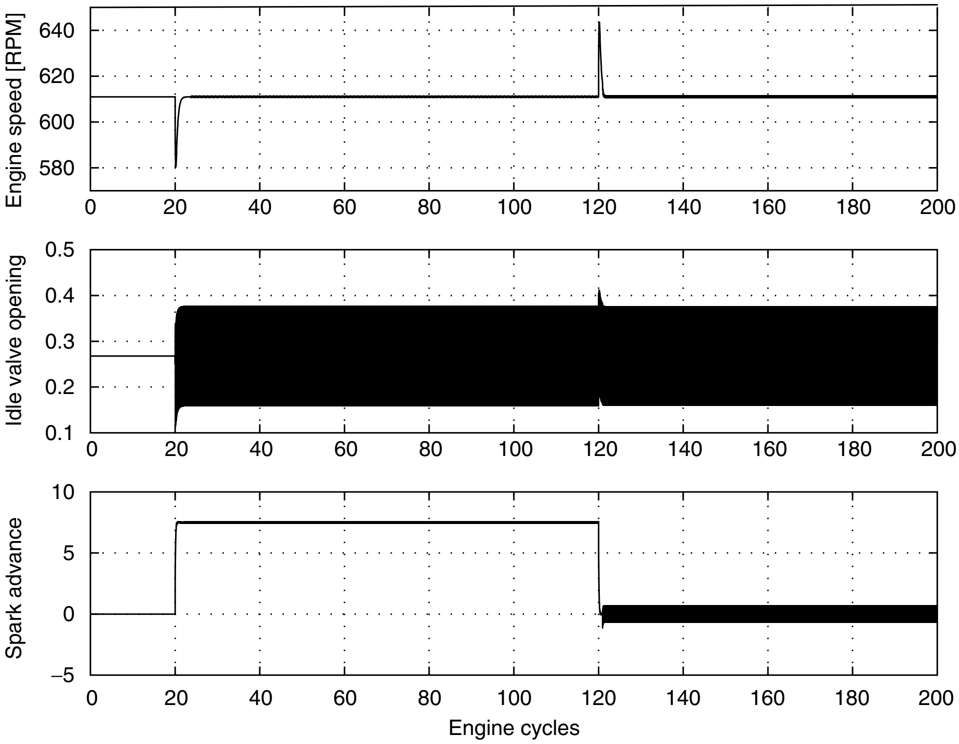

FIGURE 10.2 Engine Speed and Control Inputs (Simulation)

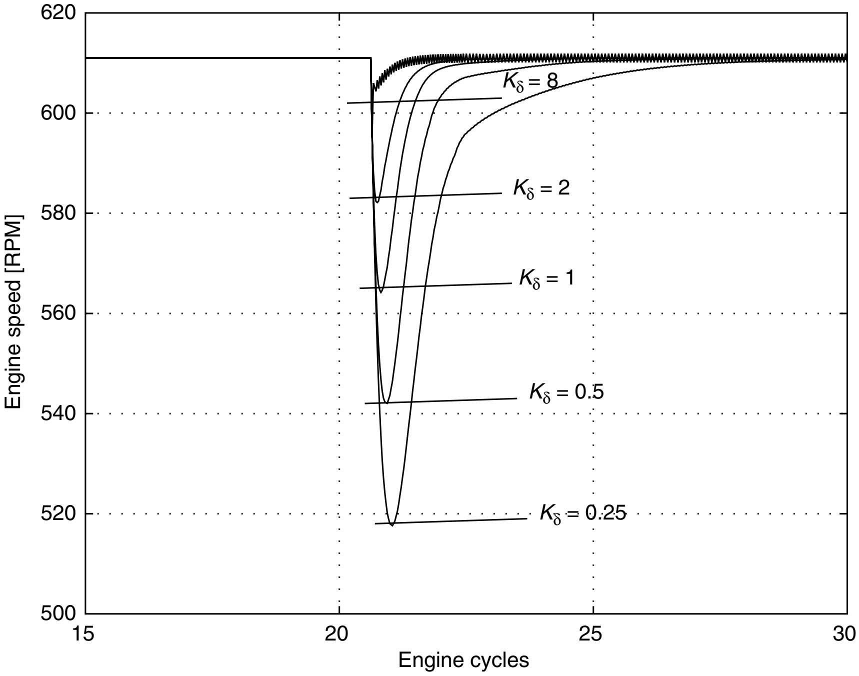

FIGURE 10.3 Engine Speed Variations with Varying K_δ

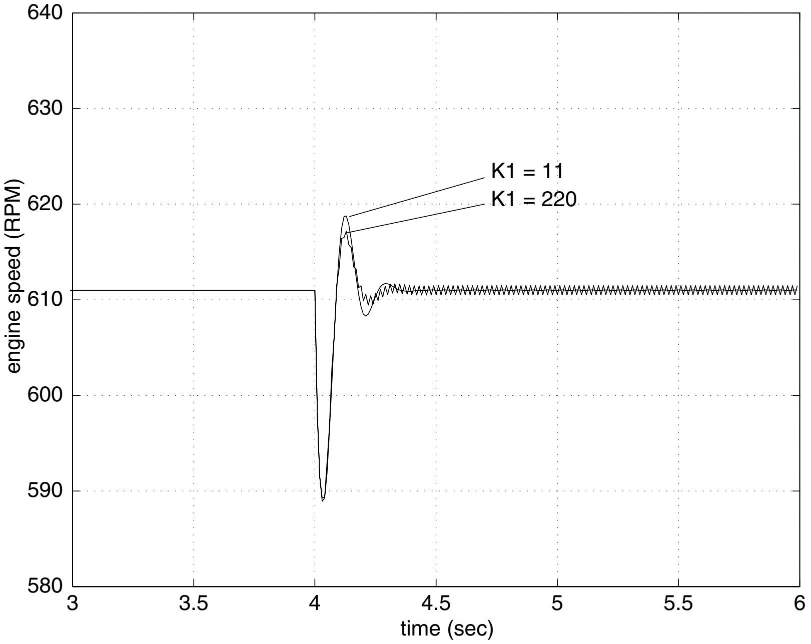

FIGURE 10.4 Engine Speed Variations with Varying K_1

idle speed. The maximum engine speed is 652 RPM when the load is removed, with a difference of 41 RPM. The engine speed variations for the production electrical engine control (EEC) IV controller, which also uses both mass airflow and spark advance as control inputs, are plotted in Figure 10.6 for comparison. Note that the production controller uses a set point (nominal) of 740 RPM. The minimum engine speed is 601 RPM, with a difference of 139 RPM from the nominal idle speed of 740 RPM. The maximum engine speed is 837 RPM, with a difference of 126 RPM. The 5% rising time is about 40 engine cycles for the loading case and even longer for the unloading case. Hence, one can conclude that the proposed sliding-mode controller gives

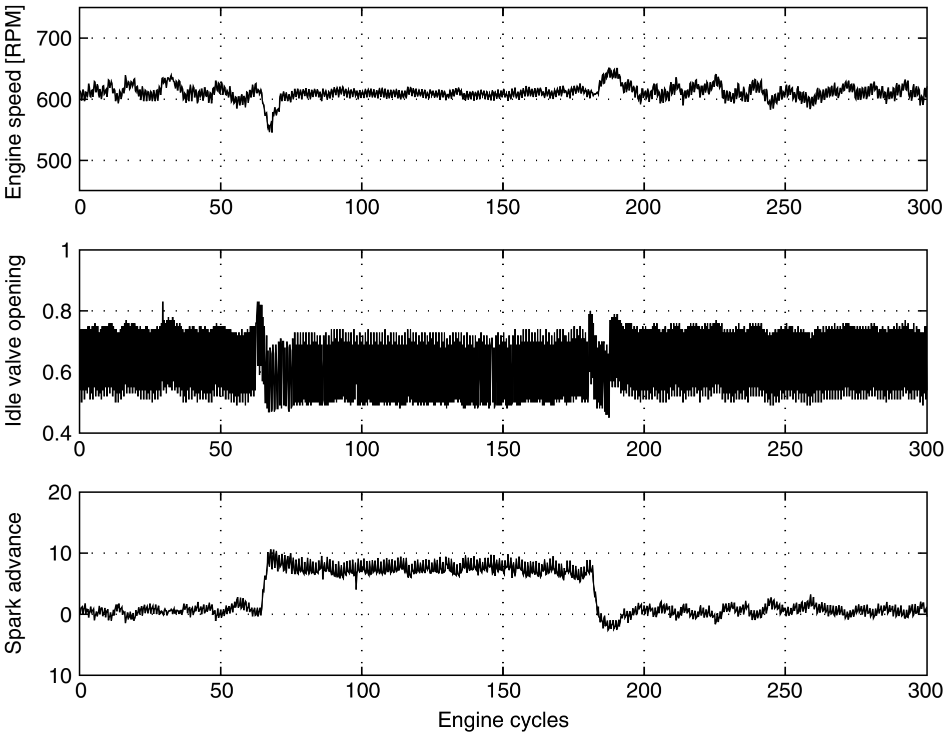

FIGURE 10.5 Point-Delayed SMC Experimental Results

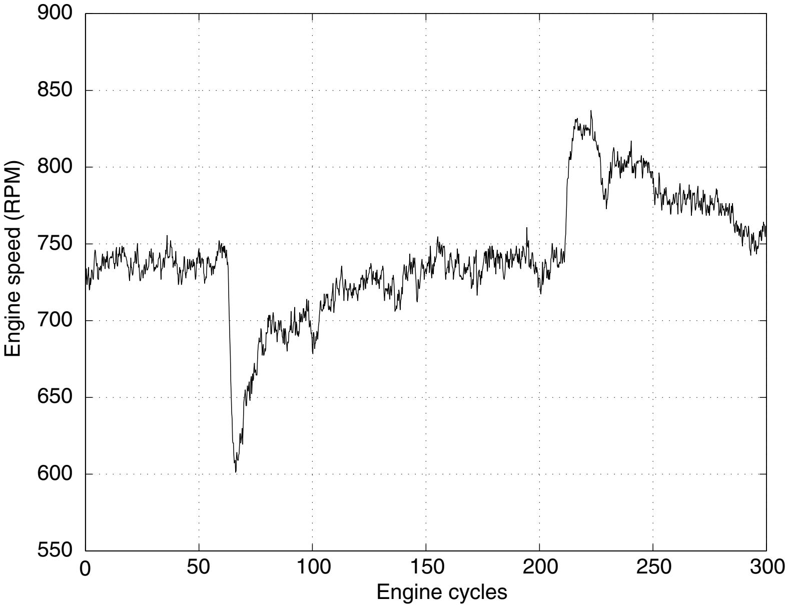

FIGURE 10.6 Engine Speed Using Production Controller (for Comparison)

much better control performance than the production EEC IV controller in this "out-of-vehicle" test. It is important to note that the control input signals shown in Figure 10.5 (idle valve opening and spark advance) are the **commanded inputs**. The actuators themselves, particularly in the case of the idle speed control valve, do not necessarily have the bandwidth capabilities to respond at such frequencies. With the pulse-width modulated controller implementation, in fact, much of the high-frequency chattering effect is essentially filtered out. This, of course, is typical in sliding-mode control applications.

10.6 Application of Adaptive DSMC

Referring now to the development and notation from Section 10.3, we next discuss the results of the **adaptive DSMC** as applied to **the idle speed control problem**. An overview of the control scheme and plant dynamics is shown in Figure 10.7.

10.6.1 Simulations

To convert equations 10.37 through 10.39 and equation 10.19, we differentiate the system output variable, $\omega(k)$, until the system input variable, $\alpha(k)$, appears on the right-hand side of the equation. Denoting $K_2 = \eta_\upsilon V_d/4\pi V_m$ and differentiating results in:

$$J\omega(\theta)\ddot{\omega}(\theta) + J(\dot{\omega}(\theta))^2 + B\dot{\omega}(\theta) = K_\tau K_1 \frac{\alpha(\theta - \theta_d)}{\omega(\theta - \theta_d)} - K_2 J\omega(\theta)\dot{\omega}(\theta) - K_2 B\omega(\theta). \quad (10.47)$$

Discretizing the above equation using Euler's rule, it is easy to show that:

$$\omega(k+1) = f_1[\omega(k),\ \omega(k-1)] + g_1[\omega(k),\ \omega(k-1),\ \omega(k-4)]\alpha(k-4), \quad (10.48)$$

where $f_1[\,\bullet\,]$ and $g_1[\,\bullet\,]$ are nonlinear functions and continuous in their arguments. In these derivations, it is assumed that $\theta_d = 3T$ with $T = 120^\circ$ crank angle.

To get the form of equation 10.19, we need to advance the time index forward:

$$\begin{aligned}\omega(k+2) &= f_1[\omega(k+1),\ \omega(k)] + g_1[\omega(k+1),\ \omega(k),\ \omega(k-3)]\alpha(k-3)\\ &= f_1\{f_1[\omega(k),\ \omega(k-1)] + g_1[\omega(k), \omega(k-1),\ \omega(k-4)]\alpha(k-4), \omega(k)\}\\ &\quad + g_1\{f_1[\omega(k),\ \omega(k-1)] + g_1[\omega(k), \omega(k-1),\ \omega(k-4)]\alpha(k-4),\ \omega(k-1),\ \omega(k-3)\}\alpha(k-3)\\ &= f_2[\omega(k),\ \omega(k-1),\ \omega(k-4),\ \alpha(k-4)]\\ &\quad + g_2[\omega(k),\ \omega(k-1),\ \omega(k-3),\ \omega(k-4),\ \alpha(k-4)], \alpha(k-3).\\ &\ \ \dots\end{aligned}$$

$$\begin{aligned}\omega(k+5) = {} & f_5[\omega(k),\ \omega(k-1), \dots, \omega(k-4),\ \alpha(k-1), \dots,\ \alpha(k-4)]\\ & + g_5[\omega(k),\ \omega(k-1), \dots, \omega(k-4),\ \alpha(k-1), \dots, \alpha(k-4)]\alpha(k).\end{aligned} \quad (10.49)$$

Comparing with equation 10.19, we have $n = 4$, $m = 4$, and the relative degree of the system is $d = 5$. Note that we could also have determined the values of m and n by trial and error, as mentioned earlier.
Choosing $C(q^{-1}) = 1 + c_0 q^{-1}$ with $c_0 = 0.3$, one obtains:

$$\begin{aligned}s(k+5) &= C(q^{-1})f_5[\omega(k),\ \omega(k-1), \dots,\ \omega(k-4),\ \alpha(k-1), \dots,\ \alpha(k-4)]\\ &\quad + C(q^{-1})g_5[\omega(k),\ \omega(k-1), \dots,\ \omega(k-4),\ \alpha(k-1), \dots, \alpha(k-4)]\alpha(k) - C(q^{-1})r\\ &= F[\lambda(k)] + G[\lambda(k)]\alpha(k) - C(q^{-1})r,\end{aligned} \quad (10.50)$$

where $\lambda(k) = [\omega(k-1),\ \omega(k-2), \dots,\ \omega(k-5),\ \alpha(k-1), \dots,\ \alpha(k-5)]$ is the regression vector, and $r = 611$ RPM is the desired engine speed.

The control law is as written here:

$$u(k) = -\hat{G}[\lambda(k)]^{-1}\{\hat{F}[\lambda(k)] + C(q^{-1})r\}. \quad (10.51)$$

A three-layer feed-forward neural network, with 11 inputs and 5 hidden nodes, is used to approximate both $F[\,\bullet\,]$ and $G[\,\bullet\,]$. A projection algorithm is applied to ensure $0 < g_{\min} < G[\,\bullet\,]$, while $u(k)$ is bounded by $0.05 \leq u(k) \leq 0.95$. Simulation results are shown in Figure 10.8. As before, a step disturbance of 15 Nm is applied to the system as a load torque after 40 engine cycles and then removed (unloaded) after 120 engine cycles. Elements of the neural network structure vector A are initially chosen as random numbers between 0 and 1, and the data shown in the figures are collected after training the neural networks for 500 engine cycles. Engine speed variations are evident, but it can be seen that the controller is capable of rejecting typical bad disturbances. We note the presence of a small steady-state error (about 0.5 RPM). This is because the controller can only bring the system state trajectories into a

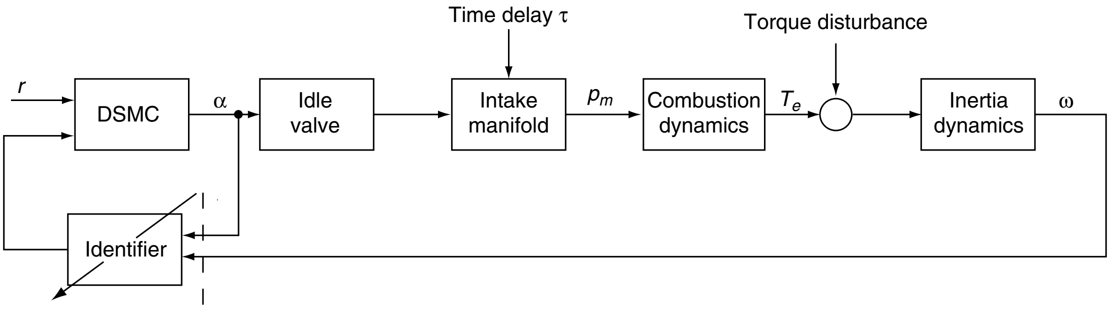

FIGURE 10.7 Adaptive DSMC Structure

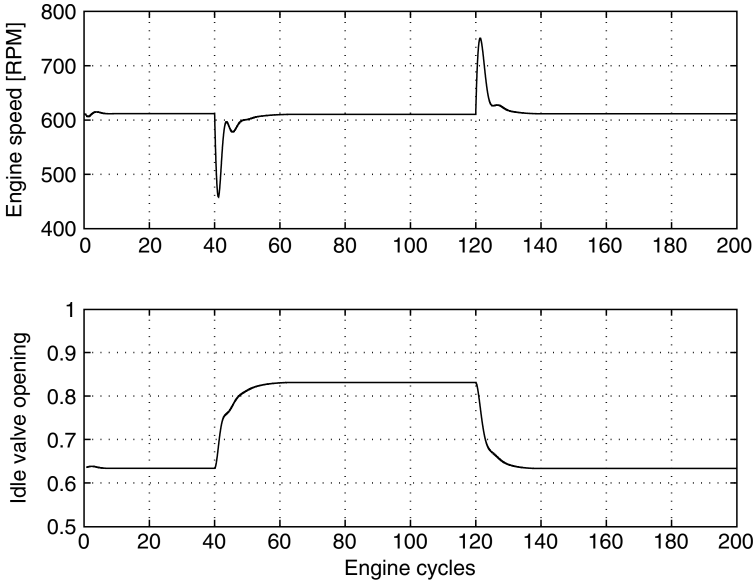

FIGURE 10.8 Engine Speed Variations and Control Input (Simulation)

small predefined sliding sector, which, in this case, is chosen as 0.2. The simulation input is shown as the idle bypass valve opening.

10.6.2 Experimental Results

The engine speed variations for the adaptive DSMC are plotted in Figure 10.9. To shorten the computation time for a step, we use $\lambda(k) = [\omega(k), \omega(k-1), \alpha(k-1)]$ as the regression vector for the neural network (obtained by trial and error). The disturbance torque (electrical load) is applied after 65 engine cycles and removed after 271 engine cycles. The engine speed drops to 532 RPM after the torque disturbance is loaded, which has a deviation of 79 RPM from the desired idle speed of 611 RPM. The engine speed increases to 681 RPM after the torque load is removed, with a difference of 70 RPM. The disturbance is rejected (5% rise time) after about 22 engine cycles for the loading case and 25 engine cycles for the unloading case. The minimum engine speed is 601 RPM, with a difference of 139 RPM from the nominal idle speed of 740 RPM. Once again, this response may be compared with that of the production controller, which uses both mass airflow and spark advance as control inputs, shown in Figure 10.6. When comparing Figure 10.9 to Figure 10.6, it is important to note that the production controller regulates to a nominal engine speed of 740 RPM (as opposed to 611 for the controller of Figure 10.9). We therefore conclude that the adaptive DSMC as developed, *which uses only the idle valve opening as control input*, exhibits superior performance over the production controller that uses two control inputs.

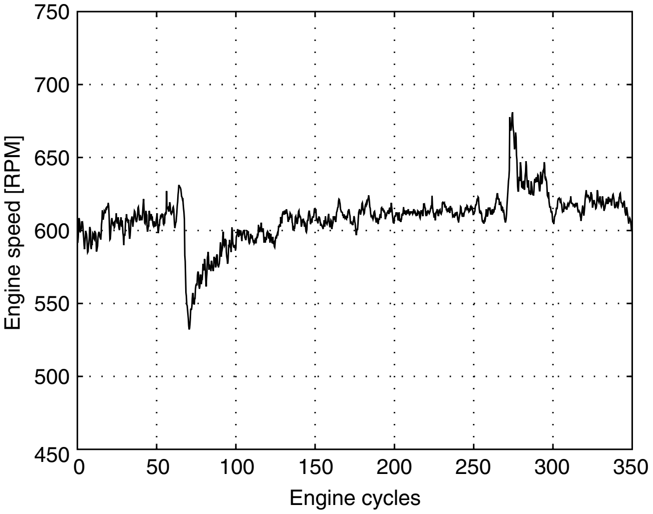

FIGURE 10.9 Adaptive DSMC Experimental Results

10.7 Summary

It is well-known that delays in system states and control input degrade controller performance and worsen the so-called chattering problems for sliding-mode control. Two recent approaches to counteract the effects of system delay and chattering in SMC were presented in this chapter.

For the first method, described fully in Li and Yurkovich (2001), a continuous SMC design method was given for systems with point delay in both states and control. A linear transformation was applied to convert the delay system to a delay-free system whose spectra embed all the unstable poles of the original system within a given stability margin. SMC was then designed based on the delay-free system. Asymptotic stability is ensured for both the delay-free system and the original delayed system in the case of bounded and matched disturbance for the designed control law. The control design method was applied to the IC engine idle speed control problem, not for stabilization (because the engine is stable itself during idling) but for compensation with the effects of the delay.

With the second method, described in more detail in Li and Yurkovich (2000), a discrete adaptive sliding-mode control design algorithm was presented for nonlinear systems. Feedforward neural networks are used to approximate the unknown system dynamics, where system outputs and previous control inputs are used as the inputs for the function approximators, and the defined sliding surface is applied to tune their structure online using gradient methods. There are three main advantages to the adaptive DSMC algorithm described herein:

1. Explicit knowledge of the system dynamics is not necessary for the controller design.
2. The controller is adaptive to the system parameter uncertainties and external disturbances.
3. The time delay in the system can be addressed by increasing the relative order of the system.

Simulation and experimental results for the IC engine idle speed control problem showed that both SMC controllers developed are capable of maintaining a low idle speed (611 RPM) while rejecting torque disturbances.

Acknowledgments

We wish to gratefully acknowledge the many helpful suggestions and numerous discussions on this work with Professor Vadim Utkin at the Ohio State University. For the experimental aspects, we wish to thank Professor Giorgio Rizzoni for use of the laboratory facilities and for giving us expert advice along the way. Finally, we also wish to acknowledge the Center for Automotive Research at Ohio State for fellowship support of second author Xiaoqiu Li.

Nonlinear Input/Output Control: Volterra Synthesis

Patrick M. Sain
Raytheon Company,
EI Segundo, California, USA

11.1 Introduction

A power series expansion, provided it exists, often provides a useful representation of a nonlinear plant. The same can be said for the desired closed-loop input/output map of a feedback control system. Given a Volterra series representation for each of these components, then **Volterra feedback synthesis** (VFS) can be used to design and realize a nonlinear controller that uses a finite consecutive number of Volterra kernels of the plant and desired closed-loop input/output map. A striking feature of this method is that it permits the specification of a nonlinear desired closed-loop behavior. The control design takes place in the frequency domain and is realized as an interconnected set of linear systems. The controller possesses an interesting recursive structure that is readily exploited to produce an equivalent reduced-order realization. In fact, this simplified controller implementation can be computed to an arbitrarily high order in an automatic manner.

The VFS approach is reasonably general; the specific development presented herein draws upon the total synthesis problem (TSP) framework, and so this chapter begins with concise descriptions of the TSP paradigm, Volterra plant representation, and controller synthesis. The length of the general formulas at this point is only to be admired; the intrepid reader will note, no doubt with some relief, that the following section describes an equivalent simplified reduced-order implementation of the controllers represented by these formulas, complete with block diagrams. An example application is provided using a based-isolated single degree of freedom structure with nonlinear hysteretic damping.

11.2 Problem Definition Using Total Synthesis

Based on Rugh's results (1981) using Volterra series to represent nonlinear systems, Al-Baiyat and Sain (1986, 1989) applied the use of Volterra operators to nonlinear regulator design in the context of the **total synthesis problem** (TSP) in 1986. Since then, Sain *et al.* (1990, 1991) have used the TSP framework to apply Volterra operators in nonlinear servomechanism design, and in 1995, Doyle *et al.* (1995) cast the method into a model-predictive control design. Al-Baiyat showed that the Volterra operators comprising the controller can be realized as interconnections of linear systems, and Sain (1997) derived an equivalent reduced-order realization. For brevity, a partial linearization regulator design (Sain *et al.*, 1997b) is presented herein. The approach extends to servomechanisms, and the general controller design is given by Sain (1997).

Let R, U, and Y denote real vector spaces of dimensions p, m, and p, respectively representing the spaces of requests, plant inputs, and plant outputs. Let P: $U \rightarrow Y$ denote an input output description of a nonlinear plant. Define the desired closed-loop response to a command by T: $R \rightarrow Y$ and the desired plant input for a command by M: $R \rightarrow U$. The operators P, T, M, and E are assumed to have Volterra series

FIGURE 11.2 Commutative Diagram

representations at the point or in the region of operation. An illustration of these operators for a regulator design is given in Figure 11.1 In general, a pair (M, T) is desired such that $T = P \ o \ M$ and the diagram in Figure 11.2 commutes. In the sequel, T is given, and the objective is to find and realize a controller G: $Y \rightarrow U$ such that $M = G \ o \ E$, where E: $R \rightarrow Y$; in this case, Y is the space of output errors.

11.3 Plant Representation

Within the TSP framework, consider linear analytic plants, that is, plants for which the state and output equations are given by:

$$\dot{x} = f(x) + g(x)u, \quad x(0) = x_0. \tag{11.1}$$

$$y = h(x). \tag{11.2}$$

In equations 11.1 and 11.2, $x \in X$; $u \in U$; $y \in Y$; f, g: $X \rightarrow X$; $g(x)$: $U \rightarrow X$; h: $X \rightarrow Y$; and f, g, and h are analytic in x. Such plants can be represented using a so-called bilinear approximation, obtained by denoting the approximation of the state and output equations $f_1(x, u)$ and $f_2(x)$, respectively and by taking a multivariable Taylor series expansion about the operating point (x_0, u_0), truncating all terms of order higher than n, yielding:

$$\begin{aligned} f_1(x_0, u_0) = &\sum_{i=1}^{n} A_{1i}(x_0, u_0)\tilde{x}^{[i]} \\ &+ \sum_{i=1}^{n-1} D_{1i}(x_0, u_0)\tilde{x}^{[i]} \otimes \tilde{u} + D_{10}\tilde{u}. \end{aligned} \tag{11.3}$$

$$f_2(x_0) = \sum_{i=1}^{n} C_{1i}(x_0, u_0)\tilde{x}^{[i]}. \tag{11.4}$$

In these equations, $\tilde{x} = x - x_0$, $\tilde{u} = u - u_0$, and $x^{[i]} = x \otimes \cdots \otimes x$, the i-fold Kronecker tensor product of x with itself. To reduce notational complexity, $\otimes$ is assumed to have precedence over matrix and scalar multiplication. Suppressing the explicit dependence on (x_0, u_0) and if f_1^j denotes $\partial^j f_1/\partial x^j$, then the following results:

$$f_1^j = \sum_{i=j}^{n} A_{ji}\tilde{x}^{[i]} + \sum_{i=j}^{n-1} D_{j(i-1)}\tilde{x}^{[i]} \otimes \tilde{u}. \tag{11.5}$$

$$\begin{aligned} \frac{d}{dt}\begin{bmatrix} \tilde{x} \\ \tilde{x}^{[2]} \\ \vdots \\ \tilde{x}^{[n]} \end{bmatrix} &= \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1n} \\ 0 & A_{22} & \cdots & A_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & A_{nn} \end{bmatrix}\begin{bmatrix} \tilde{x} \\ \tilde{x}^{[2]} \\ \vdots \\ \tilde{x}^{[n]} \end{bmatrix} \\ &+ \begin{bmatrix} D_{11} & D_{12} & \cdots & D_{1(n-1)} \\ D_{21} & D_{22} & \cdots & D_{2(n-1)} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & D_{n(n-1)} \end{bmatrix}\begin{bmatrix} \tilde{x} \\ \tilde{x}^{[2]} \\ \vdots \\ \tilde{x}^{[n]} \end{bmatrix} \otimes \tilde{u} \\ &+ \begin{bmatrix} D_{10} \\ 0 \\ \vdots \\ 0 \end{bmatrix}\tilde{u}. \end{aligned} \tag{11.6}$$

Equations 11.5 and 11.6 apply for $2 \leq j \leq n$, or, more compactly, $\dot{\tilde{\tilde{x}}} = A\tilde{\tilde{x}} + D\tilde{\tilde{x}} \otimes \tilde{u} + B\tilde{u}, y = C\tilde{\tilde{x}}, \tilde{\tilde{x}}(0) = \tilde{\tilde{x}}_0$. In the sequel, the notation A_k denotes the matrix partition composed of the leftmost k partitions of the top k rows of A; C_k denotes the leftmost k partitions of C; and D_k denotes the leftmost $k - 1$ partitions in the top k rows of D, with $D_1 = D_{10}$.

For a multiple-input, multiple-output, finite-dimensional, causal, time-invariant plant, define the homogenous multilinear Volterra operator as:

$$P_i[u(t)] = \int_0^t \cdots \int_0^{\tau_i - 1} p_i(\tau_1, \ldots, \tau_i)u(t - \tau_1) \otimes \cdots \otimes u(t - \tau_i)d\tau_i \cdots d\tau_1, \tag{11.7}$$

where $t \geq \tau_1 \geq \cdots \geq \tau_i \geq 0$ and where p_i is its ith Volterra kernel. A Volterra representation then has the form (Al-Baiyat and Sain, 1986, 1989):

$$y(t) = \sum_{i=1}^{\infty} P_i[u(t)]. \tag{11.8}$$

The convolutional nature of this representation makes it expedient to work in the transform domain. Define the multidimensional Laplace transform of the *i*th Volterra kernel as (Bussgang *et al.*, 1974):

$$P_i(s_1, \ldots, s_i) = \int_0^{\infty} \cdots \int_0^{\infty} p_i(\tau_1, \ldots, \tau_i) e^{-(s_1\tau_1 + \cdots + s_i\tau_i)} d\tau_1 \ldots d\tau_i. \quad (11.9)$$

Al-Baiyat and Sain (1986) showed that for a stationary time invariant bilinear system of the form given above, where $\overline{P}_i^j = ((s_1 + \cdots + s_j)\ I - A_i)^{-1} D_i$, the transforms of the first three kernels are as follows:

$$P_1(s) = C_1 \overline{P}_1^1. \quad (11.10)$$

$$P_2(s_1, s_2) = C_2 \overline{P}_2^2 \{\overline{P}_1^1 \otimes I_m\}. \quad (11.11)$$

$$P_3(s_1, s_2, s_3) = C_3 \overline{P}_3^3 \{[\overline{P}_2^2 \{\overline{P}_1^1 \otimes I_m\}] \otimes I_m\}. \quad (11.12)$$

The general form is the following:

$$P_j(s_1, \ldots, s_j) = C_j \overline{P}_j^j \{[\overline{P}_{j-1}^{j-1} \{[\cdots \overline{P}_2^2 \{\overline{P}_1^1 \otimes I_m\} \cdots] \otimes I_m\}] \otimes I_m\}. \quad (11.13)$$

11.4 Controller Design

Now, the goal is to formulate an expression for the Volterra kernels of the controller G in the frequency domain in terms of the kernels of the plant, given above, and those of the desired closed-loop map, T. The development follows that given in Al-Baiyat Sain (1986). Similarly to the Volterra operator $P_i[u(t)]$, define Volterra operators associated with the maps T and M such that:

$$y(t) = \sum_{j=1}^{\infty} T_j[r(t)]. \quad (11.14)$$

$$u(t) = \sum_{k=1}^{\infty} M_k[r(t)]. \quad (11.15)$$

To obtain a relation between the operators P_i, T_j, and M_k, replace the request signal $r(t)$ by $cr(t)$, where c is an arbitrary constant; because Volterra operators are multilinear, equating expressions for y yields:

$$\sum_{j=1}^{\infty} c^j T_j[r(t)] = \sum_{i=1}^{\infty} P_i\left(\sum_{j=1}^{\infty} c^j M_j[r(t)]\right). \quad (11.16)$$

Let r_i denote $r(t - \tau_i)$ and define:

$$\sum_{i=1}^{\infty} P_i\left(\sum_{j=1}^{\infty} c^j M_j[r(t)]\right) = \sum_{j_1=1}^{\infty} \cdots \sum_{j_i=1}^{\infty} c^{j_1+\cdots+j_i} P_i\big(M_{j_1}[r(t)], \ldots, M_{j_i}[r(t)]\big), \quad (11.17)$$

where the following is true:

$$P_i\big(M_{j_1}[r(t)], \ldots, M_{j_i}[r(t)]\big) = \int_0^{t} \int_0^{\tau_1} \cdots \int_0^{\tau_{i-1}} p_i(\tau_1, \ldots, \tau_i) M_{j_1}(r_1) \otimes \cdots \otimes M_{j_i}(r_i) d\tau_i \ldots d\tau_1. \quad (11.18)$$

Equating output equation expressions and suppressing the argument $[r(t)]$ yields:

$$\sum_{j=1}^{\infty} c^j T_j = \sum_{i=1}^{\infty} \left(\sum_{j_1=1}^{\infty} \cdots \sum_{j_i=1}^{\infty} c^{j_1+\cdots+j_i} P_i(M_{j_1}, \ldots, M_{j_i})\right). \quad (11.19)$$

Equating powers of c on both sides of equation 11.19 gives:

$$T_1 = P_1 M_1. \quad (11.20)$$

$$T_2 = P_1 M_2 + P_2(M_1, M_1). \quad (11.21)$$

$$T_3 = P_1 M_3 + P_2(M_1, M_2) + P_2(M_2, M_1) + P_3(M_1, M_1, M_1). \quad (11.22)$$

For $\kappa_i = \sum_{j=1}^{i} k_j$, $\kappa_0 = 0$:

$$T_i = P_1 M_i + \sum_{j=2}^{i} \left(\sum_{k_1=1}^{i-j+1} \sum_{k_2=1}^{i-j-k_1+2} \cdots \sum_{k_{j-1}=1}^{i-\kappa_{j-2}-1} P_j(M_{k_1}, M_{k_2}, \ldots, M_{k_{j-1}}, M_{i-\kappa_j-1})\right). \quad (11.23)$$

Applying the multidimensional Laplace transform yields:

$$T_1(s) = P_1(s) M_1(s). \quad (11.24)$$

$$\begin{aligned} T_2(s_1, s_2) = {} & P_1(s_1 + s_2) M_2(s_1, s_2) \\ & + P_2(s_1, s_2)[M_1(s_1) \otimes M(s_2)]. \end{aligned} \quad (11.25)$$

$$\begin{aligned} T_3(s_1, s_2, s_3) = {} & P_1(s_1 + s_2 + s_3) M_3(s_1, s_2, s_3) \quad (11.26) \\ & + P_2(s_1, s_2 + s_3)[M_1(s_1) \otimes M_2(s_2, s_3)] \\ & + P_2(s_1 + s_2, s_3)[M_2(s_1, s_2) \otimes M_1(s_3)] \\ & + P_3(s_1, s_2, s_3)[M_1(s_1) \otimes M_1(s_2) \otimes M_1(s_3)]. \quad (11.27) \end{aligned}$$

$$\begin{aligned} T_i(s_1, \ldots, s_i) = {} & P_1(s_1 + \cdots + s_i) M_i(s_1, \ldots, s_i) \\ & + \sum_{j=2}^{i} \Bigg\{ \sum_{k_1=1}^{i-j+1} \sum_{k_2=1}^{i-j-k_1+2} \cdots \sum_{k_{j-1}=1}^{i-\kappa_{j-2}-1} \\ & P_j(s_1 + \cdots + s_{\kappa_1}, s_{\kappa_1+1} + \cdots + s_{\kappa_2}, \ldots, s_{\kappa_{j-1}+1} + \cdots + s_i) \\ & [M_{k_1}(s_1, \ldots, s_{\kappa_1}) \otimes M_{k_2}(s_{\kappa_1+1}, \ldots, s_{\kappa_2}) \otimes \cdots \otimes \\ & M_{i-\kappa_{j-1}}(s_{\kappa_{j-1}+1}, \ldots, s_i)] \Bigg\}. \end{aligned} \quad (11.28)$$

Observe that if the pair $(M_1(s),\ T_1(s))$ is chosen for $P_1(s)$, then one can proceed to the design equation involving $P_2(s_1, s_2)$, where the pair $(M_2(s_1, s_2)$ and $T_2(s_1, s_2))$ is chosen and so on. To complete the design, consider the synthesis of the controller

G that realizes the desired mappings (M, T) shown in Figure 11.1 Note that the similarity of the relation $M = G\ o\ E$ permits expressions for the operators M_j to be obtained in a manner similar to the one for the operators T_i. Also from Figure 11.1, note that $e = r - y$, which can be written as:

$$\sum_{i=1}^{\infty} E_i[r(t)] = I[r(t)] - \sum_{i=1}^{\infty} T_i[r(t)], \tag{11.29}$$

where I is the identity operator, and, thus, $E_1(s) = I - T_1(s)$. In addition, for $i > 1$, $E_i(s_1, \ldots, s_i) = -T_i(s_1, \ldots, s_i)$. A direct relation between the Volterra kernels of the operators T, M, and G can be found if the design is well-posed on the first order or linear level, implying that $E_1(s)$ has an inverse. As T is usually open to choice, the latter requirement is reasonable.

11.5 Simplified Partial Linearization Controller Design

Consider designing a feedback system for a given nonlinear system so that $T_i = 0$, $1 < i < n$, where T_i is the ith Volterra kernel of the closed loop. Such a design is called **partial linearization**, and it has the desirable attribute of greatly lessening the complexity of the controller design equations. Both the general controller design and the partial linearization controller design, as derived using the equations above, yield realizations with repeated structures. Collecting terms with like coefficients yields the simplified controller design. The result is presented here for the partial linearization controller, with the general result given by Sain (1997).

Suppose for T that the second and higher order kernels are zero. Then, if $P_1(s)$ inverts, the following results:

$$M_1(s) = P_1^{-1}(s)T_1(s). \tag{11.30}$$

$$M_2(s_1, s_2) = -P_1^{-1}(s_1 + s_2)P_2(s_1, s_2)[M_1(s_1) \otimes M_1(s_2)]. \tag{11.31}$$

$$\begin{aligned} M_3(s_1, s_2, s_3) = -P_1^{-1}(s_1 + s_2 + s_3)\{&P_2(s_1, s_2 + s_3)[M_1(s_1) \\ &\otimes M_2(s_2, s_3)] + P_2(s_1 + s_2, s_3)[M_2(s_1, s_2) \otimes M_1(s_3)] \\ &+ P_3(s_1, s_2, s_3)[M_1(s_1) \otimes M_1(s_2) \otimes M_1(s_3)]\}. \end{aligned} \tag{11.32}$$

In general, the following is true:

$$\begin{aligned} &M_i(s_1, \ldots, s_i) = -P_1^{-1}(s_1 + \ldots + s_i) \\ &\sum_{j=2}^{i} \left\{ \sum_{k_1=1}^{i-j+1} \sum_{k_2=1}^{i-j-k_1+2} \cdots \sum_{k_{j-1}=1}^{i-\kappa_{j-2}-1} \right. \\ &P_j(s_1 + \ldots + s_{\kappa_1}, s_{\kappa_1+1} + \ldots + s_{\kappa_2}, \ldots, s_{\kappa_{j-1}+1} + \ldots + s_i) \\ &\big[M_{k_1}(s_1, \ldots, s_{\kappa_1}) \otimes M_{k_2}(s_{\kappa_1+1}, \ldots, s_{\kappa_2}) \\ &\left. \otimes \ldots \otimes M_{i-\kappa_{j-1}(s_{\kappa_{j-1}+1}, \ldots, s_i)}\big] \right\}. \end{aligned} \tag{11.33}$$

A nice feature of these equations is their recursive nature. Once $M_1(s)$ has been found, it can be used to obtain an expression for $M_2(s_1, s_2)$ and so forth. Under partial linearization, the operators are represented by $E_k = 0$, $k > 1$. Assuming $E_1(s)$ and $P_1(s)$ to be invertible, then the kernels of the controller G are given by:

$$G_1(s) = P_1^{-1}(s)T_1(s)E_1^{-1}(s). \tag{11.34}$$

$$G_2(s_1, s_2) = -P_1^{-1}(s_1 + s_2)P_2(s_1, s_2)[G_1(s_1) \otimes G_1(s_2)]. \tag{11.35}$$

$$\begin{aligned} G_3(s_1, s_2, s_3) = -P_1^{-1}(s_1 + s_2 + s_3)\{&P_2(s_1, s_2 + s_3)[G_1(s_1) \\ &\otimes G_2(s_2, s_3)] + P_2(s_1 + s_2, s_3)[G_2(s_1, s_2) \otimes G_1(s_3)] \\ &+ P_3(s_1, s_2, s_3)[G_1(s_1) \otimes G_1(s_2) \otimes G_1(s_3)]\}. \end{aligned} \tag{11.36}$$

In general:

$$\begin{aligned} &G_i(s_1, \ldots, s_i) = -P_1^{-1}(s_1 + \ldots + s_i) \\ &\sum_{j=2}^{i} \left\{ \sum_{k_1=1}^{i-j+1} \sum_{k_2=1}^{i-j-k_1+2} \cdots \sum_{k_{j-1}=1}^{i-\kappa_{j-2}-1} \right. \\ &P_j(s_1 + \ldots + s_{\kappa_1}, s_{\kappa_1+1} + \ldots + s_{\kappa_2}, \ldots, s_{\kappa_{j-1}+1} + \ldots + s_i) \\ &\big[G_{k_1}(s_1, \ldots, s_{\kappa_1}) \otimes G_{k_2}(s_{\kappa_1+1}, \ldots, s_{\kappa_2}) \\ &\left. \otimes \ldots \otimes G_{i-\kappa_{j-1}}(s_{\kappa_{j-1}-1}, \ldots, s_i)\big] \right\}. \end{aligned} \tag{11.37}$$

Again, note the recursive nature of the controller design equations. Once $G_1(s)$ has been computed, it can be used to find $G_2(s_1, s_2)$ and so on.

The next step in the realization process is to substitute the expression for the plant kernels P_i in the frequency domain. Given $\bar{G}_i^j = G_i(s_j, s_{j+1}, \ldots, s_{j+i-1})$, then:

$$\bar{G}_2^1 = -(C_1\bar{P}_1^2)^{-1}C_2\bar{P}_2^2\{[\bar{P}_1^1\bar{G}_1^1] \otimes \bar{G}_1^2\}. \tag{11.38}$$

$$\begin{aligned} \bar{G}_3^1 = -(C_1\bar{P}_1^3)^{-1}\{&C_2\bar{P}_2^3\{[\bar{P}_1^1\bar{G}_1^1] \otimes \bar{G}_2^2\} + C_2\bar{P}_2^3\{[\bar{P}_1^2\bar{G}_2^1] \otimes \bar{G}_1^3\} \\ &+ C_3\bar{P}_3^3\{[\bar{P}_2^2\{[\bar{P}_1^1\bar{G}_1^1] \otimes \bar{G}_1^2\}] \otimes \bar{G}_1^3\}\}. \end{aligned} \tag{11.39}$$

$$\begin{aligned} \bar{G}_i^1 = -(C_1\bar{P}_1^i)^{-1} &\sum_{j=2}^{i} \left\{ \sum_{k_1=1}^{i-j+1} \sum_{k_2=1}^{i-j-\kappa_1+2} \sum_{k_3=1}^{i-j-\kappa_2+3} \cdots \sum_{k_{j-1}=1}^{i-\kappa_{j-2}-1} \right. \\ &C_j\bar{P}_j^i\Big\{\Big[\bar{P}_{j-1}^{\kappa_{j-1}}\Big\{\Big[\ldots\Big[\bar{P}_2^{\kappa_2}\Big\{\Big[\bar{P}_1^{\kappa_1}\bar{G}_{k_1}^1\Big] \otimes \bar{G}_{k_2}^{\kappa_1+1}\Big\}\Big]\ldots\Big] \\ &\left. \otimes\bar{G}_{k_{j-1}}^{\kappa_{j-2}+1}\Big\}\Big] \otimes \bar{G}_{i-\kappa_{j-1}}^{\kappa_{j-1}+1}\Big\} \right\}. \end{aligned} \tag{11.40}$$

Each of equations 11.38 through 11.40 can be realized as a set of interconnected linear subsystems. These realizations possess a number of interesting features that are nicely illustrated using block diagrams. In doing so, certain notational conveniences are employed.

First, the superscripts on the quantities $\bar{P}_i^j$ and $\bar{G}_i^j$ in equations 11.38 through 11.40 are redundant and can be neglected without loss (Sain, 1997). The proof lies in observing that the ordering of terms in a controller design equation, together with the established use of parentheses and brackets, are sufficient to determine what the superscripts should be.

Second, if $e \in Y$ represents the output error of the closed loop, and δ_{11} is its Laplace transform, then let $\delta_{11}^{(i)}$ denote the i-fold tensor product of δ_{11} with itself, then define:

$$\beta_{i1} = \sum_{k=1}^{i} \bar{G}_k^1\left(\delta_{11}^{(k)}\right), \tag{11.41}$$

making β_{i1} the Laplace transform of the ith order controller output.

Finally, the layout of the block diagrams follows certain conventions. If the controller design equations are fully expanded and each written on one line, then their addends, as read from left to right, appear in the block diagrams proceeding from top to bottom.

The fundamental observation behind the simplification process is that quantities present in the realization for $\bar{G}_i^1$ reappear in the realizations for $\bar{G}_j^1$, $j > i$. The motivation behind the simplification process is that in computing the output of a given controller component $\bar{G}_i^1$, the most efficient algorithm is to compute these repeated quantities only once, store them in memory, and then reuse them as needed. The reduction process is thus a problem of identifying a set Γ of elements common to a sequence of controller components $\bar{G}_i^1$, $i = 1, 2, 3, \ldots, n$, and determining which ones to save for later reuse.

In computing the n components $\bar{G}_i^1(\delta_{11}^{(i)})$, $1 \leq i \leq n$, of the output of an nth order controller, many quantities are computed repeatedly. Therefore, a system of notation is now introduced with the primary goal of eliminating redundant calculations by identifying members of the common set Γ and the secondary goal of further simplifying the controller output calculation. The identification of Γ presented here is not unique. Therefore, the notation Γ_0 will be used to denote the particular identification described herein and to distinguish it from the general notion of the common set represented by Γ. Here and in the sequel, superscripts are suppressed.

The first members of Γ_0 have already been introduced, namely β_{i1}. Given $\alpha_{ij} \in \Gamma_0$ and $2 \leq j \leq i$ defined by $\alpha_{ij} = \bar{P}_{j-1}\beta_{(i-1)(j-1)}$, then:

$$\beta_{ij} = \sum_{k=1}^{i-j+1} \alpha_{(i-k+1)j} \otimes \beta_{k1}. \tag{11.42}$$

The simplified partial linearization nth order controller output can now be calculated as follows. First, compute the output of the first order controller, $\beta_{11} = P_1^{-1}T_1(I - T_1)^{-1}\delta_{11}$, and then the output of the nth order controller for $n \geq 2$ is computed using:

$$\beta_{n1} = \beta_{11} - \sum_{i=2}^{n} \sum_{j=2}^{i} P_1^{-1}C_j\bar{P}_j\beta_{ij}. \tag{11.43}$$

The members of the common set Γ_0, (namely α_{ij} and β_{ij}), are computed and stored the first time they are encountered and then recalled as needed. In the sequel, the equation $g_{ij} = -P_1^{-1}C_jP_j\beta_{ij}$ and the following identifications are convenient:

$$g_i = \sum_{j=2}^{i} -P_1^{-1}C_j\bar{P}_j\beta_{ij} \tag{11.44}$$

$$= \sum_{j=2}^{i} g_{ij}. \tag{11.45}$$

The above algorithm for calculating the output of the simplified partial linearization controller takes full advantage of the recursive nature of the design equations, reducing the number of states and floating-point computations. Furthermore, the simplified form is amenable to the construction of general software routines, capable of computing the controller output for an arbitrary value of the controller order n.

The simplified block diagrams for the second third-order controller components are shown in Figures 11.3 and 11.4. A general form for the ith order component is shown in Figure 11.5.

11.6 SDOF Base-Isolated Structure Example

Consider a single degree of freedom (SDOF) structure sitting on a base isolation system consisting of hysteretically damped bearings, and let the structure be subject to ground acceleration $\ddot{x}_g(t)$ and a control force $f(t)$ supplied by a hydraulic actuator. Such a system is shown in Figure 11.6 The forces exerted by the individual bearings are modeled collectively. The equation of motion for the horizontal displacement of the mass m of the structure is as follows:

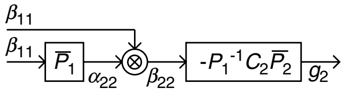

FIGURE 11.3 Simplified G_2 Realization

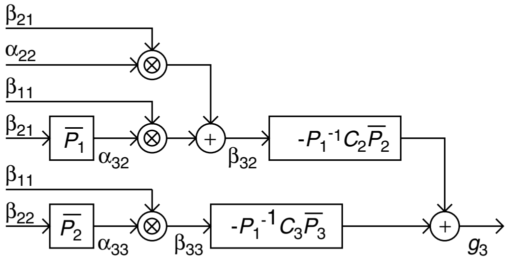

FIGURE 11.4 Simplified G_3 Realization

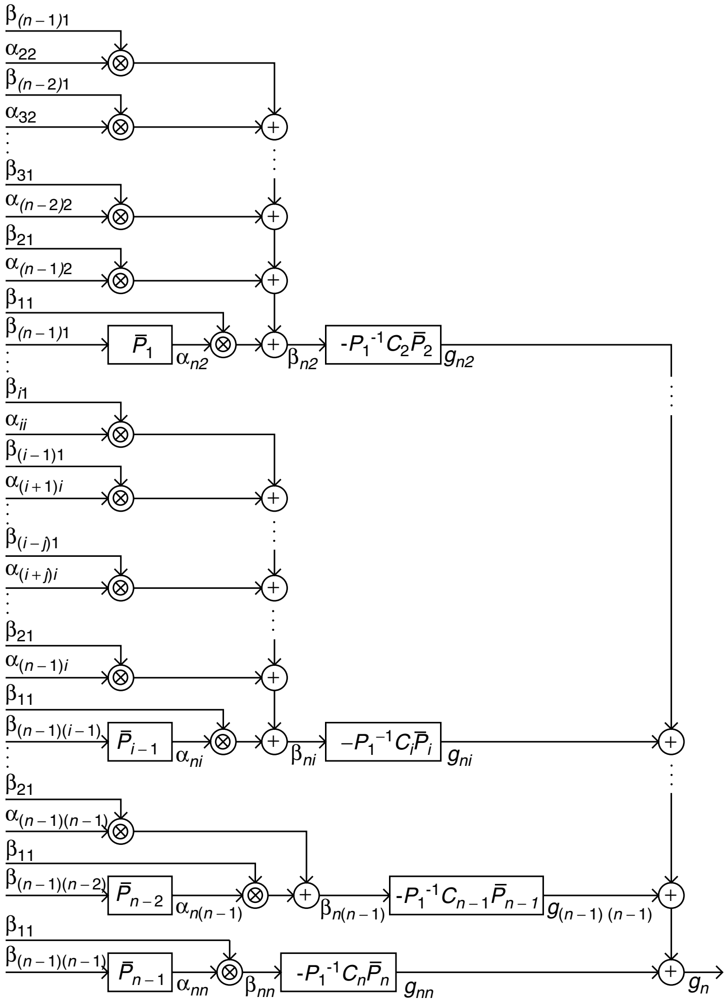

FIGURE 11.5 General Form for Simplified Realization

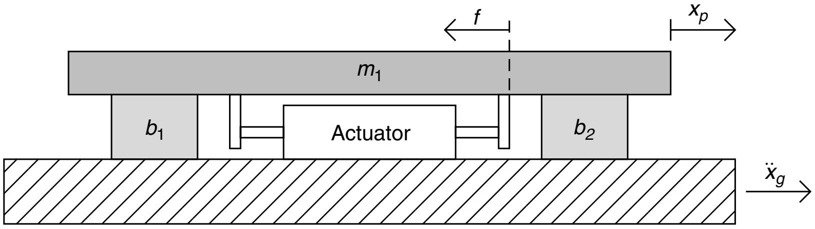

FIGURE 11.6 A Base-Isolated SDOF Structure of Mass m_1. The structure is supported by hysteretically damped bearings b_1 and b_2 that are subject to ground acceleration $\ddot{x}_g$ and control force f.

$$f(t) = m[\ddot{x}_p(t) + \ddot{x}_g(t)] + c\dot{x}_p(t) + kx_p(t) + Q[x(t), \dot{x}(t)]. \tag{11.46}$$

Descriptions of the variables and parameter values are given in Table 11.1 Both the bearings and the actuator affect the stiffness and damping coefficients c and k, and it should be understood that the values identified for these parameters provided in Table 11.1 are meant to represent the behavior of the system with the actuator and bearings in place. The hysteretic restoring force Q generated by the base isolating bearings is given by:

$$Q[x_p(t), \dot{x}_p(t)] = \alpha\frac{F_y}{Y}x_p(t) + (1-\alpha)F_y z(t), \tag{11.47}$$

TABLE 11.1 Parameters for the SDOF System

Variable	Description	Value
c	Damping coefficient	600π kg/s
f	Force applied by actuator	(N)
k	Stiffness coefficient	$3 \times 10^6 \pi^2$ kg/s^2
m	Mass of structure	3000 kg
Q	Hysteretic restoring force of base-isolation bearing	N
x_g	Horizontal ground acceleration	m/s^2
x_p	Horizontal displacement of the mass m	m
f_p	Natural undamped frequency	5 Hz
ξ_p	Damping ratio	1%

TABLE 11.2 Parameters for the Hysteretically Damped Base-Isolation System

Variable	Description	Value
A	Hysteresis loop-shaping parameter	1
F_y	Force of equivalent hysteretic damper	40 k
n	Parameter controlling the smoothness of the transition from elastic to plastic response	2
x_p	Horizontal displacement	m
Y	Yield displacement of equivalent hysteretic damper	1 mm
z	Hysteretic displacement	
α	Post yielding to preyielding stiffness ratio	0.2
β	Hysteresis loop-shaping parameter	-0.25
γ	Hysteresis loop-shaping parameter	0.75

TABLE 11.3 Parameters for the Actuator

Variable	Description	Value
A_f	Cross-sectional area of actuator	m^2
B	Bulk modulus of hydraulic fluid	N/m^2
f	Force applied to SDOF structure by actuator	N
g	Proportional feedback gain	2.5
k_c	Flow–pressure coefficient	m$^4 \cdot$ s/kg
k_q	Flow gain	m^2/s
x_p	Horizontal displacement	m
V	Characteristic hydraulic fluid volume	m^3
$2BA_f k_q G/V$	Displacement coefficient	3.6484×10^8 N/m/s
$2Bk_c/V$	Force feedback coefficient	66.67 1/s
$2BA^2/V$	Velocity feedback coefficient	2.1891×10^7 N/m

where $z(t)$ is a dimensionless quantity representing hysteretic displacement (Fan *et al.*, 1988; Sain *et al.*, 1997) satisfying the first-order differential equation:

$$Y\dot{z}(t) = \gamma\left|\dot{x}_p(t)\right|\left|z(t)\right|^{n-1}z(t) - \beta\dot{x}_p(t)|z(t)|^n + A\dot{x}_p(t). \quad (11.48)$$

Table 11.2 lists descriptions of the variables and parameter values. The actuator force f applied to the SDOF structure is governed by the equation (Dyke *et al.*, 1995; DeSilva, 1989):

$$\dot{f}(t) = \frac{2BA_f k_q \gamma_f}{V}[u(t) - x_p(t)] - \frac{2Bk_c}{V}f(t) - \frac{2BA_f^2}{V}\dot{x}_p(t). \quad (11.49)$$

The $u(t)$ is the control signal generated by the controller. Descriptions of the quantities in equation 11.49 are provided in Table 11.3.

Defining $A_z = \frac{A}{Y}$, $\beta_z = \frac{\beta}{Y}$, and $\gamma_z = \frac{\gamma}{Y}$ and using the fact that $|z| = z \text{ sgn } z$, then:

$$\dot{z}(t) = [A_z - (\beta_z + \gamma_z \text{ sgn } \dot{x}_p \text{ sgn } z)z^n(t)]\dot{x}_p(t) \quad (11.50)$$

$$= [A_z + \sigma(t)z^n(t)]\dot{x}_p(t), \quad (11.51)$$

where $\sigma(t) = -[\beta_z + \gamma_z \text{ sgn } \dot{x}_p(t) \text{ sgn } z(t)]$. Substitution of the expression for Q into the equation of motion of the structure yields the following system of equations. For convenience, the explicit dependence on time is suppressed:

$$\ddot{x}_p = -\left(\frac{k}{m} + \alpha\frac{F_y}{Ym}\right)x_p - \frac{c}{m}\dot{x}_p + \frac{1}{m}f(t) - (1-\alpha)\frac{Fy}{m}z - \ddot{x}_g. (11.52)$$

$$\dot{f} = -\frac{2BA_f k_q \gamma_f}{V}x_p - \frac{2BA_f^2}{V}\dot{x}_p - \frac{2Bk_c}{V}f(t) + \frac{2BA_f k_q \gamma_f}{V}u. \quad (11.53)$$

$$\dot{z} = (A_z + \sigma z^n)\dot{x}_p. \quad (11.54)$$

Given z with $n = 2$, with $z_0 = z(t_\sigma)$ and $x_{p0} = x_p(t_\sigma)$ (where t_σ represents the most recent point in time where $\sigma(t)$ switched value yields (for $\sigma \geq 0$ and $\sigma < 0$) closed-form expressions for z are readily obtained (Sain, 1997).

An example application of a third-order VFS partial linearization regulator design for the SDOF structure described previously is simulated in equations 11.55 to 11.57, using the simplified controller design derived above. Choosing the state vector $[x_1\ x_2\ x_3]' = [x_p\ \dot{x}_p\ f]'$, where z can be expressed as previously noted, depending on the sign of σ, the resulting state-space description has the form $y = x_1$, and the following results:

$$\dot{x}_1 = x_2. \quad (11.55)$$

$$\dot{x}_2 = -\left(\frac{k}{m} + \alpha\frac{F_y}{Ym}\right)x_1 - \frac{c}{m}x_2 + \frac{1}{m}x_3 - (1-\alpha)\frac{F_y}{m}z. \quad (11.56)$$

$$\dot{x}_3 = -\frac{2BA_f k_q \gamma_f}{V}x_1 - \frac{2BA_f^2}{V}x_2 - \frac{2Bk_c}{V}x_3 + \frac{2BA_f k_q \gamma_f}{V}u. \quad (11.57)$$

This example represents a preliminary test of the control system to demonstrate that the actuator can be commanded to move the first floor of the structure to a specific location. Under the hypothesis that the VFS control designs work to make small errors smaller, a command request $r = \bar{x}_1 = 0.004$ m was specified, and a constant offset of $y_0 = 0.001$ m, representing a biased position sensor, was added to the measured output of the plant. Regulation about a nonzero set point

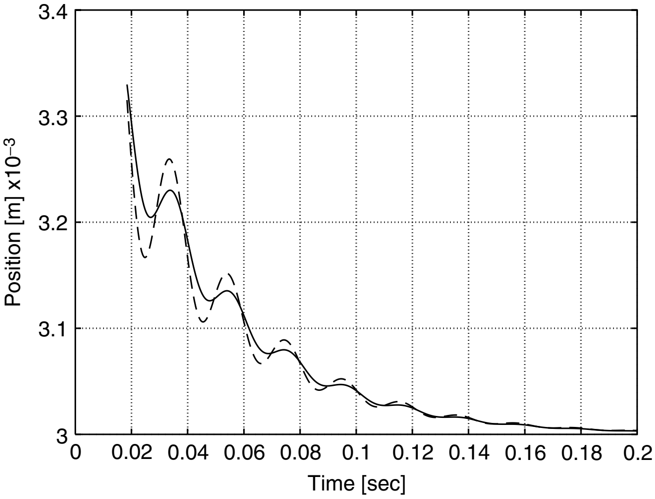

FIGURE 11.7 Position of First Floor Following Initial Transient for Linear Controller Design (Dashed) and Third-Order Controller Design (Solid)

was chosen because the higher order Taylor series coefficients of the control model are zero if $\bar{x}_1 = 0$. Primarily for computational convenience, the desired closed-loop map $T_1(s)$ was given four poles at $s =$ -1000 in this example.

A result is shown in Figure 11.7 The initial transient response was omitted so as not to obscure the effect of the higher order controller. The response of the closed-loop system, meaning the position of the first floor, x_1, is shown for the linear controller design and the third-order controller design. Note that the magnitude of the oscillations in the response as the output tends toward the commanded position are much smaller for the third-order design when compared to those produced by the linear controller design.

11.7 Conclusion

Volterra feedback synthesis is shown to provide a capability for specifying nonlinear input output behavior for a closed-loop feedback system. The procedure is developed for the class of linear analytic plants that admit Volterra series representation, and a simplified means of systematically realizing the Volterra kernels and computing the output of the resulting controller is provided, up to an arbitrary order. The simplified form is recursive in nature and lends itself to an automated design and simulation procedure. The procedure is applied to a regulator design for a base-isolated SDOF structure with hysteretic damping.

Intelligent Control of Nonlinear Systems with a Time-Varying Structure

Raúl Ordóñez
Department of Electrical and Computer Engineering, University of Dayton, Dayton, Ohio, USA

Kevin M. Passino
Department of Electrical and Computer Engineering, The Ohio State University, Columbus, Ohio, USA

12.1 Introduction

The field of nonlinear adaptive control developed rapidly in the 1990s. Work by Polycarpou and Ioannu (1991) and others gave birth to an important branch of adaptive control theory: the nonlinear online function approximation-based control, which includes neural (Polycarpou, 1996) and fuzzy (Su and Stepanenko, 1994) approaches (note that several other relevant works are focused on neural and fuzzy control, many of them cited in the references within the above publications). The neural and fuzzy approaches are most of the time equivalent, differing between each other only for the structure of the approximator chosen (Spooner and Passino, 1996). Most of these publications deal with indirect adaptive control, trying first to identify the dynamics of the systems and eventually generating a control input according to the certainty equivalence principle (with some modification to add robustness to the control law), whereas very few authors (Spooner and Passino, 1996; Rovithakis and Christodoulou, 1995) use the direct approach in which the controller *directly* generates the control input to guarantee stability.

Plants whose dynamics can be expressed in the so-called **strict feedback form** have been considered, and techniques like **back-stepping** and **adaptive back-stepping** (Krstic *et al.*, 1995) have emerged for their control. Publications of Polycarpou (1996) and Polycarpou and Mears (1998) present an extension of the tuning functions approach in which the nonlinearities of the strict feedback system are not assumed to be parametric uncertainties but are rather completely unknown nonlinearities to be approximated online with nonlinearly parameterized function approximators. Both the adaptive methods in Krstic *et al.* (1995) and in Polycarpou (1996) and Polycarpou and Mears (1998) attempt to approximate the dynamics of the plant online, so they may be classified as indirect adaptive schemes.

In this chapter, we combine an extension of the class of strict feedback systems considered in Polycarpou (1996) and Polycarpou and Mears (1998) with the concept of a dynamic structure that depends on time; this combination allows us to propose a class of nonlinear systems with a time-varying structure, for which we develop a *direct* adaptive control approach. This class of systems is a generalization of the class of strict feedback systems traditionally considered in the literature. Moreover, the direct adaptive control developed here is, to our knowledge, the first of its kind in this context, and it presents several advantages with respect to indirect adaptive methods, including the fact that it needs less plant information to be implemented.

12.2 Direct Adaptive Control

Consider the class of continuous time nonlinear systems given by:

$$\begin{aligned}\dot{x}_i &= \sum_{j=1}^{R} \rho_j(\upsilon)\left(\phi_i^j(X_i) + \psi_i^j(X_i)x_{i+1}\right).\\ \dot{x}_n &= \sum_{j=1}^{R} \rho_j(\upsilon)\left(\phi_n^j(X_n) + \psi_n^j(X_n)u\right).\end{aligned} \tag{12.1}$$

The $i = 1, 2, \ldots, n-1$, $X_i = [x_1, \ldots, x_i]^\top$, $X_n \in \mathbb{R}^n$ is the state vector, which we assume measurable, and $u \in \mathbb{R}$ is the control input. The variable $\upsilon \in \mathbb{R}^q$ may be an additional input or a possibly exogenous **scheduling variable**. We assume that υ and its derivatives up to and including the $(n-1)^{th}$ one are bounded and available for measurement, which may imply that υ is given by an external dynamical system. The functions ρ_j, $j = 1, \ldots, R$ may be considered to be **interpolating functions** that produce the time-varying structural nature of system (Polycarpou and Ioannou, 1991) because they combine R systems in strict feedback form (given by the ϕ_i^j and ψ_i^j functions, $i = 1, \ldots, n$, $j = 1 \ldots, R$), and the combination depends on time through the variable υ (thereby, the dynamics of the plant may be different at each time point depending on the scheduling variable). Here, we assume that the functions ρ_j are n times continuously differentiable and that they satisfy, for all $\upsilon \in \mathbb{R}^q$, $\sum_{j=1}^{R} \rho_j(\upsilon) < \infty$ and $\partial^i \rho_j(\upsilon)/\partial \upsilon^i < \infty$. Denote for convenience $\phi_i^c(X_i, \upsilon) = \sum_{j=1}^{R} \rho_j(\upsilon)\phi_i^j(X_i)$ and $\psi_i^c(X_i, \upsilon) = \sum_{j=1}^{R} \rho_j(\upsilon)\psi_i^j(X_i)$. We will assume that ϕ_i^c and ψ_i^c are sufficiently smooth in their arguments and that they satisfy (for all $X_i \in \mathbb{R}^i$ and $\upsilon \in \mathbb{R}^q$) $i = 1, \ldots, n$, $\phi_i^c(0, \upsilon) = 0$ and $\psi_i^c(X_i, \upsilon) \neq 0$.

Here, we will develop a direct adaptive control method for the class of systems in equation 12.1. We assume that the interpolation functions ρ_j are known, but the functions ϕ_i^j and ψ_i^j (which constitute the underlying time-varying dynamics of the system) are unknown. In an indirect adaptive methodology, one would attempt to identify the unknown functions and then construct a stabilizing control law based on the approximations to the plant dynamics. Here, however, we will postulate the existence of an ideal control law (based on the assumption that the plant belongs to the class of systems of equation 12.1) that possesses some desired stabilizing properties, and then we devise adaptation laws that attempt to approximate the ideal control equation. This approximation will be performed within a compact set $\mathcal{S}_{x_n} \subset \mathbb{R}^n$ of arbitrary size that contains the origin. In this manner, the results obtained are semiglobal, in the sense that they are valid as long as the state remains within $\mathcal{S}_{x_n}$; this set can be made as large as desired by the designer. In particular, with enough plant information, the set can be made large enough so that the state never exits it because, as will be shown, a bound can be placed on the state transient. Furthermore, as will be indicated, the stability can be made global by using bounding control terms.

For each vector X_i, we will assume the existence of a compact set $\mathcal{S}_{x_i} \subset \mathbb{R}^i$ specified by the designer. We will consider trajectories in the compact sets $\mathcal{S}_{x_i}$, $i = 1, \ldots, n$, where the sets are constructed such that $\mathcal{S}_{x_i} \subset \mathcal{S}_{x_{i+1}}$, for $i = 1, \ldots, n-1$. We assume the existence of bounds $\underline{\psi}_i^c$, $\bar{\psi}_i^c \in \mathbb{R}$, and $\psi_{i_d}^c \in \mathbb{R}$, $i = 1, \ldots, n$ (*not necessarily known*), such that for all $\upsilon \in \mathbb{R}^q$ and $X_i \in \mathcal{S}_{x_i}$, $i = 1, \ldots, n$:

$$\begin{aligned} &0 < \underline{\psi}_i^c \le \psi_i^c(X_i, \upsilon) \le \bar{\psi}_i^c < \infty.\\ &|\dot{\psi}_i^c| = \left| \sum_{j=1}^{R} \left(\frac{\partial \rho_j(\upsilon)}{\partial \upsilon} \dot{\upsilon} \psi_i^j(X_i) + \rho_j(\upsilon) \frac{\partial \psi_i^j(X_i)}{\partial X_i} \dot{X}_i \right) \right| \le \psi_{i_d}^c. \end{aligned} \tag{12.2}$$

This assumption implies that the affine terms in the plant dynamics have a bounded gain and a bounded rate of change. Since the functions ψ_i^c are assumed continuous, they are therefore bounded in $\mathcal{S}_x$. Similarly, note that even though the term $|\dot{X}_i|$ may not necessarily be globally bounded, it will have a constant bound in $\mathcal{S}_x$ due to the continuity assumptions we make. Therefore, the assumption of equation 12.2 will always be satisfied in $\mathcal{S}_{x_n}$. Moreover, in the simplest of cases, the first part of assumption of equation 12.2 is satisfied globally when the functions ψ_i^j are constant or sector bounded for all $X_i \in \mathbb{R}^i$.

The class of plants of equation 12.1 is, to our knowledge, the most general class of systems considered so far within the context of adaptive control based on back-stepping. In particular, in Krstić *et al.* (1995), which are indirect adaptive approaches, the input functions ψ_i^j are assumed to be constant for $i = 1, \ldots, n$. This assumption allows the authors of those works to perform a simpler stability analysis, which becomes more complex in the general case (Ordoñez and Passino, 2001). The addition of the interpolation functions ρ_j, $j = 1, \ldots, R$ also extends the class of strict feedback systems to one including systems with a time-varying structure (Ordoñez and Passino, 2000a) as well as systems falling in the domain of gain scheduling (where the plant dynamics are identified at different operating points and then interpolated between using a scheduling variable). Note that if we let $R = 1$ and $\rho_1(\upsilon) = 1$ for all υ, together with $\psi_i^c = 1$, $i = 1, \ldots, n$, we have the particular case considered in Polycarpou (1996) and Polycarpou and Mears (1998).

The direct approach presented here has several advantages with respect to indirect approaches such as in Krstić *et al.* (1995), Polycarpou (1996), and Polycarpou and Mears (1998). In particular, bounds on the input functions ψ_i^j are only assumed to exist and need *neither to be known nor to be estimated.* This is because the ideal law is formulated so that there is not an explicit need to include information about the bounds in the actual control law. Moreover, although assumption of equation 12.2 appears to be more restrictive than what is needed in the indirect adaptive case, it is in fact not so because the stability results are semiglobal [i.e., since we are operating in the compact sets $\mathcal{S}_{x_n}$, continuity of the affine terms automatically implies the satisfaction of the second part of assumption 12.2].

12.2.1 Direct Adaptive Control Theorem

Next, we state our main result and then show its proof. For convenience, we use the notation $\nu_i = [\upsilon, \dot{\upsilon}, \ldots, \upsilon^{(i-1)}] \in \mathbb{R}^{q \times i}$, $i = 1, \ldots, n$.

Theorem

Consider system of equation 12.1 with the state vector X_n measurable and the scheduling matrix ν_{n-1} measurable and bounded, together with the above stated assumptions on ϕ_i^c, ψ_i^c, ρ_j, and equation 12.2. Assume also that $\nu_i(0) \in \mathcal{S}_{\upsilon_i} \subset \mathbb{R}^{q \times i}$, $X_n(0) \in \mathcal{S}_{x_i} \subset \mathbb{R}^i$, $i = 1, \ldots, n$ where $\mathcal{S}_{\upsilon_i}$ and $\mathcal{S}_{x_i}$ are compact sets specified by the designer and large enough that ν_i and X_i do not exit them. Consider the diffeomorphism $z_1 = x_1$, $z_i = x_i - \hat{\alpha}_{i-1} - \alpha_{i-1}^s$, $i = 2, \ldots, n$, with $\hat{\alpha}_i(X_i, \nu_i) = \sum_{j=1}^R \rho_j(\upsilon)\hat{\theta}_{\alpha_i^j}^\top \zeta_{\alpha_i^j}(X_i, \nu_i)$, and $\alpha_i^s(z_i, z_{i-1}) = -k_i z_i - z_{i-1}$, with $k_i > 0$ and $z_0 = 0$. Assume the functions $\zeta_{\alpha_i^j}(X_i, \nu_i)$ to be at least $n - i$ times continuously differentiable; to satisfy, for $i = 1, \ldots, n$, $j = 1, \ldots, R$:

$$\left| \frac{\partial^{n-i} \zeta_{\alpha_i^j}}{\partial [X_i, \nu_i]^{n-i}} \right| < \infty. \tag{12.3}$$

Consider the adaptation laws for the parameter vectors $\hat{\theta}_{\alpha_i^j} \in \mathbb{R}^{N_{\alpha_i^j}}$, $N_{\alpha_i^j} \in \mathbb{N}$, $\dot{\hat{\theta}}_{\alpha_i^j} = -\rho_j \gamma_{\alpha_i^j} \zeta_{\alpha_i^j} z_i - \sigma_{\alpha_i^j} \hat{\theta}_{\alpha_i^j}$, where $\gamma_{\alpha_i^j} > 0$, $\sigma_{\alpha_i^j} > 0$, $i = 1, \ldots, n$, $j = 1, \ldots, R$ are design parameters. Then, the control law $u = \hat{\alpha}_n + \alpha_n^s$ guarantees boundedness of all signals and convergence of the states to the residual set:

$$\mathcal{D}_d = \left\{ X_n \in \mathcal{R}^n : \sum_{i=1}^n z_i^2 \leq \frac{2\underline{\psi}_m W_d}{\beta_d} \right\}, \tag{12.4}$$

where $\underline{\psi}_m = \min_{1 \leq i \leq n} \bar{\psi}_i^c$, β_d is a constant and where W_d measures approximation errors and ideal parameter sizes, and its magnitude can be reduced through the choice of the design constants k_i, $\gamma_{\alpha_i^j}$, and $\sigma_{\alpha_i^j}$.

Proof

The proof requires n steps and is performed inductively. First, let $z_1 = x_1$ and $z_2 = x_2 - \hat{\alpha}_1 - \alpha_1^s$, where $\hat{\alpha}_1$ is the approximation to an ideal signal α_1^* ("ideal" in the sense that if we had $\hat{\alpha}_1 = \alpha_1^*$, we would have a globally asymptotically stable closed loop without need for the stabilizing term α_1^s), and α_1^s will be given below. Let $c_1 > 0$ be a constant such that $c_1 > \psi_{1d}^c / 2\psi_1^c$ and $\alpha_1^*(x_1, \nu) = (1/\psi_1^c)(-\phi_1^c - c_1 z_1)$. Because the ideal control α_1^* is smooth, it may be approximated with arbitrary accuracy for ν and x_1 within the compact sets $\mathcal{S}_{\nu_1} \subset \mathbb{R}^q$ and $\mathcal{S}_{x_1} \subset \mathbb{R}$, respectively, as long as the size of the approximator can be made arbitrarily large.

For approximators of finite size, let $\alpha_1^*(x_1, \nu) = \sum_{j=1}^R \rho_j(\nu)\theta_{\alpha_1^j}^{*^\mathrm{T}} \zeta_{\alpha_1^j}(\nu, x_1) + \delta_{\alpha_1}(\nu, x_1)$, where the parameter vectors $\theta_{\alpha_1^j}^* \in \mathbb{R}^{N_{\alpha_1^j}}$ and $N_{\alpha_1^j} \in \mathbb{N}$ are optimum in the sense that they minimize the representation error δ_{α_1} over the set $\mathcal{S}_{x_1} \times \mathcal{S}_{\nu_1}$ and suitable compact parameter spaces $\Omega_{\alpha_1^j}$, in addition, $\zeta_{\alpha_1^j}(x_1, \nu)$ are defined via the choice of the approximator structure [see Ordoñez and Passino (2000b) for an example of a choice for $\zeta_{\alpha_1^j}$]. The parameter sets $\Omega_{\alpha_1^j}$ are simply mathematical artifacts. As a result of the stability proof, the approximator parameters are bounded using the adaptation laws in theorem 1, so $\Omega_{\alpha_1^j}$ does not need to be defined explicitly, and no parameter projection (or any other "artificial" means of keeping the parameters bounded) is required. The representation error δ_{α_1} arises because the sizes $N_{\alpha_i^j}$ are finite, but it may be made arbitrarily small within $\mathcal{S}_{x_1} \times \mathcal{S}_{\nu_1}$ by increasing $N_{\alpha_i^j}$ (i.e., we assume the chosen approximator structures possess the **universal approximation property**). In this way, there exists a constant bound $d_{\alpha_1} > 0$ such that $|\delta_{\alpha_1}| \leq d_{\alpha_1} < \infty$. To make the proof logically consistent, however, we need to assume that some knowledge about this bound and a bound on $\theta_{\alpha_1^j}^*$ is available (since, in this case, it becomes possible to guarantee a priori that $\mathcal{S}_{x_1} \times \mathcal{S}_{\nu_1}$ is large enough). However, in practice, some amount of redesign may be required because these bounds are typically guessed by the designer.

Let $\Phi_{\alpha_1^j} = \hat{\theta}_{\alpha_1^j} - \theta_{\alpha_1^j}^*$ denote the parameter error and approximate α_1^* with $\hat{\alpha}_1(x_1, \nu, \hat{\theta}_{\alpha_1^j}; j = 1, \ldots, R) = \sum_{j=1}^R \rho_j(\nu)\hat{\theta}_{\alpha_1^j}^\top \zeta_{\alpha_1^j}(x_1, \nu)$. Hence, we have a linear in the parameters approximator with parameter vectors $\hat{\theta}_{\alpha_1^j}$. Note that the structural dependence on time of system of equation 12.1 is reflected in the controller because $\hat{\alpha}_1$ can be viewed as using the functions $\rho_j(\nu)$ to interpolate between "local" controllers of the form $\hat{\theta}_{\alpha_1^j}^\top \zeta_{\alpha_1^j}(x_1, \nu)$, respectively. Notice that since the functions ρ_j are assumed continuous and ν bounded, the signal $\hat{\alpha}_1$ is well defined for all $\nu \in \mathcal{S}_{\nu_1}$.

Consider the dynamics of the transformed state $\dot{z}_1 = \phi_1^c + \psi_1^c(z_2 + \hat{\alpha}_1 + \alpha_1^s) + \psi_1^c(\alpha_1^* - \alpha_1^*) = -c_1 z_1 + \psi_1^c z_2 + \psi_1^c(\hat{\alpha}_1 - \alpha_1^*) + \psi_1^c \alpha_1^s = -c_1 z_1 + \psi_1^c z_2 + \psi_1^c \Big(\sum_{j=1}^R \rho_j \Phi_{\alpha_1^j}^\top \zeta_{\alpha_1^j} - \delta_{\alpha_1^j} \Big) + \psi_1^c \alpha_1^s$. Let $V_1 = \frac{1}{2\psi_1^c} z_1^2 + \frac{1}{2}\sum_{j=1}^R \Phi_{\alpha_1^j}^\top \Phi_{\alpha_1^j} / \gamma_{\alpha_1^j}$, and examine its derivative $\dot{V}_1 = (2\psi_1^c(2z_1\dot{z}_1) - 2z_1^2\dot{\psi}_1^c)/(4\psi_1^{c^2}) + \sum_{j=1}^R \Phi_{\alpha_1^j}^\top \dot{\Phi}_{\alpha_1^j} / \gamma_{\alpha_1^j}$. Using the expression for $\dot{z}_1$, $\dot{V}_1 = -c_1 z_1^2/\psi_1^c + z_1 z_2 + z_1 \sum_{j=1}^R \rho_j \Phi_{\alpha_1^j}^\top \zeta_{\alpha_1^j} - z_1 \delta_{\alpha_1^j} + z_1 \alpha_1^s - \frac{1}{2} z_1^2 \dot{\psi}_1^c / \psi_1^{c^2} + \sum_{j=1}^R \Phi_{\alpha_1^j}^\top \dot{\Phi}_{\alpha_1^j} / \gamma_{\alpha_1^j}$. Choose the adaptation law $\dot{\hat{\theta}}_{\alpha_1^j} = \dot{\Phi}_{\alpha_1^j} = -\rho_j \gamma_{\alpha_1^j} \zeta_{\alpha_1^j} z_1 - \sigma_{\alpha_1^j} \hat{\theta}_{\alpha_1^j}$ with design constants $\gamma_{\alpha_1^j} > 0$, $\sigma_{\alpha_1^j} > 0$, $j = 1, \ldots, R$ (we think of $\sigma_{\alpha_1^j} \hat{\theta}_{\alpha_1^j}$ as a "leakage term"). Also, note that for any constant $k_1 > 0$, $-z_1 \delta_{\alpha_1^j} \leq |z_1| d_{\alpha_1} \leq k_1 z_1^2 + d_{\alpha_1}^2 / (4k_1)$. We pick $\alpha_1^s = -k_1 z_1$.

Notice also that in completing squares, $-\Phi^{\top}_{\alpha_1^j}\hat{\theta}_{\alpha_1^j} = -\Phi^{\top}_{\alpha_1^j}\left(\Phi_{\alpha_1^j} + \theta^*_{\alpha_1^j}\right) \leq -|\Phi_{\alpha_1^j}|^2/2 + |\theta^*_{\alpha_1^j}|^2/2$. Finally, observe that $-z_1^2 \psi_1^c\left(c_1 + \psi_1^c/2\psi_1^c\right) \leq -z_1^2/\psi_1^c\left(c_1 - \psi^c_{1_d}/2\underline{\psi}_1^c\right) \leq -\bar{c}_1 z_1^2/\psi_1^c$ with $\bar{c}_1 = c_1 - \psi^c_{1_d}/2\underline{\psi}_1^c > 0$. Then, we obtain $\dot{V}_1 \leq -\bar{c}_1 z_1^2/\psi_1^c - \frac{1}{2}\sum_{j=1}^R \sigma_{\alpha_1^j}|\Phi_{\alpha_1^j}|^2/\gamma_{\alpha_1^j} + z_1 z_2 + d^2_{\alpha_1}/4k_1 + \frac{1}{2}\sum_{j=1}^R \sigma_{\alpha_1^j}|\Phi_{\alpha_1^j}|^2/\gamma_{\alpha_1^j} + z_1 z_2 + d^2_{\alpha_1}/4k_1 + \frac{1}{2}\sum_{j=1}^R \sigma_{\alpha_1^j}\theta^*_{\alpha_1^j}/\gamma_{\alpha_1^j}$. This completes the first step of the proof.

We may continue in this manner up to the nth step (we omit intermediate steps for brevity), where we have $z_n = x_n - \hat{\alpha}_{n-1} - \alpha^s_{n-1}$, with $\hat{\alpha}_{n-1}$ and α^s_{n-1} defined as in theorem 1. Consider the ideal signal $\alpha_n^*(X_n, \nu_n) = (1/\psi_n^c)\left(\phi_n^c - c_n z_n + \dot{\hat{\alpha}}_{n-1} + \dot{\alpha}^s_{n-1}\right)$ with $c_n > \psi^c_{n_d}/(2\underline{\psi}_n^c)$. Notice that, even though the terms $\dot{\hat{\theta}}_{\alpha^j_{n-1}}$ appear in α_n^* through the partial derivatives in $\dot{\hat{\alpha}}_{n-1}$, $\hat{\theta}_{\alpha^j_{n-1}}$ does not need to be an input to α_n^*, since the resulting product of the partial derivatives and $\dot{\hat{\theta}}_{\alpha^j_{n-1}}$ can be expressed in terms of $z_1, \ldots, z_{n-1}$, ν and $\sigma_{\alpha^j_{n-1}}\hat{\alpha}_{n-1}$. To simplify the notation, however, we will omit the dependencies on inputs other than X_i and ν_i, but bearing in mind that, when implementing this method, more inputs may be required to satisfy the proof. Note also that by assumption in equation 12.3, $|\alpha_n^*| < \infty$ for bounded arguments. Therefore, we may represent α_n^* with $\alpha_n^*(X_n, \nu_n) = \sum_{j=1}^R \rho_j(\nu)\theta^{*\top}_{\alpha_n^j}\zeta_{\alpha_n^j}(X_n, \nu_n) + \delta_{\alpha_n}(X_n, \nu_n)$ for $X_n \in \mathcal{S}_{x_n} \subset \mathbb{R}^n$ and $\nu_n \in \mathcal{S}_{\nu_n} \subset \mathbb{R}^{q\times n}$. The parameter vector $\theta^*_{\alpha_n^j} \in \mathbb{R}^{N\alpha_n^j}$, $N_{\alpha_n^j} \in \mathbb{N}$ is an optimum within a compact parameter set Ω_{α_n}, in a sense similar to $\theta^*_{\alpha_1^j}$, so that for $(X_n, \nu_n) \in \mathcal{S}_{x_n} \times \mathcal{S}_{\nu_n,\, |\delta_{\alpha n}| \leq d_{\alpha n} < \infty}$ for some bound $d_{\alpha_n} > 0$. Let $\Phi_{\alpha_n^j} = \hat{\theta}_{\alpha_n^j} - \theta^*_{\alpha_n^j}$, and consider the approximation $\hat{\alpha}_n$ as given in theorem 1. The control law $u = \hat{\alpha}_n + \alpha_n^s$ yields $\dot{z}_n = \phi_n^c + \psi_n^c(\hat{\alpha}_n + \alpha_n^s) - \dot{\hat{\alpha}}_{n-1} - \dot{\alpha}^s_{n-1} + \psi_n^c(\alpha_n^* - \alpha_n^*) = -c_n z_n + \psi_n^c\left(\sum_{j=1}^R \rho_j(\nu)\Phi^{\top}_{\alpha_n^j}\zeta_{\alpha_n^j} - \delta_{\alpha_n}\right) + \psi_n^c\alpha_n^s$. Choose the Lyapunov function candidate $V = V_{n-1} + \frac{1}{2\psi_n^c}z_n^2 + \frac{1}{2}\sum_{j=1}^R \Phi^{\top}_{\alpha_n^j}\Phi_{\alpha_n^j}/\gamma_{\alpha_n^j}$, and examine its derivative $\dot{V} = \dot{V}_{n-1} - c_n z_n^2/\psi_n^c + z_n\sum_{j=1}^R \rho_j(\nu)\Phi^{\top}_{\alpha_n^j}\zeta_{\alpha_n^j} - z_n\delta_{\alpha_n} + z_n\alpha_n^s - \frac{1}{2}z_n^2\dot{\psi}_n^c/\psi_n^{c^2} + \sum_{j=1}^R \Phi^{\top}_{\alpha_n^j}\Phi_{\alpha_n^j}/\gamma_{\alpha_n^j}$. One can show inductively that $\dot{V}_{n-1} \leq -\sum_{i=1}^{n-1}\dot{c}_i z_i^2/\psi_i^c - \frac{1}{2}\sum_{i=1}^{n-1}\sum_{j=1}^R \sigma_{\alpha_i^j}|\Phi_{\alpha_i^j}|^2\gamma_{\alpha_i^j} + z_{n-1}z_n + \sum_{i=1}^{n-1} d_{\alpha_i^2}/(4k_i) + \frac{1}{2}\sum_{i=1}^{n-1}\sum_{j=1}^R \sigma_{\alpha_i^j}|\theta^*_{\alpha_i^j}|^2/\gamma_{\alpha_i^j}$ with constants $\bar{c}_i = c_i - \psi_{i_d}/(2\underline{\psi}_i^c) > 0$, $i = 1, \ldots, n$. The choice of adaptation laws for $\theta_{\alpha_n^j}$ and of α_n^s in theorem 1, together with the observations that $-(\sigma_{\sigma_n^j}/\gamma_{\alpha_n^j})\Phi^{\top}_{\alpha_n^j}\hat{\theta}_{\alpha_n^j} \leq -(\sigma_{\alpha_n^j}/\gamma_{\alpha_n^j})(|\Phi_{\alpha_n^j}|^2/2) + \sigma_{\alpha_n^j}/\gamma_{\alpha_n^j}|\theta^*_{\alpha_n^j}|^2/2$, $z_n\delta_{\alpha_n^j} \leq k_n z_n^2 + d_{\alpha_n}/4k_n$, with $k_n > 0$ and $(-z_n^2/\psi_n^c)\,(c_n + \dot{\psi}_n^c/2\psi_n^c) \leq -\bar{c}_n z_n^2/\psi_n^c$ imply the following:

$$\dot{V} \leq -\sum_{i=1}^{n}\frac{\bar{c}_i z_i^2}{\bar{\psi}_i^c} - \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{R}\sigma_{\alpha_i^j}\frac{|\boldsymbol{\Phi}_{\alpha_i^j}|^2}{\gamma_{\alpha_i^j}} + W_d, \qquad (12.5)$$

where W_d contains the combined effects of representation errors and ideal parameter sizes and is given by $W_d = \sum_{i=1}^n d^2_{\alpha_i}/4k_i + 1/2\sum_{i=1}^n\sum_{j=1}^R \sigma_{\alpha_i^j}|\theta_{\alpha_i^j}|^2\,\gamma_{\alpha_i^j}$. Note that if $\sum_{i=1}^n \bar{c}_i z_i^2/\psi_i^c \geq W_d$ or $1/2\sum_{i=1}^n\sum_{j=1}^R \sigma_{\alpha_i^j}|\Phi_{\alpha_i^j}|^2/\gamma_{\alpha_i^j} \geq W_d$, then we have $\dot{V} \leq 0$. Furthermore, letting $\underline{\psi}_m = \min_{1\leq i\leq n(\underline{\psi}_i^c)}$ and $\bar{\psi}_m = \max_{1\leq i\leq n}(\bar{\psi}_i^c)$ and defining $\bar{c}_0 = \min_{1\leq i\leq n}(\bar{c}_i)$, $\psi_m = \underline{\psi}_m/\bar{\psi}_m$, and $\sigma_0 = \min_{1\leq i\leq n,\, 1\leq j\leq R}\left(\sigma_{\alpha_i^j}\right)$, we have $-\sum_{i=1}^n \bar{c}_i z_i^2/\bar{\psi}_i^c \leq -\bar{c}_0\sum_{i=1}^n z_i^2/\psi_i^c = -\bar{c}_O\sum_{i=1}^n (z_i^2/\psi_{\bar{i}}^c)(\psi_i^c/\psi_i^c) \leq -\bar{c}_0\sum_{i=1}^n (z_i^2/\psi_i^c)\,(\underline{\psi}_i^c/\psi_i^c) \leq -\bar{c}_0\psi_m\sum_{i=1}^n z_i^2/\psi_i^c$ and $-\frac{1}{2}\sum_{i=1}^n\sum_{j=1}^R \sigma_{\alpha_i^j}|\Phi_{\alpha_i^j}|^2/\gamma_{\alpha_i^j} \leq -\sigma_0\frac{1}{2}\sum_{i=1}^n\sum_{j=1}^R |\Phi_{\alpha_i^j}|^2/\gamma_{\alpha_i^j}$. Then, letting $\beta_d = \min(2\bar{c}_0\psi_m, \sigma_0)$, we have that if:

$$V = \frac{1}{2}\sum_{i=1}^{n}\frac{z_i^2}{\psi_i^c} + \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{R}\frac{|\Phi_{\alpha_i^j}|^2}{\gamma_{\alpha_i^j}} \geq V_0, \qquad (12.6)$$

with $V_0 = W_d/\beta_d$, then $\dot{V} \leq 0$ and all signals in the closed loop are bounded. Furthermore, we have $\dot{V} \leq -\beta_d V + W_d$, which implies that $0 \leq V(t) \leq W_d/\beta_d + (V(0) - W_d/\beta_d)\,e^{-\beta_d t}$, so both the transformed states and the parameter error vectors converge to a bounded set. Finally, we conclude from the upper bound on $V(t)$ that the state vector X_n converges to the residual set of equation 12.4

Remark 1

The representation error bounds and the size of the ideal parameter vectors are assumed known because they affect the size of the residual set to which the states converge. It is possible to augment the direct adaptive algorithm with "auto-tuning" capabilities similar to Polycarpou and Mears (1998), which would relax the need for these bounds.

Furthermore, note that the stability result of theorem 1 is semiglobal in the sense that it is valid in the compact sets $\mathcal{S}_{\nu_i}$ and $\mathcal{S}_{x_i}$, $i = 1, \ldots, n$, which can be made arbitrarily large. The stability result may be made global by adding a high-gain bounding control term to the control law. Such a term may be particularly useful when, due to a complete lack of a priori knowledge, the control designer is unable to guarantee that the compact sets $\mathcal{S}_{x_i}$, $i = 1, \ldots, n$, are large enough so that the state will not exit them before the controller has time to bring the state inside D_d; moreover, it may also happen that due to a poor design and poor system knowledge, D_d is not contained in $\mathcal{S}_{x_n}$. In this case, too, bounding control terms may be helpful until the design is refined and improved. Using bounding control, however, requires explicit knowledge of functional upper bounds of $|\psi_i^c(\nu, X_i)|$ and also of the lower bounds $\underline{\psi}_i^c$, $i = 1, \ldots, n$, whose knowledge we do not mandate in theorem 1. Bounding terms may be added to the diffeomorphism in theorem 1, but we do not present the analysis since it is similar to the one we present here and it is algebraically tedious; we simply note, though, that the bounding terms have to be smooth (because they need to be differentiable), so they need to be defined in terms of smooth approximations to the sign, saturation, and absolute value functions that are typically used in this approach.

Remark 2

If the bounds $\underline{\psi}_i^c$, $\bar{\psi}_i^c$, and $\psi_{i_d}^c$ are known, it becomes possible for the designer to directly set the constants c_i in the control law. Notice that with knowledge of these bounds, the term $\underline{\psi}_m$ is also known, and we can pick constants c_i such that $c_i > \psi_{i_d}^c / 2\underline{\psi}_i^c$. Define the auxiliary functions $\eta_i = c_i z_i$. We may explicitly set the constant c_i in α_i^* if we let η_i be an input to the ith approximator structure (i.e., if we let $\alpha_i^*(X_i, \nu_i, \dot{X}_{ri}, \eta_i) = \sum_{j=1}^R \rho_j(\upsilon) \theta^{*\top}_{\alpha_i^j} \zeta_{\alpha_i^j}(X_i, \nu_i, \dot{X}_{r_i}, \eta_i) + \delta_\alpha$). Then, the approximators used in the control procedure are given by $\hat{\alpha}_i(X_i, \nu_i, \dot{X}_{r_i}, \eta_i) = \sum_{j=1}^R \rho_j(\nu) \hat{\theta}^\top_{\alpha_i^j} \zeta_{\alpha_i^j}(X_i, \nu_i, \dot{X}_{ri}, \eta_i)$, and the stability analysis can be carried out as expected.

12.2.2 Performance Analysis: $\mathcal{L}_2$ Bounds and Transient Design

The stability result of theorem 1 is useful because it indicates conditions to obtain a stable closed-loop behavior for a plant belonging to the class given by equation 12.1. However, it is not immediately clear how to choose the several design constants to improve the control performance. Here, we concentrate on the tracking problem and present design guidelines with respect to an $\mathcal{L}_2$ bound on the tracking error. We are interested in having x_1 track the reference model state x_{r_1} of the reference model $\dot{x}_{r_i} = x_{r_{i+1}}$, $i = 1, 2, \ldots, n-1$, $\dot{x}_{r_n} = f_r(X_{r_n}, r)$ with bounded reference input $r(t) \in \mathbb{R}$. Now, we need to use the diffeomorphism $z_1 = x_1 - x_{r_1}$, $z_i = x_i - \hat{\alpha}_{i-1} - \alpha_{i-1}^s$, $i = 2, \ldots, n$, with $\alpha_1^*(x_1, \upsilon, \dot{x}_{r_1}) = 1/\psi_i^c(-\phi_1^c - c_1 z_1 + x_{r_2})$ and $\alpha_i^*(X_i, \nu_i, \dot{X}_{r_i}) = 1/\psi_i^c\left(-\phi_i^c - c_i z_i + \dot{\hat{\alpha}}_i + \dot{\alpha}_i^s\right)$ for $i = 2, \ldots, n$. The stability proof needs to be modified accordingly, and it can be shown that the tracking error $|x_1 - x_{r_1}|$ converges to a neighborhood of size $\sqrt{2\underline{\psi}_m W_d / \beta_d}$.

From the upper bound on $V(t)$, we can write $V(t) \leq W_d/\beta_d + V(0)e^{-\beta_d t}$. From here, it follows that $\frac{1}{2}\sum_{i=1}^n z_i^2(t)/\psi_i^c(t) \leq W_d/\beta_d + \left(\frac{1}{2}\sum_{i=1}^n z_i^2(0)/\psi_i^c(0) + \frac{1}{2}\sum_{i=1}^n \sum_{j=1}^R = |\Phi_{\alpha_i^j}(0)|^2/\gamma_{\alpha_i^j}\right)e^{-\beta_d t}$. The terms $z_i(0)$ depend on the design constants in a complex manner. For this reason, rather than trying to take them into account in the design procedure, we follow the trajectory initialization approach taken in Krstić *et al.* (1995), which allows the designer to set $z_i(0) = 0$, $i = 1, \ldots, n$ by an appropriate choice of the reference model's initial conditions. In our case, in addition to the assumption that it is possible to set the initial conditions of the reference model, we will have to assume certain invertibility conditions on the approximators. In particular, because $z_1(0) = x_1(0) - x_{r_1}(0)$, we need to set $x_{r_1}(0) = x_1(0)$ for $z_1(0) = 0$.

For the ith transformed state z_i, $i = 2, \ldots, n$, $z_i(0) = x_i(0) - \hat{\alpha}_{i-1}(0) - \alpha_{i-1}^s(0)$. Notice that $\alpha_{i-1}^s(0) = \alpha_{i-1}^s(z_{i-1}(0), z_{i-2}(0))$, so that if $z_{i-1}(0) = 0$ and $z_{i-2}(0) = 0$, we have $\alpha_{i-1}^s(0) = 0$. In particular, notice that this holds for $i = 2$. In this case, to set $z_2(0) = 0$, we need to have $\hat{\alpha}_1(x_1(0), \upsilon(0), x_{r_2}(0)) = x_2(0)$. This equation can be solved analytically (or numerically) for $x_{r_2}(0)$, provided $\partial\hat{\alpha}_1/\partial x_{r_2}|_{t=0} \neq 0$. This is not an unreasonable condition because it depends on the choice of approximator structure the designer makes. The structure can be chosen so that it satisfies this condition. Granted this is the case, it clearly holds that $\alpha_2^s(0) = 0$, and the same procedure can be inductively carried out for $i = 3, \ldots, n$, with the choices $\hat{\alpha}_{i-1}(X_{i-1}(0), \nu_{i-1}(0), x_{r_i}(0)) = x_i(0)$.

This procedure yields the simpler bound $\sum_{i=1}^n z_i^2(t) \leq 2\underline{\psi}_m W_d/\beta_d + \underline{\psi}_m\left(\sum_{i=1}^n \sum_{j=1}^R |\Phi_{\alpha_i^j}(0)|^2/\gamma_{\alpha_i^j}\right)e^{-\beta_d t}$. We would like to make this bound small so that the transient excursion of the tracking error is small. Notice that we do not have direct control on the size of β_d because this term depends on the unknown constants c_i, which appear in the ideal signals α_i^*. Even though it is not necessary to be able to set β_d to reduce the size of the bound, it is possible to do so if the bounds $\underline{\psi}_i^c$, $\bar{\psi}_i^c$, and $\psi_{i_d}^c$ are known.

At this point, it becomes more clear how to choose the constants to achieve a smaller bound. Recalling the expression of W_d, note that one may first want to have $\beta_d > 1$, so W_d is not made larger when divided by β_d and so the convergence is faster. This may be achieved by setting c_i such that $2\bar{c}_i\psi_m > 1$ (if enough knowledge is available to do so) and $\sigma_{\alpha_i^j} > 1$. However, having a large $\sigma_{\alpha_i^j}$ makes W_d larger; this can be offset, however, by also choosing the ratio $\sigma_{\alpha_i^j}/\gamma_{\alpha_i^j} < 1$ or smaller. Finally, it is clear that making k_i larger reduces the effects of the representation errors and, therefore, makes W_d smaller. Observe that there is enough design freedom to make W_d small and β_d large independently of each other.

These simple guidelines may become very useful when performing a real control design. Moreover, notice that the bound on $\sum_{i=1}^n z_i^2(t)$ makes it possible to specify the compact sets of the approximators so that, even throughout the transient, it can be guaranteed that the states will remain within the compact sets without the need for a global bounding control term. This has been a recurrent shortcoming of many online function approximation-based methods, and the explicit bound on the transient makes it possible to overcome it.

These simple guidelines, which are obvious under careful observation, may become very useful when performing a real control design. The next section illustrates these guidelines and shows their practical effect in a real application.

12.3 Application: Direct Adaptive Wing Rock Regulation with Varying Angle of Attack

Subsonic wing rock is a nonlinear phenomenon experienced by an aircraft with slender delta wings, in which limit cycle roll and roll rate oscillations or unstable behavior are experienced by the aircraft with pointed forebodies at high angles of attack. Wing rock may diminish flight effectiveness or even present serious danger due to potential instability of the aircraft. Here, we will apply the method of local control laws of theorem 1 to the problem of **wing rock regulation**.

Other approaches to this problem can be found in Joshi *et al.* (1998), Singh *et al.* (1995), Luo and Lan (1993), and Krstić *et al.* (1995), among others. In Singh *et al.* (1995), the authors present conventional adaptive and neural adaptive control methods for wing rock control. In Luo and Lan (1993), an optimal feedback control using Beecham-Titchener's averaging technique is applied. They present a single-neuron controller trained with backpropagation to regulate wing rock, and this controller is tested in a wind tunnel. In Krstić *et al.* (1995) the authors use the tuning functions method of adaptive backstepping to develop a wing rock regulator.

It is interesting to note that all these methods are developed at a *fixed* angle of attack and, in some cases, are tested at another angle close to the design point, which serves to help the researchers claim robustness of the designs. Here, the problem is considered in a more general setting, where the angle of attack is allowed to vary with time according to the evolution of an external dynamical system (which may represent the commands of the pilot together with the aircraft dynamics). As will be noted subsequently, the dynamics of the wing rock phenomenon change nonlinearly with the angle of attack, which makes the problem of developing controllers that are robust against angle of attack a challenging one. However, this problem fits the class of time-varying systems (Polycarpou and Ioannu, 1991) considered in this chapter, so development of a controller that can operate at all angles of attack is greatly simplified by following theorem 1.

There exist several analytical nonlinear models that characterize the phenomenon of wing rock (Hsu and Lan, 1985; Nayfeh *et al.*, 1989; Elzebda *et al.*, 1989). The model we use here is the one presented in Nayfeh *et al.* (1989) and Elzebda *et al.* (1989), which has the advantage over the model in Hsu and Lan (1985) of being differentiable and, according to the authors, slightly more accurate. This model is given by:

$$\ddot{\phi} = -\omega_j^2\phi + \mu_1^j\dot{\phi} + b_1^j\dot{\phi}^3 + \mu_2^j\phi^2\dot{\phi} + b_2^j\phi\dot{\phi}^2 + g\delta_a, \qquad (7)$$

where ϕ is the roll angle, δ_a is the output of an actuator with first-order dynamics, $g = 1.5$ is an input gain, and $\omega_j^2 = -c_1 a_1^j$, $\mu_1^j = c_1 a_2^j - c_2$, $b_1^j = c_1 a_3^j$, $\mu_2^j = c_1 a_4^j$, and $b_2^j = c_1 a_5^j$ are system coefficients that depend on the parameters a_i^j, which in turn are functions of the angle of attack, denoted here by υ (aircraft notation conventions dictate the use of α as the angle of attack; however, to avoid confusions with the notation here, we will use υ instead). From Nayfeh *et al.* (1989), we let $c_1 = 0.354$ and $c_2 = 0.001$, constants given by the physical parameters of a delta wing used in wind tunnel experiments in Levin and Katz (1984) to develop the analytical model of equation 12.7. In Nayfeh *et al.* (1989), four angles of attack are considered, at which the coefficients a_i^j are given. We added three points to the table in Nayfeh *et al.* (1989) by assuming that the functions passing through the points a_i^j are approximately piecewise linear (a reasonable assumption, considering the plots presented in this publication). Thus, the points used are given in Table 12.1, where the points at $v = 17, 19$ and 23.75 have been added to the table in question.

TABLE 12.1 Parameters for the Coefficients in the Wing Rock Model

25	−0.05686	0.03254	0.07334	−0.3597	1.4681

To build a smooth, time-varying model of the wing rock that depends on the angle of attack v, we will consider the interpolation functions:

$$\rho_j(v) = \frac{e^{-\left((v-v_j)/s_j\right)^2}}{\sum_{l=1}^{7} e^{-((-v_l)/s_l)^2}}, \qquad (12.8)$$

where the centers v_j and spreads s_j, $j = 1, \ldots, 7$, are given in Table 12.2. Notice that the interpolation functions of equation 12.8 satisfy the assumptions stated in theorem 1.

To test the accuracy of the interpolations, let:

$$a_i(v) = \sum_{j=1}^{7} \rho_j(v) a_i^j, \qquad (12.9)$$

for $i = 1, \ldots, 5$. Figure 12.1 contains the plots of the interpolated coefficients $a_i(v)$ (solid lines) as well as the data points in Table 12.1 marked by circles. We see that the interpolations are generally close to the data points, so we may consider the resulting time-varying model accurate enough.

We will assume the control input u affects the wing through an actuator with linear, first-order dynamics. To express the model in the form of equation 12.1, we let $x_1 = \phi$, $x_2 = \dot{\phi}$, and $x_3 = \delta_a$. Then, the time-varying wing rock model is given by:

TABLE 12.2 Centers and Spreads for Wing Rock Interpolation Functions

j	1	2	3	4	5	6	7
v_j	15	17	19	21.5	22.5	23.75	25
s_j	1.5	1.5	1.5	2.0	1	1	1

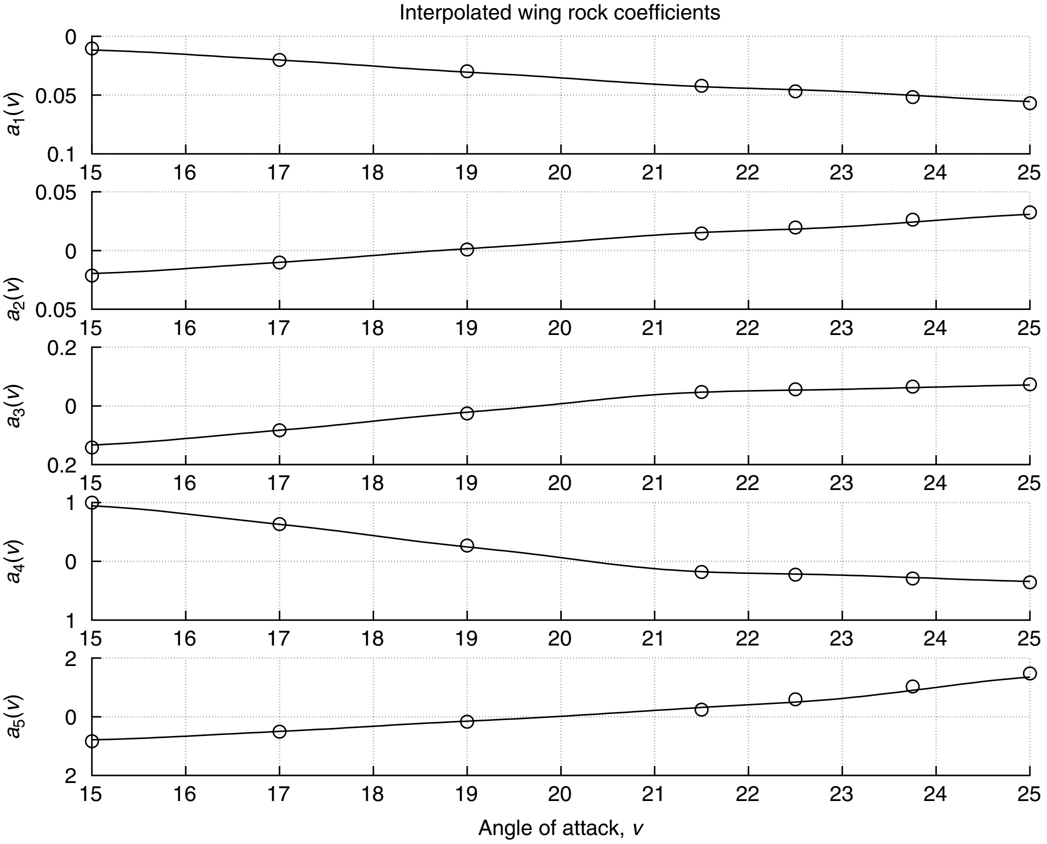

FIGURE 12.1 Interpolated Coefficients for the Time-Varying Wing Rock Model

$$\dot{x}_1 = x_2.$$

$$\dot{x}_2 = \sum_{j=1}^{7} \rho_j(v)\left(-w_j^2\phi + \mu_1^j\dot{\phi} + b_1^j\dot{\phi}^3 + \mu_2^j\phi^2\dot{\phi} + b_2^j\phi\dot{\phi}^2\right) + gx_3.$$

$$\dot{x}_3 = -\frac{1}{\tau}x_3 + \frac{1}{\tau}u. \tag{12.10}$$

The actuator time constant is $\tau = 1/15$. We will assume that the angle of attack v varies according to an exogenous dynamical system:

$$\begin{bmatrix} \dot{v}_1 \\ \dot{v}_2 \end{bmatrix} = \begin{bmatrix} 0 & 25 \\ -25 & -10 \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 500 \end{bmatrix} + \begin{bmatrix} 0 \\ 62.5 \end{bmatrix} r, \tag{12.11}$$

where $v_1 = v$, $v_2 = \dot{v}$, and r is a command input that can take values between minus one and one. System 12.11 has its poles at $-5 \pm 24.5i$ ($i = \sqrt{-1}$), and its equilibrium is at $v_1 = 20$ and $v_2 = 0$.

According to the analysis performed in Nayfeh *et al.* (1989), the wing rock system has a stable focus at the origin for angles of attack v less than approximately 19.5. For larger angles, the origin becomes an unstable equilibrium, and a limit cycle appears around it. In both cases, however, the system is unstable and may diverge to infinity if the initial conditions are large enough (since we are dealing with angles, such a divergence means that the wings rotate faster and faster). The problem we consider here has the angle of attack varying within the range between 15 and 25, so the qualitative behavior of equation 12.10 changes periodically, as v becomes respectively smaller or larger than 19.5. To gain a better insight into how the dynamic behavior of the wing rock phenomenon changes qualitatively with v, consider Figure 12.2, where we let the system start at the initial condition $X_3(0) = [-4, 0, 0]$ and $v_2(0) = [20, 0]$. Initially, we set $r = 1$, so the angle of attack stabilizes at 22.5, and we let the system run in open loop for 200 sec. We observe that x_1 and x_2 are approaching a limit cycle, which would be reached if the system were allowed to run for a longer time: however, at $t = 200$, we let $r = -1$ (this is marked by an arrow in Figure 12.2), so the angle of attack changes and after a short transient stabilizes at 17.5. Not being close enough to the origin to be attracted by the local stable focus, the system starts to diverge.

We will consider two designs with the purpose of illustrating how different design constants may in fact reduce or enlarge the $\mathcal{L}_2$ bound stated in Subsection 12.2.2. In order to do so, we will let the controller track the state x_{r_1} of a reference trajectory given by:

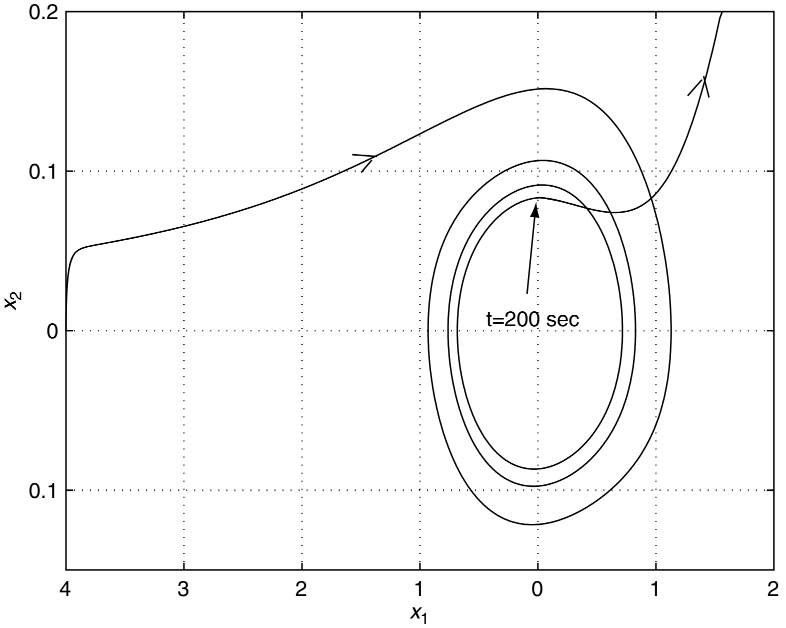

FIGURE 12.2 Qualitative Change in Wing Rock Dynamics with Varying Angle of Attack

$$\begin{aligned}\dot{x}_{r_1} &= x_{r_2}.\\ \dot{x}_{r_2} &= x_{r_3}.\\ \dot{x}_{r_3} &= -45x_{r_1} - 39x_{r_2} - 11x_{r_3}.\end{aligned} \qquad (12.12)$$

That is, these equations represent a stable linear system with poles at −5, −3 and −3.

We use radial basis function neural networks (Moody and Darken, 1989) as the approximators. Since v has its equilibrium at 20, we use $\bar{v} = v - 20$ instead of v as input to the approximators. For $\hat{\alpha}_1(x_1, \bar{v}, x_{r_2})$, we choose for $j = 1, \ldots, 7$:

$$\zeta_{\alpha_{1j}} = \left[1, \frac{\exp\left((x_1 - c_{x_k})^2/s_{x_1}^2)\right)\exp\left((\bar{v} - c_{v_l})^2/s_{v_1}^2\right)\exp\left((x_{r_2} - c_{r_m})^2/s_{r_2}^2\right)}{\sum_{d=1}^{2}\sum_{p=1}^{2}\sum_{q=1}^{2}\exp\left((x_1 - c_{x_d})^2/s_{x_1}^2\right)\exp\left((\bar{v} - c_{v_p})^2/s_{v_1}^2\right)\exp\left((x_{r_2} - c_{r_q})^2/s_{r_2}^2\right)} \right]^{\top}, \qquad (12.13)$$

for $k = 1, 2$, $l = 1, 2$, and $m = 1, 2$, with the centers c_{x_k}, c_{v_l}, and c_{r_m} evenly spaced along the intervals $[-15, 15]$, $[-5, 5]$, and $[-5, 5]$, respectively, and the spreads $s_{x_1} = 30$, $s_{v_1} = 10$, and $s_{r_1} = 10$ (i.e., $\mathcal{S}_{x_1} = \{x_1 \in \mathbb{R}\colon -15 \leq x_1 \leq 15\}$ and $\mathcal{S}_{v_1} = \{v \in \mathbb{R}\colon 15 \leq v \leq 25\}$; the other compact sets are defined in a similar manner).

For $\hat{\alpha}_2(X_2, v_2, x_{r_3})$, we space three centers evenly on the interval $[-15, 15]$ for x_1 and x_2, two centers evenly spaced on the interval $[-5, 5]$ for v_1 and v_2, and two centers evenly spaced on the interval $[-10, 10]$ for x_{r_3}. The spreads are chosen as $s_{x_1} = s_{x_2} = 15$, $s_{v_1} = s_{v_2} = 10$, and $s_{r_2} = 20$. The functions $\zeta_{\alpha_2^j}$ are all chosen the same for $j = 1, \ldots, 7$ and with a similar structure to equation 12.13. The same is done for $\hat{\alpha}_3(X_3, v_3, \dot{x}_{r_3})$, where we evenly space the centers for x_i and v_i, $i = 1, 2, 3 (v_3 = \dot{v}_2)$, along the intervals $[-20, 20]$ and $[-5, 5]$, respectively, and along $[-100, 100]$ for $\dot{x}_{r_3}$, where we use three centers for each x_i, two for each v_i, and two for $\dot{x}_{r_3}$. The spreads are $s_{x_i} = 20$, $s_{v_i} = 10$, $i = 1, 2, 3$, and $s_{r_3} = 200$. Again, for all $\zeta_{\alpha_2^j}$ and $\zeta_{\alpha_3^j,\, j=1,\ldots,7}$, we replace v by $\bar{v}$ in v_i, $i = 2, 3$.

All the coefficient vectors are initialized with zeros. Since the approximator's parameters are guaranteed to be bounded, we do not need to set explicitly the parameter spaces $\Omega_{\alpha_i^j}$, and no parameter projection is used. We will use the tracking diffeomorphism given in Subsection 12.2.2, and we will also perform trajectory initialization to be able to better apply the analysis there. Because of the choice we make for the system's initial conditions $(X_3(0) = [-4, 0, 0])$ and because all parameter coefficients are picked initially equal to zero, the choice $X_{r_3}(0) = X_3(0) = [-4, 0, 0]$ guarantees $z_i(0) = 0$ and $i = 1, 2, 3$.

We will let the reference to the angle of attack system alternate between −1 and 1 every 0.5 sec, and we choose $v_2(0) = [20, 0]$ as the initial condition for the angle of attack system. We will consider two designs. In the first one, we let $k_1 = 0.3$, $k_2 = 0.6$, and $k_3 = 0.4$. For the adaptation laws, we pick $\gamma_{\alpha_1^j} = 0.1$, $\sigma_{\alpha_1^j} = 0.2$, $\gamma_{\alpha_s^j} = 0.5$, and $\sigma_{\alpha_1^j} = 0.1$ as well as $\gamma_{\alpha_3^j} = 0.2$, $\sigma_{\alpha_1^j} = 0.3$, and $j = 1, \ldots, 7$. Figures 12.3 and 12.4 show the control results. In Figure 12.3 we first observe the plant's behavior in open loop, plotted with a dashed line. The

FIGURE 12.4 Angle of Attack and Control Input

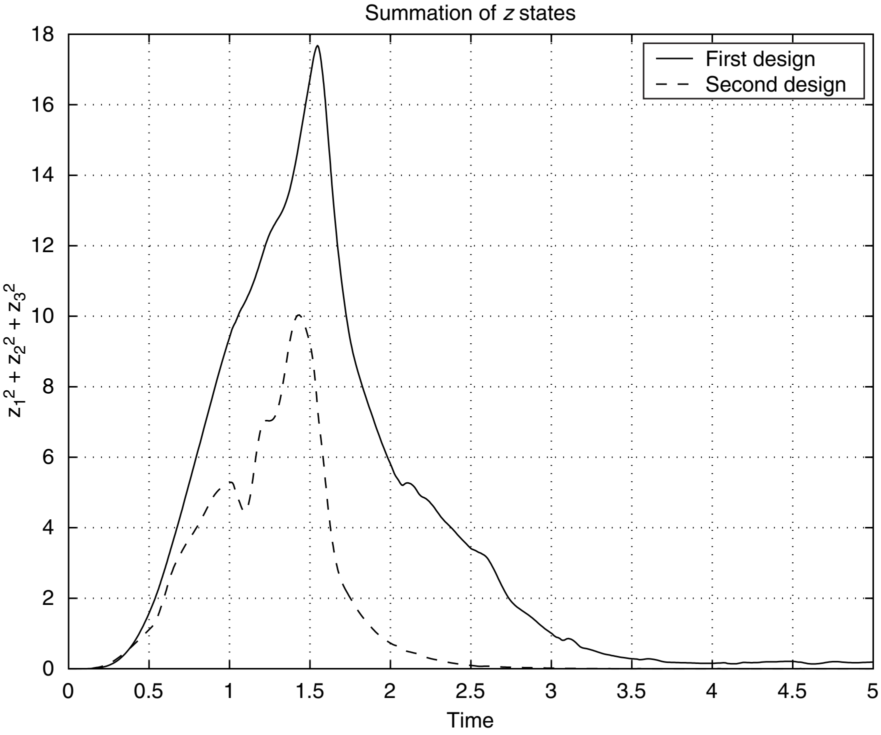

FIGURE 12.5 Different Plots of $\sum_{i=1}^{3} z_i^2(t)$ for the Two Designs

oscillations are due to the changing angle of attack; eventually, if allowed to run uncontrolled, the system diverges. The solid line in Figure 12.3 corresponds to the first design just described. Notice that x_1 has an overshoot beyond zero. In Figure 12.4(A), we can see the evolution of the angle of attack. In Figure 12.4(B), we observe the control input generated by this first design.

Next, with the purpose of improving the controller's performance, we follow the guidelines given in subsection 12.2.2 and change the design constants in the following manner: we let $k_1 = 1$, $k_2 = 3$, $k_3 = 2.5$, $\gamma_{\alpha_1^j} = 0.1$, $\sigma_{\alpha_1^j} = 0.1$, $\gamma_{\alpha_2^j} = 1.5$, $\sigma_{\alpha_2^j} = 0.5$, $\gamma_{\alpha_3^j} = 1.2$, and $\sigma_{\alpha_2^j} = 0.4$, $j = 1, \ldots, 7$. Notice that we have chosen larger constants k_i as well as larger $\gamma_{\alpha_i j}$, which we expect should help reduce the size of W_d. At the same time, we have set the ratios between $\sigma_{\alpha_i^j}$ and their respective $\gamma_{\alpha_i^j}$ to be less than or equal to one, which was not the case in the first design.

Figure 12.3 shows the resulting closed-loop behavior, plotted in a solid line with circles, and the bottom plot in Figure 12.4 corresponds to the control input generated by the second design. Although it cannot be seen from Figure 12.3, the convergence to zero is about twice as fast with the second design than with the first one, taking less than 4 secs for x_1 and x_2 to become small enough, versus about 8 sec with the first design. Furthermore, there is now no overshoot for x_1. Note that in the second design, x_2 reaches a slightly larger value than in the first design; this results from the fact that the $\mathcal{L}_2$ bound in subsection 12.2.2 is a measure of $\sum_{i=1}^{3} z_i^2$ and not of $\sum_{i=1}^{3} x_i^2$. This means that the only conclusion one can reach for sure is that x_1 will have a smaller bound in the second design. However, observe in Figure 12.5 the plots of $\sum_{i=1}^{3} z_i^2(t)$ for both designs. The solid line, corresponding to the first design, is always above the dashed line, which corresponds to the second design, as expected.

12.4 Conclusion

In this chapter, we have developed a direct adaptive control method for a class of uncertain nonlinear systems with a time-varying structure using a Lyapunov approach to construct the stability proofs. The systems we considered are composed of a finite number of "pieces," or dynamic subsystems, that are interpolated by functions depending on a possibly exogenous scheduling variable. We assumed that each piece is in strict feedback form and showed that the methods yield stability of all signals in the closed loop as well as show convergence of the state vector to a residual set around the equilibrium, whose size can be set by the choice of several design parameters

We argued that the direct adaptive method presents several advantages over indirect methods in general, including the need for a smaller amount of information about the plant and a simpler design. We also provided design guidelines based on $\mathcal{L}_2$ bounds on the transient, and we argued that this bound makes it possible to precisely determine how large the compact sets for the function approximators should be so that the states do not exit them. Finally, we applied the direct adaptive method to the problem of wing rock regulation, where the wing rock dynamics are uncertain and where the angle of attack is allowed to vary with time.

13.1 Introduction

This chapter focuses on a systematic treatment for developing a generic online learning control system based on the fundamental principle of **reinforcement learning** or, more specifically, **neural dynamic programming**. This online learning system improves its performance over time in two aspects. First, it learns from its own mistakes through the reinforcement signal from the external environment and tries to reinforce its action to improve future performance. Second, system states associated with the positive reinforcement are memorized through a network learning process where in the future, similar states will be more positively associated with a control action leading to a positive reinforcement. This discussion also introduces a successful candidate of online learning control design. Real-time learning algorithms are derived for individual components in the learning system. Some analytical insight are provided to give guidelines on the learning process that takes place in each module of the online learning control system. The performance of the online learning controller is measured by its learning speed, success rate of learning, and the degree to meet the learning control objective. The overall learning control system performance is tested on a single cart–pole balancing problem and a pendulum swing-up and balancing task.

13.2 A General Framework for Direct Learning Through Association and Reinforcement

Consider a class of learning decision and control problems in terms of optimizing a performance measure over time with the following constraints. First, a model of the environment or the system that interacts with the learner is not available a priori. The environment/system can be stochastic, nonlinear, and subject to change. Second, learning takes place "on-the-fly" while interacting with the environment. Third, even though measurements from the environment are available from one decision and control step to the next, a final outcome of the learning process from a generated sequence of decisions and controls comes as a delayed signal in an indicative "win or lose" format. Figure 13.1 is a schematic diagram of an online learning control scheme. The binary reinforcement signal $r(t)$ is provided from the external environment and is either a 0 or a -1 corresponding to success or failure, respectively.

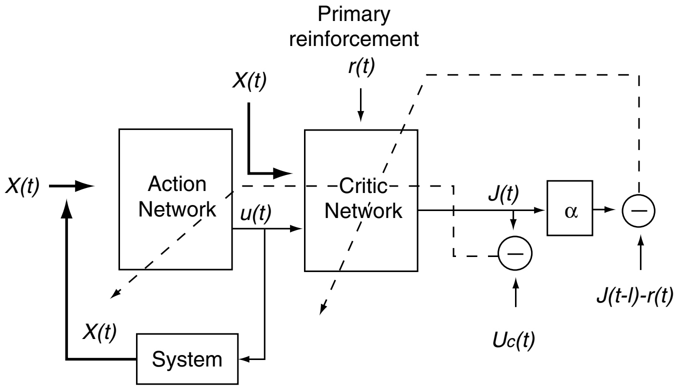

FIGURE 13.1 Schematic Diagram for Implementations of Neural Dynamic Programming as a Direct Learning Mechanism. The solid lines represent signal flow, and the dashed lines are the paths for parameter tuning.

In our direct online learning control design, the controller is "naive" when it just starts to control; the action network and the critic network are both randomly initialized in their weights and parameters. Once a system state is observed, an action will be subsequently produced based on the parameters in the action network. A "better" control value under the specific system state will lead to a more balanced equation of the principle of optimality. This set of system operations will be reinforced through memory or association between states and control output in the action network. Otherwise, the control value will be adjusted through tuning the weights in the action network to make the equation of the principle of optimality more balanced.

To be more quantitative, consider the critic network as depicted in Figure 13.1. The output of the critic element, the J function, approximates the discounted total **reward-to-go**. Specifically, it approximates $R(t)$ at time t given by:

$$R(t) = r(t+1) + \alpha r(t+2) + \cdots, \tag{13.1}$$

where $R(t)$ is the future accumulative reward-to-go value at time t and where α is a discount factor for the infinite-horizon problem ($0 < \alpha < 1$). We have used $\alpha = 0.95$ in our implementations; $r(t+1)$ is the external reinforcement value at time $t+1$.

13.2.1 The Critic Network

The **critic network** is used to provide $J(t)$ as an approximate of $R(t)$ in equation 13.1. The prediction error for the critic element is defined as:

$$e_c(t) = \alpha J(t) - [J(t-1) - r(t)], \tag{13.2}$$

and the objective function to be minimized in the critic network is as follows:

$$E_c(t) = \frac{1}{2} e_c^2(t). \tag{13.3}$$

The weight update rule for the critic network is a gradient-based adaptation given by:

$$w_c(t+1) = w_c(t) + \Delta w_c(t). \tag{13.4}$$

$$\Delta w_c(t) = l_c(t)\left[-\frac{\partial E_c(t)}{\partial w_c(t)}\right]. \tag{13.5}$$

$$\frac{\partial E_c(t)}{\partial w_c(t)} = \left[-\frac{\partial E_c(t)\partial J(t)}{\partial J(t)\partial w_c(t)}\right]. \tag{13.6}$$

In equations 13.4 to 13.6, $l_c(t) > 0$ is the learning rate of the critic network at time t, which usually decreases with time to a small value, and w_c is the weight vector in the critic network.

13.2.2 The Action Network

The principle in adapting the **action network** is to indirectly back-propagate the error between the desired ultimate objective, denoted by U_c, and the approximate J function from the critic network. Since 0 is defined as the reinforcement signal for success, U_c is set to 0 in the discussion is design paradigm and in the following case studies. In the action network, the state measurements are used as inputs to create a control as the output of the network. In turn, the action network can be implemented by either a linear or a nonlinear network, depending on the complexity of the problem. The weight updating in the action network can be formulated as follows. Let the following be true:

$$e_a(t) = J(t) - U_c(t). \tag{13.7}$$

The weights in the action network are updated to minimize the following performance error measure:

$$E_a(t) = \frac{1}{2} e_a^2(t). \tag{13.8}$$

The update algorithm is then similar to the one in the critic network. By a gradient descent rule:

$$w_a(t+1) = w_a(t) + \Delta w_a(t). \tag{13.9}$$

$$\Delta w_a(t) = l_a(t)\left[-\frac{\partial E_a(t)}{\partial w_a(t)}\right]. \tag{13.10}$$

$$\frac{\partial E_a(t)}{\partial w_a(t)} = \frac{\partial E_a(t)}{\partial J(t)}\frac{\partial J(t)}{\partial u(t)}\frac{\partial u(t)}{\partial w_a(t)}. \tag{13.11}$$

In equations 13.9 to 13.11, $l_a(t) > 0$ is the learning rate of the action network at time t, which usually decreases with time to a small value, and w_a is the weight vector in the action network.

13.2.3 Online Learning Algorithms

This chapter is online learning configuration introduced in the previous subsections involves two major components in the learning system: the **action network** and the **critic network.** The following devises learning algorithms and elaborates how learning takes place in each of the two modules. In the discussion is NDP design, both the action network and the critic network are nonlinear multilayer feed-forward networks. In these designs, one hidden layer is used in each network. The neural network structure for the nonlinear, multilayer critic network is shown in Figure 13.2. In the critic network, the output $J(t)$ will be of the form:

$$J(t) = \sum_{i=1}^{N_h} w^{(2)}_{c_i}(t)p_i(t). \tag{13.12}$$

$$p_i(t) = \frac{1-\exp^{-q_i(t)}}{1+\exp^{-q_i(t)}},\ i = 1, \ldots, N_h. \tag{13.13}$$

$$q_i(t) = \sum_{j=1}^{n+1} w^{(1)}_{c_{ij}}(t)x_j(t),\ i = 1, \ldots, N_h. \tag{13.14}$$

The q_i is the ith hidden node input of the critic network, and p_i is the corresponding output of the hidden node. The N_h is the total number of hidden nodes in the critic network, and $n+1$ is the total number of inputs into the critic network including the analog action value $u(t)$ from the action network. By applying the chain rule, the adaptation of the critic network is summarized below.

(1) For $\Delta w^{(2)}_c$ (hidden to output layer):

$$\Delta w^{(2)}_{ci}(t) = l_c(t)\left[-\frac{\partial E_c(t)}{\partial w^{(2)}_{c_i}(t)}\right], \tag{13.15}$$

$$\frac{\partial E_c(t)}{\partial w^{(2)}_{c_i}(t)} = \frac{\partial E_c(t)}{\partial J(t)}\frac{\partial J(t)}{\partial w^{(2)}_{c_i}(t)} = \alpha e_c(t)p_i(t). \tag{13.16}$$

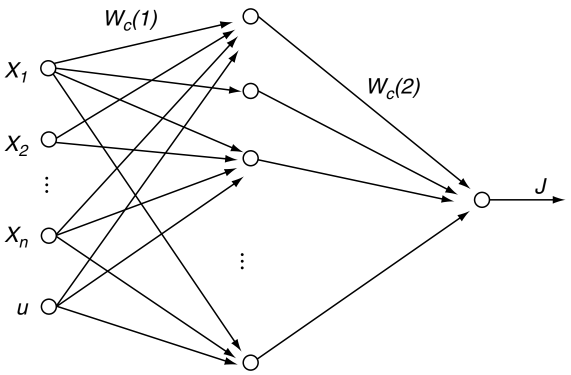

FIGURE 13.2 Schematic Diagram for the Implementation of a Nonlinear Critic Network Using a Feed-Forward Network with one Hidden Layer

(2) For $\Delta w^{(1)}_c$ (input to hidden layer):

$$\Delta w^{(1)}_{c_{ij}}(t) = l_c(t)\left[-\frac{\partial E_c(t)}{\partial w^{(1)}_{c_{ij}}(t)}\right], \tag{13.17}$$

$$\frac{\partial E_c(t)}{\partial w^{(1)}_{c_{ij}}(t)} = \frac{\partial E_c(t)}{\partial J(t)}\frac{\partial J(t)}{\partial p_i(t)}\frac{\partial p_i(t)}{\partial q_i(t)}\frac{\partial q_i(t)}{\partial w^{(1)}_{c_{ij}}(t)} \tag{13.18}$$

$$= \alpha e_c(t)w^{(2)}_{c_i}(t)\left[\frac{1}{2}\left(1-p_i^2(t)\right)\right]x_j(t). \tag{13.19}$$

Now, investigate the adaptation in the action network, which is implemented by a feed-forward network similar to the one in Figure 13.2, except that the inputs are the n measured states and the output is the action $u(t)$. The following are the associated equations for the action network:

$$u(t) = \frac{1-\exp^{-u(t)}}{1+\exp^{-u(t)}}. \tag{13.20}$$

$$v(t) = \sum_{i=1}^{N_h} w^{(2)}_{a_i}(t)g_i(t). \tag{13.21}$$

$$g_i(t) = \frac{1-\exp^{-h_i(t)}}{1+\exp^{-h_i(t)}},\ i = 1, \ldots, N_h. \tag{13.22}$$

$$h_i(t) = \sum_{j=1}^{n} w^{(1)}_{a_{ij}}(t)x_j(t),\ i = 1, \ldots, N_h. \tag{13.23}$$

The v is the input to the action node, and g_i and h_i are the output and the input of the hidden nodes of the action network, respectively. Since the action network inputs the state measurements only, there is no $(n+1)th$ term in equation 13.23 as in the critic network (see equation 13.14 for comparison). The update rule for the nonlinear multilayer action network also contains two sets of equations:

(1) For $\Delta w^{(2)}_a$ (hidden to output layer):

$$\Delta w^{(2)}_{a_i}(t) = l_a(t)\left[-\frac{\partial E_a(t)}{\partial w^{(2)}_{a_i}(t)}\right], \tag{13.24}$$

$$\frac{\partial E_a(t)}{\partial w^{(2)}_{a_i}(t)} = \frac{\partial E_a(t)}{\partial J(t)}\frac{\partial J(t)}{\partial u(t)}\frac{\partial u(t)}{\partial v(t)}\frac{\partial v(t)}{\partial w^{(2)}_{a_i}(t)}, \tag{13.25}$$

$$= e_a(t)\left[\frac{1}{2}\left(1-u^2(t)\right)\right]g_i(t)\sum_{i=1}^{N_h}$$

$$\left[w^{(2)}_{c_i}(t)\frac{1}{2}\left(1-p_i^2(t)\right)w^{(1)}_{c_{i,n+1}}(t)\right]. \tag{13.26}$$

In equations 13.24 to 13.26, $\partial J(t)/\partial u(t)$ is obtained by changing variables and by a chain rule. The result is the summation term, and $w^{(1)}_{c_i,n+1}$ is the weight associated with the input element from the action network.

(2) For $\Delta w_a^{(1)}$ (input to hidden layer):

$$\Delta w_{a_{ij}}^{(1)}(t) = l_a(t)\left[-\frac{\partial E_a(t)}{\partial w_{a_{ij}}^{(1)}(t)}\right], \tag{13.27}$$

$$\frac{\partial E_a(t)}{\partial w_{a_{ij}}^{(1)}(t)} = \frac{\partial E_a(t)}{\partial J(t)}\frac{\partial J(t)}{\partial u(t)}\frac{\partial u(t)}{\partial v(t)}\frac{\partial v(t)}{\partial g_i(t)}\frac{\partial g_i(t)}{\partial h_i(t)}\frac{\partial h_i(t)}{\partial w_{a_{ij}}^{(1)}(t)} \tag{13.28}$$

$$= e_a(t)\left[\frac{1}{2}\left(1-u^2(t)\right)\right]w_{a_i}^{(2)}(t)\left[\frac{1}{2}\left(1-g_i^2(t)\right)\right]x_j(t).$$

$$\sum_{i=1}^{N_h}\left[w_{c_i}^{(2)}(t)\frac{1}{2}\left(1-p_i^2(t)\right)w_{c_{i,\,n+1}}^{(1)}(t)\right]. \tag{13.29}$$

In implementation, equations 13.16 and 13.19 are used to update the weights in the critic network and equations 13.26 and 13.29 are used to update the weights in the action network.

13.3 Analytical Characteristics of an Online NDP Learning Process

This section is dedicated to expositions of analytical properties of the online learning algorithms in the context of **neural dynamic programming** (NDP). It is important to note that in contrast to usual neural network applications, there is no readily available training sets of input/output pairs to be used for approximating J^* in the sense of least-squares-fit in NDP applications. Both the control action u and the approximated J function are updated according to an error function that changes from one time-step to the next. Therefore, the convergence argument for the steepest descent algorithm does not hold valid for any of the two networks, action or critic. This results in a simulation approach to evaluate the cost-to-go function J for a given control action u. The online learning takes place, aiming at iteratively improving the control policies based on simulation outcomes. This creates analytical and computational difficulties that do not arise in a more typical neural network training context. The closest analytical results in terms of approximating J function was obtained by Tsitsiklis (1997) where a linear in parameter function approximator was used to approximate the J function. The limit of convergence was characterized as the solution to a set of interpretable linear equations, and a bound was placed on the resulting approximation error.

It is worth pointing out that the existing implementations of NDP are usually computationally very intensive (Bertsekas and Tsitsiklis, 1996) and often require a considerable amount of trial and error. Most of the computations and experimentations with different approaches were conducted offline. The following paragraphs provide some analytical insight on the online learning process for proposed NDP designs in this chapter. Specifically, the stochastic approximation argument is used to reveal the asymptotic performance of this discussion's online NDP learning algorithms in an averaged sense for the action and the critic networks under certain conditions.

13.3.1 Stochastic Approximation Algorithms

The original work in **recursive stochastic approximation algorithms** was introduced by Robbins and Monro (1951), who developed and analyzed a recursive procedure for finding the root of a real-valued function $g(w)$ of a real variable w. The function is not known, but noise-corrupted observations could be taken at values of w selected by the experimenter.

A function $g(w)$ with the form $g(w) = Ex[f(w)]$ ($Ex[]$ is the expectation operator) is called a regression function of $f(w)$ and, conversely, $f(w)$ is called a sample function of $g(w)$. The following conditions are needed to obtain the Robbins-Monro algorithm (Robbins and Monro, 1951):

- **C1**: The $g(w)$ has a single root w^*, $g(w^*) = 0$, and:

  $$g(w) < 0 \text{ if} w < w^*.$$

  $$g(w) > 0 \text{ if} w > w^*.$$

  This first condition is assumed with little loss of generality since most functions of a single root not satisfying this condition can be made to do so by multiplying the function by -1.
- **C2**: The variance of $f(w)$ from $g(w)$ is finite:

  $$\sigma^2(w) = Ex[g(w) - f(w)]^2 < \infty. \tag{13.30}$$

- **C3**:

  $$|g(w)| < B_1|w - w^*| + B_0 < \infty. \tag{13.31}$$

  This third condition is a very mild condition. The values of B_1 and B_0 need not be known to prove the validity of the algorithm. As long as the root lies in some finite interval, the existence of B_1 and B_0 can always be assumed.

If the conditions C1 through C3 are satisfied, the algorithm from Robbins and Monro (1951) can be used to iteratively seek the root w^* of the function $g(w)$:

$$w(t+1) = w(t) - l(t)f[w(t)], \tag{13.32}$$

where $l(t)$ is a sequence of positive numbers that satisfy the following conditions:

$$\begin{aligned} &1)\ \lim_{t\to\infty} l(t) = 0 \\ &2)\ \sum_{t=0}^{\infty} l(t) = \infty \\ &3)\ \sum_{t=0}^{\infty} l^2(t) < \infty. \end{aligned} \tag{13.33}$$

Furthermore, $w(t)$ will converge toward w^* in the mean square error sense and with probability of value 1:

$$\lim_{t\to\infty} Ex[\|w(t) - w^*\|^2] = 0. \tag{13.34}$$

$$\text{Prob}\left\{\lim_{t\to\infty} w(t) = w^*\right\} = 1. \tag{13.35}$$

The convergence with probability 1 in equation 13.35 is also called **convergence almost truly**. In this chapter, the Robbins-Monro algorithm is applied to optimization problems (Kusher and Yin, 1997). In that setting, $g(w) = \partial E/\partial W$, where E is an objective function to be optimized. If E has a local optimum at w^*, $g(w)$ will satisfy the condition C1 locally at w^*. If E has a quadratic form, $g(w)$ will satisfy the condition C1 globally.

13.3.2 Convergence in Statistical Average for Action and Critic Networks

Neural dynamic programming is still in its early stage of development. The problem is not trivial due to several consecutive learning segments being updated simultaneously. A practically effective on-line learning mechanism and a step-by-step analytical guide for the learning process do not coexist at this time. This chapter is dedicated to reliable implementations of NDP algorithms for solving a general class of on-line learning control problems. As demonstrated in previous sections, experimental results in this direction are very encouraging. This section provides some asymptotic convergence results for each component of the NDP system. The Robbins-Monro algorithm provided in the previous section is the main tool to obtain results. Throughout this chapter, it is implied that the state measurements are samples of a continuous state-space. Specifically, the discussion assumes without loss of generality that the input $X_j \in \chi \subset \mathcal{R}^n$ has discrete probability density $p(X) = \sum_{j=1}^{N} p_j\delta(X - X_j)$, where $\delta()$ is the delta function.

The following paragraphs analyze one component of the NDP system at a time. When one component (e.g., the action network) is under consideration, the other component (e.g., the critic network) is considered to have completed learning; their weights do not change anymore.

To examine the learning process taking place in the action network, the following objective function for the action network is defined as:

$$\begin{aligned}\tilde{E}_a &= \frac{1}{2}\sum_i p_i[J(X_i) - U_c]^2 \\ &= \frac{1}{2}Ex[(J - U_c)^2].\end{aligned} \tag{13.36}$$

It can be seen that equation 13.36 is an "averaged" error square between the estimated J and a final desired value U_c. To contrast this notion, equation 13.8 is an "instantaneous" error square between the two. To obtain a (local) minimum for the averaged error measure in equation 13.38, the Robbins-Monro algorithm can be applied by first taking a derivative of this error with respect to the parameters, which are the weights in the action network in this case. Let:

$$\tilde{e}_a = J - U_c. \tag{13.37}$$

Since J is smooth in $\tilde{w}_a$, and $\tilde{w}_a$ belongs to a bounded set, the derivative of $\tilde{E}_a$ with respect to the weights of the action network is then of the form:

$$\frac{\partial \tilde{E}_a}{\partial \tilde{w}_a} = Ex\left[\tilde{e}_a \frac{\partial \tilde{e}_a}{\partial \tilde{w}_a}\right]. \tag{13.38}$$

According to the Robbins-Monro algorithm, the root (can be a local root) of $\partial\tilde{E}_a/\partial\tilde{w}_a$ as a function of $\tilde{w}_a$ can be obtained by the following recursive procedure *if* the root exists and *if* the step size $l_a(t)$ meets all the requirements described in equation 13.35:

$$\tilde{w}_a(t+1) = \tilde{w}_a(t) - l_a(t)\left[\tilde{e}_a \frac{\partial \tilde{e}_a}{\partial \tilde{w}_a}\right]. \tag{13.39}$$

Equation 13.37 may be considered as an instantaneous error between a sample of the J function and the desired value U_c. Therefore, equation 13.39 is equivalent to the update equation for the action network given in equations 13.9 to 13.11. From this viewpoint, the online action network updating rule of these equations 13.9 to 13.11 is actually converging to a (local) minimum of the error square between the J function and the desired value U_c in a statistical average sense. Or in other words, even if these equations represent a reduction in instantaneous error square at each iterative time-step, the action network updating rule asymptotically reaches a (local) minimum of the statistical average of $(J - U_c)^2$.

By the same token, a similar framework can be constructed to describe the convergence of the critic network. Recall that the residual of the principle of optimality equation to be balanced by the critic network is of the following form:

$$e_c(t) = \alpha J(t) - J(t-1) + r(t). \tag{13.40}$$

The instantaneous error square of this residual is given as:

$$E_c(t) = \frac{1}{2}e_c^2(t). \tag{13.41}$$

Instead of the instantaneous error square, let:

$$\tilde{E}_c = Ex[E_c], \tag{13.42}$$

and assume that the expectation is well-defined over the discrete state measurements. The derivative of $\tilde{E}_c$ with respect to the weights of the critic network is then of the form:

$$\frac{\partial \tilde{E}_c}{\partial \tilde{w}_c} = Ex\left[e_c \frac{\partial e_c}{\partial \tilde{w}_c}\right]. \tag{13.43}$$

According to the Robbins-Monro algorithm, the root (can be a local root) of $\partial \tilde{E}_c / \partial \tilde{w}_c$ as a function of $\tilde{w}_c$ can be obtained by the following recursive procedure *if* the root exists and *if* the step size $l_c(t)$ meets all the requirements described in equation 13.35:

$$\tilde{w}_c(t+1) = \tilde{w}_c(t) - l_c(t)\left[e_c \frac{\partial e_c}{\partial \tilde{w}_c}\right]. \tag{13.44}$$

Therefore, equation 13.44 is equivalent to the update rule for the critic network given in equations 13.4 to 13.6. From this viewpoint, the online critic network update rule of equations 13.4 to 13.6 is actually converging to a (local) minimum of the residual square of the equation of the principle of optimality in a statistical average sense.

13.4 Example 1

The proposed NDP design has been implemented on a **single cart–pole balancing problem**. To begin with, the self-learning controller has no prior knowledge about the plant but only of online measurements. The objective is to balance a single pole mounted on a cart, which can move either to the right or to the left on a bounded, horizontal track. The goal for the learning controller is to provide a force (applied to the cart) of a fixed magnitude in either the right or the left direction so that the pole stands balanced and avoids hitting the track boundaries. The controller receives reinforcement only after the pole has fallen.

To provide the learning controller measured states as inputs to the action and the critic networks, the cart–pole system was simulated on a digital computer using a detailed model that includes all of the nonlinearities and reactive forces of the physical system such as frictions. Note that these simulated states would be the measured ones in real-time applications.

13.4.1 The Cart–Pole Balancing Problem

The cart–pole system used in the current study is the same as the one in Barto *et al.* (1983):

$$\frac{d^2\theta}{dt^2} = \frac{g\sin\theta + \cos\theta[-F - ml\dot{\theta}^2\sin\theta + \mu_c \mathrm{sgn}(\dot{x})] - \frac{\mu_p\dot{\theta}}{ml}}{l\left(\frac{4}{3} - \frac{m\cos^2\theta}{m_c + m}\right)}. \tag{13.45}$$

$$\frac{d^2x}{dt^2} = \frac{F + ml[\dot{\theta}^2\sin\theta - \ddot{\theta}\cos\theta] - \mu_c \mathrm{sgn}(\dot{x})}{m_c + m}. \tag{13.46}$$

In equations 13.45 and 13.46, these variables and values apply:

- $g = 9.8\,\mathrm{m/s}^2$, acceleration due to gravity
- $m_c = 1.0\,\mathrm{kg}$, mass of cart
- $m = 0.1\,\mathrm{kg}$, mass of pole
- $l = 0.5\,\mathrm{m}$, half-pole length
- $\mu_c = 0.0005$, coefficient of friction of cart on track
- $\mu_p = 0.000002$, coefficient of friction of pole on cart
- $F = \pm 10$ Newtons, force applied to cart's center of mass
- $\mathrm{sgn}(x) = \begin{cases} 1, & \text{if } x > 0. \\ 0, & \text{if } x = 0. \\ -1, & \text{if } x < 0. \end{cases}$

The nonlinear differential equations of 13.45 and 13.48 are numerically solved by a fourth-order Runge-Kutta method. This model provides four state variables: (1) $x(t)$, position of the cart on the track; (2) $\theta(t)$, angle of the pole with respect to the vertical position; (3) $\dot{x}(t)$, cart velocity; and (4) $\theta(t)$, angular velocity.

In the current study, a run consists of a maximum of 1,000 consecutive trials. It is considered successful if the last trial (trial number less than 1,000) of the run has lasted 600,000 time-steps. Otherwise, if the controller is unable to learn to balance the cart–pole within 1,000 trials (i.e., none of the 1,000 trials has lasted over 600,000 time-steps), then the run is considered unsuccessful. This chapter's simulations have used 0.02 sec for each time-step, and a trial is a complete process from start to fall. A pole is considered fallen when the pole is outside the range of [−12°, 12°] and/or the cart is beyond the range of [−2.4, 2.4] meters in reference to the central position on the track. Note that although the force F applied to the cart is binary, the control $u(t)$ fed into the critic network as shown in Figure 13.1 is continuous.

13.4.2 Simulation Results

Several experiments were conducted to evaluate the effectiveness of this chapter's learning control designs. The parameters used in the simulations are summarized in Table 13.1 with the proper notations defined in the following:

- $l_c(0)$: Initial learning rate of the critic network
- $l_a(0)$: Initial learning rate of the action network
- $l_c(t)$: Learning rate of the critic network at time t, which is decreased by 0.05 every 5 time-steps until it reaches 0.005 and stays at $l_c(f) = 0.005$ thereafter
- $l_a(t)$: Learning rate of the action network at time t, which is decreased by 0.05 every 5 time-steps until it reaches 0.005 and stays at $l_a(f) = 0.005$ thereafter
- N_c: Internal cycle of the critic network
- N_a: Internal cycle of the action network
- T_c: Internal training error threshold for the critic network
- T_a: Internal training error threshold for the action network
- N_h: Number of hidden nodes

TABLE 13.1 Summary of Parameters Used in Obtaining the Results Given in Table 13.2

Parameter	$l_c(0)$	$l_a(0)$	$l_c(f)$	$l_a(f)$	*
Value	0.3	0.3	0.005	0.005	*
Parameter	N_c	N_a	T_c	T_a	N_h
Value	50	100	0.05	0.005	6

Note that the weights in the action and the critic networks were trained using their internal cycles, N_a and N_c, respectively. That is, within each time-step, the weights of the two networks were updated for at most N_a and N_c times, respectively, or stopped once the internal training error threshold T_a and T_c has been met.

To be more realistic, both a sensor noise and an actuator noise have been added to the state measurements and the action network output. Specifically, the actuator noise has been implemented through $u(t) = u(t) + \rho$, where ρ is a uniformly distributed random variable. For the sensor noise, both uniform and Gaussian random variables were added to the angle measurements θ. The uniform state sensor noise was implemented through $\theta = (1 + \text{noise percentage}) \times \theta$. Gaussian sensor noise was zero mean with specified variance.

The proposed configuration of neural dynamic programming has been evaluated, and the results are summarized in Table 13.2. The simulation results summarized in Table 13.2 were obtained through averaged runs. Specifically, 100 runs were performed to obtain the results reported here. Each run was initialized to random conditions in terms of network weights. If a run is successful, the number of trials it took to balance the cart–pole is then recorded. The number of trials listed in the table corresponds to the one averaged over all of the successful runs. Therefore, there is a need to record the percentage of successful runs out of 100. This number is also recorded in the table. A good configuration is the one with a high percentage of successful runs as well as a low average number of trials needed to learn to perform the balancing task.

TABLE 13.2 Performance Evaluation of NDP Learning Controller when Balancing a Cart-Pole System

Noise type	Success rate	Number of trials
Noise-free	100%	6
Uniform 5% actuator	100%	8
Uniform 10% actuator	100%	14
Uniform 5% sensor	100%	32
Uniform 10% sensor	100%	54
Gaussian $\sigma^2 = 0.1$ sensor	100%	164
Gaussian $\sigma^2 = 0.2$ sensor	100%	193

Note: The second column represents the percentage of successful runs out of 100. The third column depicts the average number of trials it took to learn to balance the cart–pole. The average is taken over the successful runs.

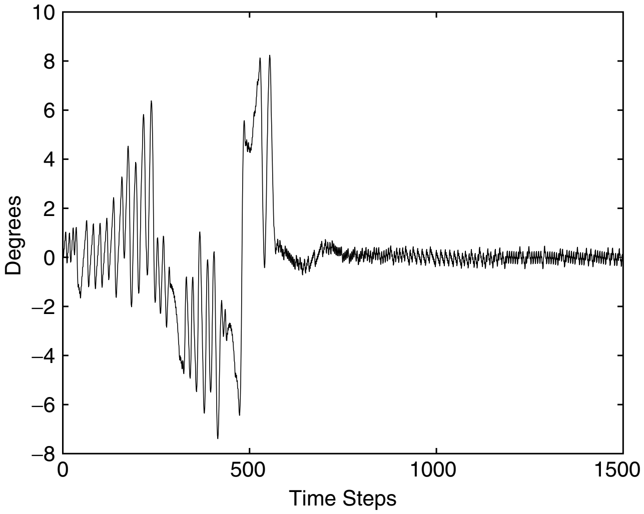

FIGURE 13.3 A Typical Angle Trajectory During a Successful Learning Trial for the NDP Controller when the System is Free of Noise

Figure 13.3 shows a typical movement or trajectory of the pendulum angle under an NDP controller for a successful learning trial. The system under consideration is not subject to any noise. Figure 13.4 represents a summary of typical statistics of the learning process in histograms. It contains vertical angle histograms when the system learns to balance the cart–pole using ideal state measurements without noise corruption.

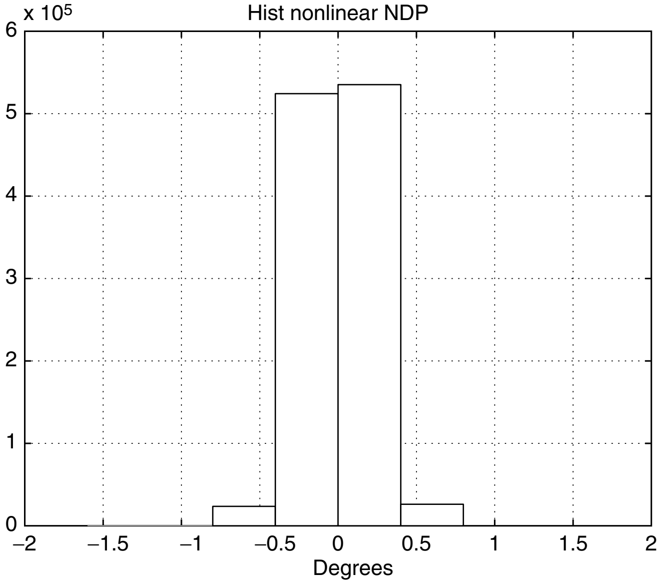

FIGURE 13.4 Histogram of Angle Variations Under the Control of NDP On-Linear Learning Mechanism in the Single Cart–Pole Problem. The system is free of noise in this case.

13.5 Example 2

This section examines the performance of the proposed NDP design in a **pendulum swing-up and balancing task**. The case under study is identical to the one in Santamaria *et al.* (1996).

The pendulum is held by one end and can swing in a vertical plane. The pendulum is actuated by a motor that applied a torque at the hanging point. The dynamics of the pendulum are as follows:

$$\frac{d\omega}{dt} = \frac{3}{4\,ml^2}(F + mlgsin(\theta)). \tag{13.47}$$

$$\frac{d\theta}{dt} = \omega. \tag{13.48}$$

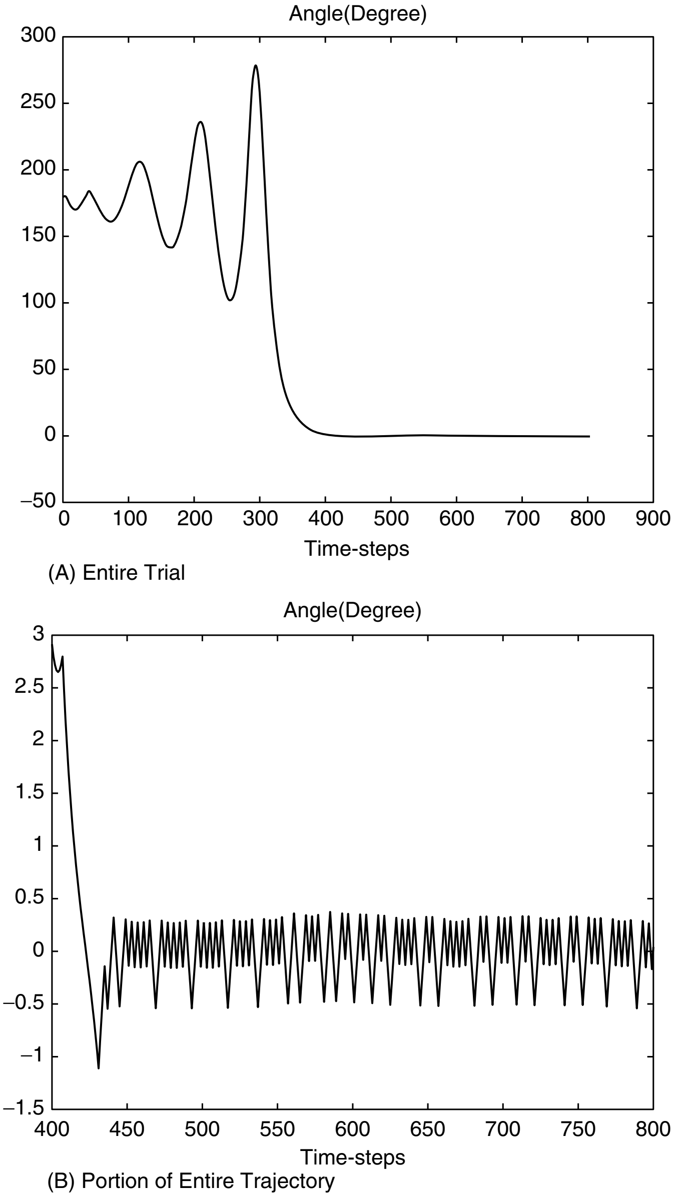
In equations 13.47 and 13.48, $m = 1/3$ and $l = 3/2$ are the mass and length of the pendulum bar, respectively, and $g = 9.8$ is the gravity. The action is the angular acceleration F, and it is bounded between -3 and 3, namely $F_{\min} = -3$ and $F_{\max} = 3$. A control action is applied every four time-steps. The system states are the current angle θ and the angular velocity ω. This task requires the controller to not only swing up the bar but also to balance it at the top position. The pendulum initially sits still at $\theta = \pi$. This task is considered difficult in the sense that (1) there is no closed-form analytical solution for the optimal solution, and complex numerical methods are required to compute it, and (2) the maximum and minimum angular acceleration values are not strong enough to move the pendulum straight up from the starting state without first creating angular momentum (Santamaria *et al.*, 1996).

In this study, a run consists of a maximum of 100 consecutive trials. It is considered successful if the last trial (trial number less than 100) of the run has lasted 800 time-steps (with a step size of 0.05 sec). Otherwise, if the NDP controller is unable to swing up and keep the pendulum balanced at the top within 100 trials (i.e., none of the 100 trails has lasted over 800 time-steps), then the run is considered unsuccessful. In this discussion's simulations, a trial is either terminated at the end of the 800 times-steps or when the angular velocity of the pendulum is greater than 2π (i.e., $\omega > 2\pi$).

The following paragraphs explain two implementation scenarios with different settings in reinforcement signal r. In setting 1, $r = 0$ when the angle displacement is within 90° from the position of $\theta = 0$; $r = -0.4$ when the angle is in the lower half of the plane: and $r = -1$ when the angular velocity $\omega > 2\pi$. In setting 2, $r = 0$ when the angle displacement is within 10° from the position of $\theta = 0$; $r = -0.4$ when the angle is in the remaining area of the plane; and $r = -1$ when the angular velocity $\omega > 2\pi$.

TABLE 13.3 Performance Evaluation of NDP Learning Controller to Swing Up and Then Balance a Pendulum

Reinforcement implementation	Success rate	Number of trials
Setting 1	100%	4.2
Setting 2	96%	3.5



(A) Entire Trial

(B) Portion of Entire Trajectory

FIGURE 13.5 A Typical Angle Trajectory During a Successful Learning Trial for the NDP Controller in the Pendulum Swing Up and Balancing Task

This chapter is proposed NDP configuration is then used to perform the described task. The same configuration and the same learning parameters as those in the first case study are used. NDP controller performance is summarized in Table 13.3. The simulation results summarized in the table were obtained through averaged runs. Specifically, 60 runs were performed to obtain the results reported here. Note that more runs have been used than those in Santamaria *et al.*

(1996) (which was 36) to generate the final result statistics. Every other simulation condition has been kept the same as that in Santamaria *et al.* (1996). Each run was initialized to $\theta = \pi$ and $\omega = 0$. The number of trials listed in the table corresponds to the one averaged over all of the successful runs. The percentage of successful runs out of 60 was also recorded in the table. Figure 13.5 shows a typical trajectory of the pendulum angle under an NDP controller for a successful learning trial. This trajectory is characteristic for both setting 1 and setting 2.

The second column represents the percentage of successful runs out of 60. The third column depicts the average number of trials it took to learn to successfully perform the task. The average is taken over the successful runs.

13.6 Conclusion

This chapter is an introduction to a learning control scheme that can be implemented in real time. It may be viewed as a model independent approach to the adaptive critic designs. The chapter demonstrates the implementation details and learning results using two illustrative examples. The chapter also provides a view on the convergence property of the learning process under the assumption that the two network models, the critic and the action, can be learned separately. The analysis of the complete learning process remains to be an open issue.

Software Technologies for Complex Control Systems

Bonnie S. Heck
School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, Georgia, USA

14.1 Introduction

Control systems and computers enjoy a very successful partnership that began modestly in the 1940s when the theoretical framework for sampled data control systems was first established. The early implementation of the control was done with minicomputers that were rather bulky and sensitive to environmental conditions (e.g., heat, humidity, etc.) and, hence, not well suited for many applications. The popularity of digital control grew dramatically shortly after microprocessors were introduced in the early 1970s. The main considerations of these early digital controllers were speed of the processor, effect of quantization, and effect of sampling rates. The software considerations revolved around the size of the executable program (in terms of memory requirements) and the speed at which it executed (to increase the sampling rate). Many early control system programs were written in assembly code because compiled C programs and Pascal programs were often too large and too slow. As computer technology advanced, the emphasis in digital control research was placed on analysis and on the development of sophisticated algorithms.

New developments in software engineering promise to make revolutionary advances in the way control systems are implemented. Moreover, advances in the implementation may inspire a new generation of digital control algorithms that take advantage of new software technologies. The challenge is that control systems are unique among computer applications since they rely on hard real-time computations. Too slow of an update rate (or an erratic update rate) means that the closed-loop system may experience stability problems. In other computer applications, such as telecommunications, slow update rates may simply degrade performance and irritate customers rather than destabilize the system.

The need for speed of operation historically resulted in tight coupling of software. **Tight coupling** means that different software modules are intertwined so that they share data or control flow information. Modification to one software module may necessitate modifications to all modules that are coupled with it. Although this is advantageous for the speed of real-time applications, it makes system integration a nightmare for large projects. Consider the flight control for an aircraft: there are many different control algorithms, sensors, and actuators that need to be integrated. Multiple processors are used generally on board. Integrating all the software for the different components through a common communications network is a huge task and often is the bottleneck in any updates to the flight controls, especially when the software is tightly coupled. Tight coupling also severely complicates the flight certification of software, which is a verification and validation procedure used to prove that the software is stable and will not have run-time errors.

As computers have become faster and as communication networks have become more efficient in the flow of information, the practice of providing speed through tight coupling of control system software modules has become less necessary. Replacing the need for speed is the need for ease of system integration and system evolution. A very desirable feature is **plug and play**, which refers to ready interchangeability of modules and system reconfiguration with minimal software or protocol changes. For example, as new sensors become available, it would be nice to pull out the old sensors and put in the new sensors with drivers that are "plug and play" with the rest of the system. Also, for the sake of adaptability, it would be helpful to have **run-time reconfiguration** of the software (such as updating or changing algorithms online in real-time). Another desirable feature would be **interoperability** among different processor platforms and different languages. For example, suppose a processor embedded in an application is running one type of operating system and a desktop computer attached to the system is running on another operating system. Data transfer between these two systems is not trivial; for example, the memory byte ordering is different between Windows-based platforms and Unix platforms, and word-size differences on 32-bit versus 64-bit processor architectures cause incompatibilities.

This chapter gives a brief tutorial on some software technologies that are important for control applications. While software is employed both in design and in implementation, this chapter concentrates on implementation technologies. This is a hot topic of current research, so readers should consult the latest information when using these technologies.

14.2 Objects and Components: Software Technologies

One of the major advances in computer science over the last few decades has been **object-oriented programming** (OOP). People who learned programming before 1990 would find OOP somewhat elusive to define and even more elusive to understand. The OOP, however, has taken hold in the constructs of the newer languages, such as Java and C++ (the object-oriented version of C). The motivation for using OOP is for the ease of evolution of software and the reuse of code for different applications. OOP builds programs in a modular fashion, where the software modules are called **objects**. Objects have well-defined interfaces that are used to interact with other objects. Each interface specifies a set of object attributes that are visible to other objects and a set of functions (or "methods") that represent the behavior or activities the object can perform. The term **class** refers to the object type and is analogous to a generic plan for building objects (like the software version of the term blueprint), whereas the objects themselves are the specific cases. Classes tend to be organized in a hierarchical relationship: the most common features of different classes are grouped together in one high-level class called a **superclass**, with specialization in **subclasses**. The class structure makes it easier to reuse modular portions of the software for multiple applications because changes can be localized in object classes.

There are three main mechanisms used in object-oriented programs:

- **Encapsulation** refers to objects being self-contained modules with well-defined interfaces for interaction with other objects. The variables used in an object are generally limited in scope so that they are *not* accessible outside of the object (unless they are specifically declared as "public" variables). An object's interface that allows it to interact with the outside world is kept constant even as the internal workings may be modified and updated, so modification to one object does not require corresponding modifications to other objects. This encapsulation property enables software updates to be accomplished more efficiently and with less risk of error.
- **Inheritance** is a property relating to the hierarchy of objects. A superclass of objects has certain properties common to all subclasses that inherit from it. The subclasses can reuse predefined methods (or function calls) of the superclass without having to redefine the methods themselves. Thus, inheritance promotes software reuse. When applying the software to a new application, only certain methods need to be specialized; the rest can remain unchanged.
- **Polymorphism** is a property relating to the ability of a subclass of a superclass to tailor itself for a specific application or override the methods defined in the superclass. Thus, one method in a superclass might mean different things in different subclasses. The primary advantage is that one set of operations can be applied to objects, and the appropriate implementation of each operation is chosen dependent on the class of object to which it is applied.

These concepts can be made more concrete by applying the OOP paradigm to sensors used in flight controls, such as the Global Positioning System (GPS), radar altimeter, and Inertial Measurement Unit (IMU). These **sensors**, typically purchased commercial-off-the-shelf (COTS), include the actual sensor hardware, a digital output, and a software driver (usually in C) for a processor to read the output. Each of these sensors constitutes an object. Moreover, all sensors perform a common function and have certain common tasks: initializing hardware, opening the data port, closing the data port, and the periodic reading of data during operation. Therefore, you can create a generic class of objects called "Sensor" that encapsulates common attributes and procedures. The hierarchy of this structure is illustrated in Figure 14.1. The Sensor class has methods (or function calls) defined for the common sensor tasks, and the three different sensor subclasses inherit

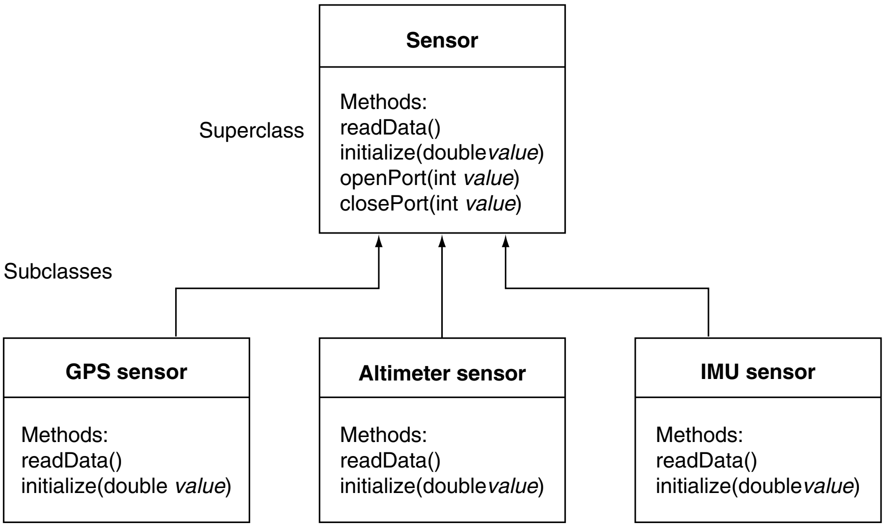

FIGURE 14.1 An OOP Class Diagram of Sensor Objects

these methods. These methods form the interface that all other objects can use to interact with these sensors (such as a control algorithm reading the current data). A Java example of a method call made from a control algorithm is $y =$ gps.readData(), where gps is an object of the GPS class and readData() is the method within the object that can be accessed publicly by other objects.

Because, as stated previously, encapsulation refers to very modular objects with constant interfaces (even as the object's internal code changes), a GPS from one vendor may be replaced by one from another vendor. As long as the method call is not changed, no other object in the system will have to be changed. Inheritance is reflected by the methods that are present in the Sensor class and used by the subclasses. In this example, you could define the methods openPort(int *value*) and closePort(int *value*) in the superclass where the argument is the number of the port to be used. Even though these methods are not explicitly defined in the subclasses, the method call gps.openPort(int *value*) has meaning because the GPS class inherits the method from the superclass.

Polymorphism can be seen in the initialize and the readData methods, which can apply to any sensor object but require different implementation depending on the type of sensor. For this purpose, the subclasses all have these methods defined, which override the method defined in the superclass. Why then would you bother to define these methods in the superclass when they are defined more specifically in the subclasses? The answer lies in the way the methods can be called from the control algorithm object. As defined, the control algorithm can group all the sensor objects into one vector; the method call would only need to be made once (on the vector object), and each sensor's appropriate method would be used automatically. This demonstrates polymorphism, where the same method call means something different to the different subclasses. Polymorphism removes the need for loops or complex case statements to determine which initialization routine to run.

The desire for more extensive reusability of software than is provided by OOP gave rise to a new concept in the late 1990s termed **software components**, which are software modules that are designed to be reused in different software applications (Szyperski, 1998). The term arises from the engineering term **component**, referring to the pieces of equipment (preferably COTS equipment) that an engineer integrates together to form a larger application. The idea is that software for large applications could also be composed of individual software modules that may be available as COTS. A software component can be an object, a group of objects, or a non-object-oriented software module. In this chapter, the term **component** will be used to represent a generic, reusable module in a control system that may be composed entirely of software, hardware, or a combination of both. The term **distributed components** is often used to describe components that are linked via a communication network.

As an example of these concepts, consider an object-oriented model of a typical flight control system. The flight control consists of a low-level stability augmentation control as well as a high-level control, such as guidance, and each one may have a dedicated processor. There are many sensors on board such as a GPS, altimeter, and an IMU. The actuators are the servomechanisms that drive the control surfaces (the ailerons, the rudder, and the elevator). The object-oriented modeling method subdivides the flight controls into components as shown in Figure 14.2. Each bubble represents an object (or more generally, a component). Some of the components consist of only software (such as the controllers), one component consists of physical features (the vehicle dynam-

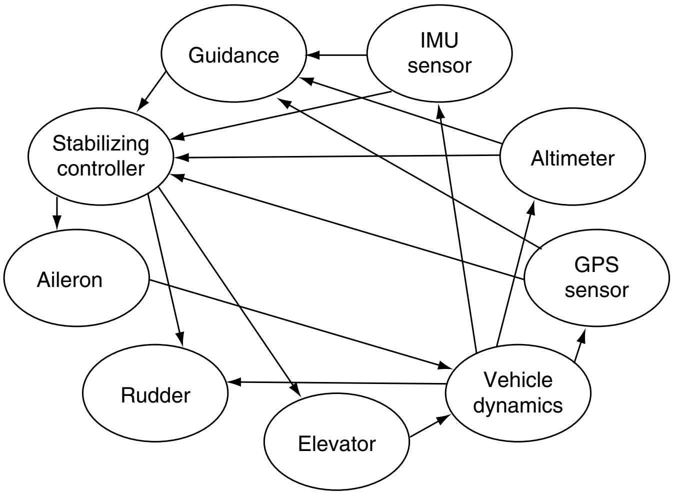

FIGURE 14.2 Objects (or Components) of a Typical Flight Control System. The links represent communication pathways.

ics), and the rest consist of both hardware and software (specifically, the software drivers for the actuators and sensors). Each of these components can be represented entirely by a software model; for example, the vehicle dynamics could be replaced by a simulation for modeling purposes. The resulting modeled software components could be applied in numerous aircraft flight control systems, demonstrating the reusability of software components. Finally, some of the links shown in the figure may be made along a communication network, so these components may be described as distributed components.

While the use of OOP and software components have become well established in computer science arenas, such as desktop computing and network software for managing local and wide area networks, the use of these concepts in the field of control systems is newer and challenges the real-time aspects of the software.

14.3 Layered Architectures

In a layered architecture, objects are designed using a building block mentality. The bottom layer is composed of objects that perform low-level, often tedious functions. The next layer has somewhat higher functionality and makes calls to the objects in the lower layer. Each successive layer upward is more high-level in its functionality. A common way of explaining this layering is that the details are "abstracted away," meaning that some of the tedious details needed to perform the function are hidden from the higher level objects simply by delegating them to the lower levels. In a layered architecture, the object calls are all downward. This architecture is the motivation for the libraries of common function calls that are available with most high-level languages, including the **application programming interfaces** (APIs) that are available for object-oriented languages such as Java.

A simple analogy in hardware to layered architecture is the design of digital circuits. At the bottom layer of the design are **transistors**. Transistors are composed together to form Boolean logic gates at the next layer, such as NAND and OR. At the next layer are devices such as **decoders** and **multiplexers** that are composed of logic gates. These devices then become the building blocks for higher layers. A complex digital circuit could be designed at the transistor level, or it could be designed at the multiplexer/decoder level. The transistor-level design would most likely yield a more efficient implementation but would be much more difficult and time-consuming to the person designing the circuit. In a similar way, this concept of abstracting away the details is the motivation for programming using higher level languages rather than programming at the assembly code level. Programming at the assembly code level produces a more efficient code but is much more tedious and harder to troubleshoot. The terms **level** and **layer** will be used throughout the rest of this chapter to reflect layers of abstraction in a layered architecture.

14.4 Networked Communications

Complex control systems often have multiple processors that must be interconnected through a communication network. All communication networks have protocols that are the specifications (or rules) by which the data is transferred. Most common model for data networks is the **open systems interconnection** (OSI) **model** (Tanenbaum, 1996), which has seven layers of protocols: the **physical layer** (the hardware that actually transmits and receives the data) at the bottom and the **application layer** (the software level that accesses mail and does FTP functions) at the top. In between are the layers that check for errors, perform routing (such as IP) tasks, create rules for providing a reliable connection including breaking information into packets (such as TCP), and handle collisions of packets (such as CSMA/CD). Typical data networks, such as ethernet, send packets of information in a nondeterministic or "bursty" manner. The desire to have a more deterministic, steady stream of information in applications such as voice and video transmission prompted the design of the **asynchronous transfer mode** (ATM) model, which is an alternative to the OSI model and has the potential for good applicability to networked control systems.

A layer of abstraction can be added on top of the protocol layers to build communication models. The three common types of models are the following:

- ***Point–to–point:*** In this model, all communication is one-to-one between pairs of entities. A common example for this type of communication is a telephone call between two parties.

- ***Client–server:*** This model is a many-to-one communication model where many clients can be connected simultaneously to one server. The server acts as a centralized source of data.
- ***Publish–subscribe:*** In this model, many components interact with one another in a many-to-many architecture. To achieve this, this publish–subscribe model introduces an intermediate level between the components that acts to mediate the communications. Components can be designated as **publishers**, which produce data, and **subscribers**, which require data as input. An example of a publisher is a sensor that produces measurements. An example of a subscriber is a control algorithm that requires the measurements from the sensor. In a complex control system, there may be many publishers and many subscribers. For example, a process control system may have distributed components using many processors, or at least many separate algorithms all using similar data, and numerous sensors producing data.

14.5 Middleware

Integrating different software applications either in a single processor or across a network requires detailed knowledge of the operating systems on the connected machines. Moreover, the use of networks requires knowledge of communication protocols that dictate how packets of data are sent and verified. Programming at the operating system level or at the network level adds a layer of complexity to the process that most control engineers would prefer to avoid. As an alternative, a new layer, called **middleware**, is inserted between the operating system and the application software as shown in Figure 14.3. The middleware sets up the communication protocols and interfaces with the operating systems for the machines on the network to allow different software applications on the different machines (or on the same machines) to communicate. As such, middleware insulates application users from the lower level operations. You can see how useful middleware is by examining the interaction of different application software programs running on one machine. For example, as long as software vendors build to an interface standard, users are able to cut and paste from one window to another application running in a different window.

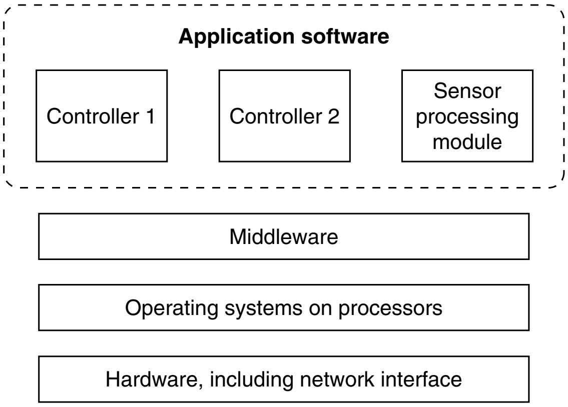

FIGURE 14.3 Architecture Showing how Middleware Acts to Insulate the Application Software from the Low-Level Computer Functions

When middleware is used as the basis for integrating applications, it can be seen as a **software substrate**. To be effective and easy to use as a substrate, middleware should have certain properties. First, it must have a standard interface so that all application software programs that use the standard can be integrated easily. Second, it must have **heterogeneous interoperability**, that is, be able to integrate application software that is written in different languages and/or running on different processor platforms. The ultimate goal for control systems would be to have middleware that has plug-and-play capability. Also, for adaptability sake, it would be helpful to have run-time reconfiguration of the software components (such as updating or changing algorithms online in real-time). The control engineering field is not yet to this point in its use of middleware. More discussion of the available products is given in the last section of this chapter; first, more fundamental concepts on software engineering are introduced.

Consider the use of **object-oriented middleware** to provide the distributed communication channel for the publish/subscribe method of communications. Object-oriented middleware treats the software and hardware components connected to it as objects. Ordinarily, when one object on a distributed communication network calls a method of another object, it would have to know which object had that method and be able to locate it on the network. The middleware makes this method request transparent to the object that makes the call by using **remote procedure calls** (RPCs). Because all objects have a standard interface and all coupling between objects is mediated through the communication channel (that is, the objects are not required to be coupled together directly), adding or removing objects from the overall system can be done in a much simpler manner than is possible if the components are all tightly coupled. Consider three different alternatives for object-oriented middleware: **DCOM**, **CORBA**, and **Java-based technologies** (including Jini technology) (Szyperski, 1998).

14.5.1 Distributed Component Object Model

Component Object Model (COM) was developed by Microsoft and is used to integrate different software applications on platforms running Microsoft Windows. Distributed Component Object Model (DCOM) extends this standard to software applications that may be running on different Windows-based platforms and are connected via a network. Applicability to other platforms is under development.

14.5.2 Common Object Request Broker Architecture

Common Object Request Broker Architecture (CORBA) is a software standard developed by a consortium called the Object Management Group (OMG). OMG has approximately 800 member companies who develop and adopt products that abide by the standards set forth by OMG. A basic feature of CORBA is the **Object Request Broker** (ORB) that handles remote procedure calls. When an object calls a method of another object distributed elsewhere on the network, the ORB intercepts the call and directs it. In this manner, the calling object does not need to know the location of the remote object. The middleware itself is available in different languages that all abide by the CORBA standard; for example, the Java 2 Platform Standard Edition, v1.3, includes a CORBA ORB. The use of CORBA in control engineering is rather new; see Wills *et al.* (2000) for details on the development of a product that is based on a CORBA substrate. Some high-level features of CORBA, however, make it very attractive for future control engineering products used to integrate systems. Its main benefits are that it has a well-accepted standard for the interface, it allows for interoperability of software components written in different languages (including Java and C++) and/or running on different platforms, it handles all network communication protocols, and it provides for run-time reconfiguration of software components. Components can also be integrated that are not object-oriented (such as legacy code) by wrapping the code in a layer that provides an object-oriented interface. Services are continually being added to the ORB structure that extend the capabilities of CORBA. For example, while CORBA is implemented as a client/server communication model, a layer (called an event service) has been added that emulates the publish/subscribe behavior.

14.5.3 Java-Based Technologies

The third common way of integrating components is with Java-based technologies. Java is an object-oriented language that is platform independent and is open source (meaning that the source code is not proprietary), so it has good promise for use in middleware development. Java is based on a layered architecture with new APIs being developed on a continuing basis. Some of the APIs that enable Java to be used for distributed applications are the Remote Method Invocation (RMI) API, the RMI over Internet Inter-ORB Protocol (IIOP) API, and the Java ORB API. The RMI API provides the means for distributed objects to interface through remote method calls (similar to remote procedure calls but specialized to Java objects). The RMI IIOP API provides the remote method call capability using a CORBA ORB. The Java ORB API provides a Java-based CORBA ORB. It should be noted that Java components can interact with non-Java components (such as those written in C) through the use of the Java Native Interface (JNI). JNI works by providing a standard for writing Java code to wrap around non-Java code; the combined code then can be treated like a Java object.

Although many of these Java APIs provide services useful in middleware, a complete package is available in Java: the Jini network technology. Jini is a software architecture for integrating hardware over a network. The lower layers of the architecture handle network protocol decisions, so these decisions are transparent to the user who interfaces at the higher layers. The user also has the option of performing remote method calls using the Java RMI technology, CORBA services, or XML. Thus, Jini can be used as a complementary technology to CORBA. There is a strong continuing effort in the Java community to build new APIs that are increasingly aimed at making Java the basis for integrating multiple components across a network with real-time specifications. Because this field changes rapidly, the reader is encouraged to visit the Sun Microsystems Java Web site for updates.

The following example illustrates how middleware can be used to facilitate control system integration and evolution of the system as new hardware components or new software algorithms become available. Consider the flight control example introduced in Figure 14.2. This control system is shown in Figure 14.4 integrated into a publish/subscribe model. The publishing components (those that produce data) are shown with arrows pointing away from them, and the subscribing components (those that require data) are shown with arrows pointing toward them. Note that some components are both publishers and subscribers.

To illustrate the communication procedure, consider the guidance module that requires altitude information. It subscribes to this data from the software substrate. When subscribing, it declares the data that it needs and the rate at which it must receive the data. The GPS and the altimeter both publish this data, so the middleware must have a strategy for deciding which of these sensors to use in retrieving data. One strategy is to give both sensors weight values (Pardo-Castellote *et al.*, 1999). The middleware sends data to the subscriber from the publisher that has a higher weight. These weights can be changed in real-time by the middleware so that alternate sensors can be used based on current flight conditions. The subscribers themselves are not changed in this process. In a similar manner, an additional sensor might be added to the system with a prescribed weight. If that weight is higher than the existing publishers of that data, the subscribers will receive the data from the new component. Note that this is a simplified example; in reality, there is usually a filtering module between the sensors and controllers that may be used to fuse sensor data. This module may be integrated as a separate component that both publishes and subscribes to data.

As mentioned previously, remote procedure calls may be used to access the methods of one object that is remote from the calling object. This is inefficient for real-time applications, such as a stabilizing controller needing sensor measurements at

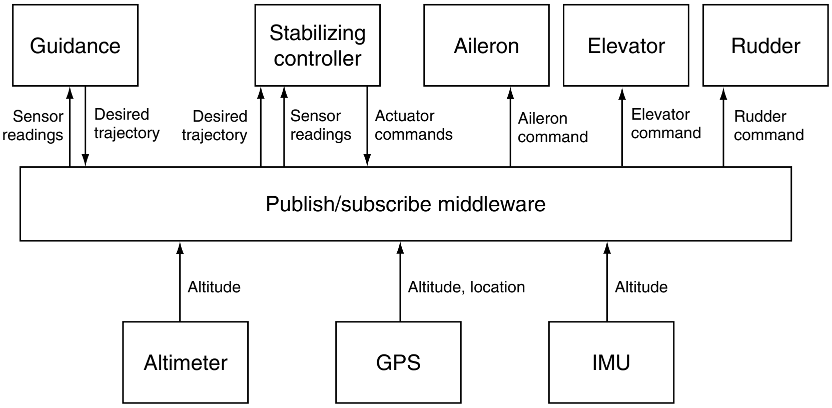

FIGURE 14.4 Flight Control Example Implemented Using Middleware That Implements a Publish/subscribe Communication Model

a high rate. One way that the controller can get its data quickly is for the middleware to duplicate the data and the sensor methods in the memory that is local to the controller program. The middleware can update the data at the specified rate by putting this information into a memory location that is accessed by the subscribing object. Hence, the stabilizing controller can call a method of a sensor object, and it is actually calling the duplicate (also called the replicate or the cache copy). Such a local method call is much faster than a remote method call across the communication channel.

14.6 Real-Time Applications

As mentioned previously, digital control systems are much more sensitive to time delays than are other software applications. There are three types of timed events that occur in typical control system: **periodic events** (such as updating control signals at a given rate), **asynchronous events** (such as set point adjustments from a supervisory control), and **sporadic events** (such as a fault occurrence). A long time delay that is incurred when processing an event could cause catastrophic behavior, such as instability or failure to recover from a fault. Making the problem more difficult to manage and to analyze is the fact that operations in typical networked computer systems occur in a nondeterministic manner, giving rise to varying time delays. The concern over how this nondeterministic behavior affects different software applications has prompted a great deal of research in the area of **real-time computing**.

Consider the real-time operation of a complex control system where different components are connected via a network. There are three places where the time delays occur: the **data transfer over the network**, the **software applications running on the processors**, and the **middleware that integrates the components**.

Consider first the network communications. Performance of a communication network is commonly measured in terms of time delays (e.g., due to access delay, message delay, transmission delays), reliability or accuracy of data, and throughput (e.g., max data rate divided by the data size). For control systems, the time delay is the most critical measure due to stability and performance considerations. To address the special concerns of control systems, some specialized protocols have been written that provide for a dedicated control area network (such as DeviceNet). The alternative is to use a standard data network such as ethernet. Data networks typically use protocols (such as TCP/IP) that result in a nondeterministic transfer of data, as opposed to the smaller but more frequent data packet transfers conducted by control area networks. Results examining the use of ethernet for real-time applications are given in Schneider *et al.* (2000), while a comparison of ethernet (using CSMA/CD) to a token ring bus and to control area networks is given in Fend-Li Lian *et al.* (2001). Networks using ATM technology have good performance with other real-time applications, such as video and voice, and have good potential for future use in control applications.

Next, consider real-time behavior of software applications. While high-level languages do have function calls that seem to imply real-time, the timings are not exact. For example, a sleep(20) command implemented in a Java thread would seem to make the thread pause for 20 msec. However, the thread may actually sleep for 19 msec or 21 msec. This can be explained by examining how an operating system on a processor handles several tasks that are running concurrently (known as **multitasking** or **multithreading**: the system must schedule a dedicated processor time to each of these different tasks. As a result, tasks are typically scheduled in a nondeterministic manner, which gives rise to the resulting **soft real-time** behavior.

While the processor itself does have an absolute clock, a real-time operating system (e.g., LinuxOS, VxWorks, Sun/Chorus

ClassiX, and QNX) must be used to get hard real-time performance out of the applications. There are products (rather kernels) that can be installed on a system with a non-real-time operating system, such as the Real-Time Linux modification of the popular Linux Operating System. Here, hard real-time applications coexist with the normal linux kernel and hard real-time tasks are always given priority for execution. The normal linux kernel as a whole is only executed when slack time is available. Most computers use hardware components to perform tasks that need real-time performance, such as video cards on desktop machines or DSP boards in signal processing applications. These tasks can be performed in parallel without the need for the nondeterministic uncertainty introduced by scheduling of processor time. Another alternative is to use separate dedicated processors to perform each concurrent task, such as having one processor perform low-level control loops and a separate processor performing high-level loops such as fault detection and supervisory control. Moreover, the software application must be able to take advantage of real-time operations. While C has been used successfully in control system implementation, Java lacks good real-time applicability. This may change in the near future because there is a large effort to develop real-time Java capability as evidenced by the release of Real-Time Java Specification (Bollella *et al.*, 2000).

Finally, the middleware must run in real-time. For example, the original version of CORBA did not support hard real-time operations because of overhead in the client/server implementation due to the ORB intercepting the remote method calls, redirecting them, and marshalling or demarshalling data to translate data values from their local representations to a common network protocol format. CORBA also lacked real-time scheduling capabilities. Extensions have been made to build a real-time CORBA (also known as TAO) (O'Ryan *et al.*, 2000). As described previously, using local replicas helps speed up the real-time behavior of the middleware. Further, real-time applications require the middleware to schedule events based on **quality of service** (QoS) measures. Typical QoS parameters include desired rates for periodic events (e.g., updates from sensors), deadlines for when a task must be completed (e.g., when the new command must be sent to the actuator), and priority values indicating the relative importance of different procedures. A real-time middleware must also time stamp transactions and prescribe efficient and fast memory usage.

14.7 Software Tools for Control Applications

Software tools for control systems are aimed at either design and analysis or at implementation. The most common design and analysis tool is MATLAB from Mathworks. MATLAB is often used in conjunction with the Simulink tool box to provide a graphical user interface along with some expanded simulation capabilities. To ease system implementation, the Real-Time Workshop tool box can be used to generate C code from a Simulink block diagram. Mathworks has a continuing effort to increase the efficiency of code generation to improve the speed of processing and to reduce the size of the compiled program (an important feature for embedded processors).

In this chapter, emphasis has been placed on using middleware for integrating complex control systems. As mentioned previously, middleware is beneficial for its ability to hide the network communications decisions from the user, its reuse in integrating multiple control system applications, and its ease of system evolution and reconfiguration. A further benefit from some middleware is its ability to integrate software written in different languages and running on different platforms. The development of middleware for control system applications is rather new. One commercial product that uses a real-time publish and subscribe communication model is NDDS made by Real-Time Innovations (RTI). NDDS has good performance for relatively fast periodic events, which is the case for the low-level stability augmentation controller used in flight controls. RTI also markets ControlShell, a graphics tool that allows integration of control systems in an object-oriented fashion. Consult the RTI Web site for more information on the publish and subscribe communications model for use in controls. While no commercial products currently use CORBA for control systems, a CORBA-based software substrate for controls is under development (Wills *et al.*, 2001). Extensions to CORBA and links to CORBA-based products for other applications can be found on the OMG Web site.

Acknowledgments

The author would like to thank Raymond Garcia, Suresh Kannan, and Dr. Linda Wills for their valuable comments. The author would also like to acknowledge the support of DARPA under the Software Enabled Control Program headed by Dr. Helen Gill.
